Evidence for a critical contribution of the environment to prostate cancer is as strong as is the case for an impact of heredity. Prostate cancer incidence and mortality vary widely throughout the world, and migrants from low-risk regions to high-risk regions tend to adopt higher prostate cancer predilection within a single generation. It has not been established whether the high rates of prostate cancer in the United States reflect ingestion of food carcinogens (such as the heterocyclic amines and polycyclic aromatic hydrocarbons in overcooked meats, which are known to cause prostate cancer in rodents) or inadequate intake of tomatoes and cruciferous vegetables (which contain antioxidant micronutrients known to protect against prostate cancer in model studies). Whatever the etiology of the disease, prostate glands removed at autopsy from high-risk parts of the world display an astonishing abundance both of chronic inflammation and of undiagnosed prostate cancers. Also, in rodent models, exposures that cause prostate cancer also trigger chronic prostatic inflammation, connecting the two disease processes. In the United States, asymptomatic prostatitis arises in nearly all men as they age, leading to the appearance of proliferative inflammatory atrophy (PIA) lesions, the earliest histologic precursors to prostate cancer. In turn, small prostate cancers ultimately appear in as many as 64% of men 60 to 70 years of age. Fortunately, the majority of these cancers pose little threat to health or to life. Nonetheless, this reservoir of indolent asymptomatic disease in the midst of chronically inflamed prostates complicates prostate cancer screening, early detection, and treatment, leading to significant overdiagnosis and overtreatment of the disease.

### Risk Factors

Key risk factors for prostate cancer include age, family history, African ancestry, a diet rich in saturated fats and red meats, and a sedentary lifestyle, all features that may motivate the use of prostate cancer screening as a part of routine primary care. The most widely used screening strategies feature blood testing for PSA with or without DRE, usually beginning at 50 to 55 years of age or earlier for African-American men, for men with a strong family history, or for men known to be carriers of prostate cancer risk genes. Unfortunately, even though the benefits of screening for reducing prostate cancer progression to metastasis and prostate cancer mortality have been demonstrated in a large randomized trial, prostate cancer screening remains highly controversial. The U.S. Preventive Services Task Force (USPSTF) formally recommends that men 55 to 69 years of age discuss the potential benefits and harms of prostate cancer screening with their physician before pursuing PSA testing and rectal examination (assigning a grade C). For men 70 years of age and older, the USPSTF recommends against prostate cancer screening (grade D).

### Pathophysiology

Nearly all of the exposures that can cause prostate cancers in laboratory mice and rats, ranging from charred meat carcinogens to estrogens to various “hit-and-run” infectious agents, trigger chronic inflammatory changes in prostate tissues that lead to PIA. Some fraction of PIA lesions, likely those exhibiting morphologic atypia and containing somatic genome alterations, in turn progress to prostatic intraepithelial neoplasia (PIN) and to prostate cancer.

The normal prostate contains an epithelium able to contribute secretions to the ejaculate. The epithelium features (1) basally located cells expressing cytokeratins K5 and K14, and p63; (2) columnar secretory cells expressing the androgen receptor (AR), PSA, cytokeratins K8 and K18, and prostate-specific membrane antigen (PSMA); and (3) neuroendocrine cells producing chromogranin A, neuron-specific enolase, and synaptophysin. PIA lesions arising in response to epithelial damage give rise to “intermediate cells” that express markers characteristic of both basal and luminal cells. The cellular target of transformation is likely such an “intermediate cell”; the resultant PIN or prostate cancer cells exhibit many of the phenotypic characteristics of columnar secretory cells, including the expression of AR, PSA, and PSMA, and acquire expression of new gene products, such

as  $\alpha$ -methylacyl-CoA racemase (AMACR). For this reason, many prostate pathologists use immunohistochemical staining for basal cells (antibodies against cytokeratins K5/K14 and p63) and for neoplastic prostate cells (antibodies against AMACR) to aid in prostate cancer diagnosis; prostate cancer cells tend to be cytokeratin K5/K14 negative, p63 negative, and AMACR positive.

Prostate cancer cells acquire a number of somatic genome and epigenome alterations. Fusion translocations of an androgen-regulated gene, *TMPRSS2*, to genes encoding various members of the E26 transformation-specific (ETS) family of transcription factors are the most common somatic genetic changes in prostate cancers. Somehow, these gene fusions allow prostate cancer cells to coopt androgen signaling to drive neoplastic transformation and malignant progression. As a result, interference with androgen signaling forms the foundation for most advanced prostate cancer treatments. When such translocations are not present, other somatic alterations, such as mutations in *SPOP*, are more frequent. Hypermethylation of *GSTP1*, encoding detoxification enzyme for carcinogens and oxidants, can be detected in >90% of cases. DNA methylation changes at other loci are also very common. The somatic defects in genes and gene function somehow allow prostate cancer cells to proliferate, escape terminal differentiation, and survive to grow in ectopic sites, such as in bones, lymph nodes, and other organs. Two notable somatic gene defects, mutations or deletions in *TP53* and in *PTEN*, have been consistently associated with malignant prostate cancer progression.

### Prevention

There are no established drugs that prevent prostate cancer, although there have been three very large randomized clinical trials of agents for prostate cancer prevention. One such trial aimed to test predictions from epidemiologic studies and earlier small clinical trials that inadequate intake of the micronutrients selenium and vitamin E might lead to increased prostate cancer risk. The trial, called the Selenium and Vitamin E Cancer Prevention Trial (SELECT), enrolled men 55 years of age or older (50 years or older for African Americans) with an unremarkable DRE and a serum PSA of 4.0 ng/mL or less to treatment with the micronutrients for 7 to 12 years (randomized to 200  $\mu$ g selenomethionine<sup>7</sup> daily, 400 IU  $\alpha$ -tocopherol<sup>7</sup> daily, the combination, or neither). Unfortunately, the study failed to show any reduction in prostate cancer, instead revealing a slight increase in prostate cancer incidence among men taking vitamin E. As a result, high-level intake of selenium, vitamin E, and other nutritional supplements for the purpose of prostate cancer prevention should be discouraged.

The two other large randomized trials tested the propensity for the 5 $\alpha$ -reductase inhibitors finasteride (Proscar)<sup>1</sup> and dutasteride (Avodart)<sup>1</sup> to prevent prostate cancer development. In one of the studies, called the Prostate Cancer Prevention Trial (PCPT), finasteride (5 mg daily or a placebo) was given to healthy men 55 years of age and older, with a normal DRE and a serum PSA of 3.0 ng/mL or less, for 7 years. During the trial, men with increasing PSA values or an abnormal DRE were subjected to prostate biopsy. At the end of the trial, biopsies were planned for all of the men. The results were a decrease in prostate cancer detection from 24.4% of men receiving a placebo to only 18.4% of men treated with finasteride, but an increase in more aggressive high-grade prostate cancers in men receiving finasteride versus placebo from 6.4% to 5.1%.

Similar results were encountered with dutasteride in the other trial, the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial, in which men with an elevated serum PSA between 2.5 and 10.0 ng/mL and a recent negative prostate biopsy were given dutasteride (0.5 mg daily) or a placebo for 4 years, with prostate biopsies obtained after 2 and 4 years on study. Overall, prostate cancer was reduced from 25.1% to 19.9% for men taking dutasteride, but high-grade prostate cancer was increased in these men from <0.1% to 0.5%. Data from

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

the PCPT and REDUCE trials clearly indicated that 5 $\alpha$ -reductase inhibitors are better at preventing low-grade cancers than high-grade cancers. Whether the development of high-grade cancers was actually increased in either trial or these cancers were just more easily detected has been controversial, and the U.S. Food and Drug Administration (FDA) has not approved either finasteride or dutasteride for prostate cancer prevention. In 2019, long-term follow-up of participants in the PCPT revealed no increases in prostate cancer mortality accompanying finasteride treatment, likely affirming the general safety of 5 $\alpha$ -reductase inhibitor treatment for BPH and male pattern baldness, and reanimating discussions about how 5 $\alpha$ -reductase inhibitors might be used to lower the overall burden of prostate cancer in some way.

### Clinical Manifestations

Most patients present for prostate cancer care after a diagnosis triggered by prostate cancer screening and are thus initially asymptomatic. Local progression of the disease can result in lower urinary tract symptoms of voiding obstruction or irritation; urinary tract infections and urosepsis; erectile dysfunction; hematospermia; and diminished ejaculate volume. Metastatic prostate cancer dissemination most often involves the skeleton, resulting in bone pain and low blood counts, and involves pelvic lymph nodes and nearby lymphatics, resulting in lower extremity edema or retroperitoneal fibrosis, respectively.

### Diagnosis

Prostate cancer diagnosis is typically made using transrectal ultrasound (TRUS)-guided prostate biopsy. The technique involves the repeated firing of an 18-gauge needle from a spring-loaded gun through a port on the TRUS probe. To sample prostate tissue, the biopsy needle passes through the rectum into the prostate, and fluoroquinolone antibiotics are typically administered before the biopsy procedure. Hematuria and/or hematospermia occur commonly after prostate biopsy. Hospital admissions, usually the result of an infection, are rare but can occur in up to 7% of men with significant comorbidities. Importantly, TRUS does not delineate the locations of prostate cancers within the prostate. For this reason, the numbers and sites of biopsies placed during a prostate biopsy procedure, typically 10 to 12 directed laterally into the peripheral zone of the gland, are designed to minimize the chance of missing life-threatening high-grade cancers.

Increasingly, magnetic resonance imaging (MRI) has been employed to better direct prostate biopsies, hoping to reduce detection of low-grade cancers that pose little threat to life and to more accurately sample high-grade disease. Multiparametric MRI (mpMRI) incorporates T2-weighted anatomic imaging, diffusion-weighted imaging, and contrast enhancement to highlight suspicious areas in the prostate for biopsy. The technique generates a standardized “suspicion” score for individual lesions, using the Prostate Imaging–Reporting and Data System (PI-RADS). The MR image itself can then be used to direct TRUS biopsies via coregistration (or “fusion”) of the acquired mpMRI data with real-time TRUS. Biopsies obtained by MRI/TRUS fusion are becoming more widespread, especially for patients who need a repeat biopsy because of a persistently elevated or increasing serum PSA. At the time of initial diagnosis, MRI-guided biopsies may result in less detection of clinically insignificant cancers.

The histologic grade and anatomic stage of newly diagnosed prostate cancer carry important prognostic information useful for treatment planning. Recently, prostate cancer grade “groups” (1 most favorable prognosis and 5 poorest prognosis) have been introduced into clinical practice as risk tools for localized prostate cancer. These “groups” are derived from Gleason scoring as conducted by an expert genitourinary pathologist. The Gleason score represents the sum of the two most common histologic patterns of growth exhibited by the cancer within the prostate; the pattern designations range from pattern 3 to pattern 5 (there are no patterns 1 or 2), providing Gleason scores from 6 to 10. The disease stage focuses on the extent of tumor in the prostate itself (T1, not palpable by DRE; T2, palpable by DRE; T3, extending outside the prostate itself; and T4, invading adjacent pelvic

structures), in regional lymph nodes (N0, no lymph node metastases; N1, lymph node metastases), and in distant sites (M0, no distant metastases; M1, metastases). Staging tools include a number of imaging modalities, including abdominopelvic CT or MR images and nuclear medicine scans for soft tissue and for bone, using <sup>11</sup>C-choline, <sup>18</sup>F-fluciclovine, and <sup>18</sup>F-sodium fluoride. Positron emission tomography (PET)-CT (or PET-MRI) scanning now features prostate-specific membrane antigen (PSMA) targeting tracers such as <sup>68</sup>Ga-PSMA and <sup>18</sup>F-piflufolastat.

### Differential Diagnosis

The critical issue surrounding the diagnosis and staging of many patients with prostate cancer is whether the disease is at risk to progress to threaten life or whether it is so indolent as to not need treatment. Most patients with indolent disease indicated by a Gleason score of 6 (grade group 1) do not need immediate treatment, and many may never need treatment. Instead, these patients can be monitored using *active surveillance*, with serum PSA tests twice yearly, DREs each year, and MRI and/or prostate biopsies as necessary or after 2 to 4 years. This surveillance strategy aims to detect higher Gleason score prostate cancer if it appears. A Gleason score greater than 7 (grade groups 2 to 5) tends to be an indication for curative local disease treatment with surgery or radiation therapy. Deferring aggressive local therapy as part of active surveillance appears safe, and as a result, active surveillance has become a common approach to prostate cancer care. By avoiding aggressive intervention until and unless necessary, active surveillance is distinct from observation or watchful waiting approaches, which are typically reserved for patients with significant comorbidities and limited life expectancy.

### Therapy

For localized prostate cancer with a Gleason score greater than 7 (grade groups 2 to 5), curative treatments include radical prostatectomy, interstitial brachytherapy, and external beam radiation therapy (EBRT). Most radical prostatectomies these days are performed using a robot-assisted laparoscopic approach. Urinary incontinence and erectile function after the procedure vary greatly among surgeons, with as many as 20% of patients describing some level of urine leakage 2 years after radical prostatectomy and at least 26% reporting significant sexual dysfunction 1 year after surgery. Ideally, following surgery, the serum PSA should decrease to an undetectable level and remain so in perpetuity if the procedure resulted in prostate cancer cure. Two-thirds of patients subjected to radical prostatectomy remain free from PSA recurrence 15 years after surgery. An increasing serum PSA after surgery is a sign that prostate cancer has recurred or persisted somewhere. Nonetheless, such a PSA increase may not herald imminent overt metastasis or death. In one analysis, only 30% of men with an increasing postsurgery serum PSA had suffered with metastatic prostate cancer by 8 years after the initial PSA increase. The rate of serum PSA increase can be informative; a rapid doubling of serum PSA values is usually associated with a greater threat of symptomatic disease progression.

Prostate brachytherapy provides for direct irradiation of localized prostate cancer via implantation of radioactive sources into the prostate using image guidance. The procedure itself is fairly convenient and can be completed as an outpatient within a couple of hours using spinal anesthesia. The most common radioactive sources used are <sup>125</sup>I (iodine) and <sup>103</sup>Pd (palladium); as many as 100 seeds might be implanted. Although the <sup>125</sup>I seeds generally decay more slowly than the <sup>103</sup>Pd seeds, prostate brachytherapy implants are essentially inert by 10 months after insertion into the prostate. Complications of brachytherapy for prostate cancer differ from those of radical prostatectomy and of EBRT, with irritative voiding symptoms reported by at least one-half of patients in the first few months after implant placement. These symptoms tend to abate after 1 year or so, persisting in some 15% to 20% of patients. Long-term side effects can include urethral stricture, incontinence, erectile dysfunction, and rectal irritation. Relative contraindications to prostate brachytherapy include large prostate size (requires a lot of seeds or use of androgen deprivation

to shrink the prostate), preimplant obstructive urinary symptoms (greatly worsen after implantation), and history of transurethral surgery for symptomatic BPH (tends to lead to incontinence).

A series of technical innovations have improved both the efficacy and safety of EBRT, including CT-based treatment planning, the use of multileaf collimators in modern linear accelerators, and improvements in treatment planning software. Three-dimensional conformal radiation therapy (3D-CRT) allows creation of more accurate target volumes using reconstructions of pelvic CT images and better sparing of vulnerable structures such as the bladder and the rectum. Intensity-modulated radiotherapy (IMRT) even further optimizes dose distribution for prostate cancer treatment by controlling the intensity of radiation dose in addition to the shape of the volume designated for treatment. Despite more accurate deposition of radiation doses to the prostate, side effects of EBRT remain mostly rectal toxicity (early irritation and late rectal bleeding), late urethral strictures, and erectile dysfunction. EBRT can also be used as adjuvant therapy for prostate cancer with positive surgical margins after radical prostatectomy or as salvage therapy for local prostate cancer recurrence after surgery.

Proton-beam radiotherapy has become available at a limited number of treatment centers. The physical properties of protons allow them to deposit energy very precisely, with little radiation dose to skin and little radiation scatter to nearby tissues. This behavior is ideal for cancers located in close proximity to sensitive structures in the body, such as at the base of the skull, near the eye, and elsewhere. For prostate cancer, proton-beam radiotherapy has emerged as an effective treatment for localized disease, but whether this approach offers an improvement over conventional EBRT using 3D-CRT with IMRT awaits the results of an ongoing randomized clinical trial.

Systemic approaches to prostate cancer include agents targeted at androgen signaling, taxane chemotherapy, radiopharmaceuticals, PARP inhibitors, and immune checkpoint inhibitors. Disruption of androgen signaling has been a mainstay of advanced prostate cancer care for seven decades. Originally accomplished by surgical removal of the testes and later by the administration of estrogens, ADT, involving a reduction in circulating testosterone levels to <50 ng/mL, is now more commonly achieved by inhibition of pituitary gonadotropin production, using luteinizing hormone-releasing hormone (LHRH) analogues that cause suppression of testosterone production. Injectable LHRH analogues are all available in long-acting depot formulations (goserelin [Zoladex] 10.8-mg depot every 3 months, leuprolide [Lupron Depot] 22.5-mg depot every 3 months, and triptorelin [Trelstar] 3.75-mg depot monthly) and antagonists (degarelix [Firmagon] 240 mg depot initially followed by 80 mg depot monthly). An oral LHRH antagonist, relugolix [Orgovyx or Relumina] 360 mg initially followed by 120 mg daily, is also available. The benefits of ADT are evident in most patients by a decrease in serum PSA, a shrinkage of metastatic cancer deposits, and improvements in symptoms, such as bone pain, that accompany metastatic prostate cancer progression. Side effects often include hot flashes, bone loss, reduced libido, decreased muscle mass, increased fat, and fatigue. An increased risk for cardiovascular disease is also suspected, and ADT may prolong the QT/QT<sub>c</sub> interval by electrocardiography.

Ultimately, most male patients on ADT for advanced prostate cancer progress to CRPC. Nonetheless, the prostate cancers in many patients with CRPC remain addicted to androgen signaling and continue to produce PSA, which requires an activated AR. In this setting, two strategies have emerged to ablate androgen signaling more completely. One involves the use of the AR antagonists enzalutamide ([Xtandi] 160 mg daily), apalutamide ([Erleada] 240 mg daily), and darolutamide ([Nubeqa] 600 mg twice daily). Each is approved by the FDA for CRPC; enzalutamide is approved for CRPC with or without overt metastases, while apalutamide and darolutamide are approved for CRPC without overt metastases (enzalutamide and apalutamide are also approved to give along with ADT for castration-sensitive metastatic prostate cancer). A second approach involves inhibition

of adrenal steroid biogenesis to further reduce circulating levels of androgenic hormones. Abiraterone ([Zytiga] 1000 mg daily with 5 mg prednisone twice daily), a CYP17 inhibitor, suppresses extragonadal androgen production and provides an effective treatment for CRPC. Abiraterone must be administered along with replacement corticosteroids (5 mg prednisone twice daily). Blood testing for circulating prostate cancer cells expressing the AR mRNA splice variant V7 (AR-V7) for patients with CRPC can predict resistance to AR antagonists and abiraterone, steering them instead toward taxane chemotherapy. Also, both AR antagonists and abiraterone are being explored in combination with LHRH analogues in clinical trials as initial systemic hormone treatment for high-risk localized prostate cancer.

ADT can be used as adjuvant therapy along with prostate radiotherapy, as initial treatment for prostate cancer recurrence manifest as a rapidly increasing serum PSA in the absence of overt metastases following surgery or radiotherapy, and as treatment for established metastatic prostate cancer, with or without taxane chemotherapy. Of these three indications, the use of ADT for patients with disease recurrence after primary therapy remains somewhat controversial. The concern is that the benefits may not be much better than waiting to initiate ADT until overt metastases can be detected, while the hazards, including bone loss, possible risk for cardiovascular complications, and poor quality of life are significant. Careful monitoring of PSA increases and periodic use of imaging studies may allow for introduction of ADT before symptoms of metastatic prostate cancer appear. PET-CT or PET-MRI scanning with <sup>68</sup>Ga-PSMA or and <sup>18</sup>F-piflufolastat for prostate recurrence in the setting of a increasing serum PSA can aid in treatment planning and timing. Another tactic for ADT in this setting has been intermittent administration. Intermittent ADT appears to control prostate cancer progression as well as continuous ADT and provides some minor improvement in quality of life. Finally, a novel strategy now in clinical trials for patients with advanced prostate cancer exposed to ADT for at least 6 months is the administration of androgenic hormones. This approach can lower serum PSA levels in more than one-half of treated patients and improve quality of life.

Of all the cytotoxic chemotherapy drugs used for advanced prostate cancer, agents targeting intracellular microtubules have exhibited disproportionate activity. Prostate cancer cells tend to have low growth rates, rendering most antineoplastic drugs that interfere with cell replication less effective than for other cancers. Taxane drugs, including docetaxel (Taxotere) and cabazitaxel (Jevtana), disrupt microtubule function in both replicating and nonreplicating cells. In nonreplicating prostate cancer cells, the taxane drugs may hinder the trafficking of AR and other critical gene regulatory proteins into the cell nucleus, triggering apoptosis. Both docetaxel (75 mg/m<sup>2</sup> every 3 weeks given along with prednisone 10 mg daily) and cabazitaxel (25 mg/m<sup>2</sup> every 3 weeks given along with prednisone 10 mg daily) are effective treatments for CRPC, able to lower serum PSA, reduce measurable volumes of cancer seen on imaging studies, and prolong disease survival. Docetaxel toxicity includes significant neutropenia, ankle edema, peripheral neuropathy, hair loss, and nail changes. Cabazitaxel, which was more effective than docetaxel for multidrug-resistant tumor cells in preclinical studies and better able to penetrate the blood-brain barrier, was initially used to treat docetaxel-resistant CRPC. In that setting, cabazitaxel caused more substantial neutropenia than docetaxel and was associated with more diarrhea and asthenia. A randomized trial comparing docetaxel to cabazitaxel as first-line treatment for metastatic CRPC revealed similar overall survival for either treatment, and docetaxel remains the preferred first-line chemotherapy option. Six doses of docetaxel given every 3 weeks is now frequently used along with ADT for patients with metastatic hormone-sensitive prostate cancer, significantly prolonging overall survival when compared with ADT alone in two large randomized clinical trials. In addition to the taxanes docetaxel and cabazitaxel, the topoisomerase poison mitoxantrone (Novantrone) is approved by the FDA as an agent capable of improving quality of life for patients with CRPC.

Palliation of symptomatic bone metastases in patients with CRPC can be achieved using the  $\alpha$ -particle-emitting calcium mimetic  $^{223}\text{Ra}$ . The agent has a brief half-life ( $t_{1/2} = 11.4$  days) and a marked proclivity for skeletal uptake; an estimated 40% to 60% of administered  $^{223}\text{Ra}$  ends up in bones.  $^{223}\text{Ra}$  (50 kBq/kg) is typically given in six injections at 4-week intervals. Side effects include nausea, vomiting, diarrhea, leg swelling, and low blood counts. More recently,  $^{177}\text{Lu}$ - and  $^{225}\text{Ac}$ -labeled PSMA ligands have been introduced into the care of patients with CRPC. Early trials hint at marked beneficial treatment responses. Nonetheless, significant xerostomia resulting from salivary gland toxicity (a site of PSMA expression) bedevils the use of these agents so far. Attempts are ongoing to optimize radiolabeled PSMA ligand dosing to limit salivary gland damage, prevent radioisotope uptake by the salivary gland, and improve treatment for salivary gland dysfunction post-radioactive PSMA ligand administration.

The up to 20% of patients with CRPC who carry germline and/or somatic mutations in homologous recombination repair genes (*BRCA1*, *BRCA2*, *ATM*, *PALB2*, *FANCA*, *RAD51D*, and *CHEK2*) may derive significant benefit from treatment with PARP inhibitors. PARPs are enzymes that contribute to several steps in DNA repair. Inhibition of PARP in cells with homologous recombination deficiency results in “synthetic lethality” and apoptosis. This phenomenon has been exploited successfully for the treatment of ovarian and breast cancers carrying defective homologous recombination repair genes. The PARP inhibitors olaparib ([Lynparza]<sup>1</sup> 300 mg twice daily), rucaparib ([Rubraca]<sup>1</sup> 600 mg twice daily), and niraparib ([Zejula]<sup>1</sup> 300 mg daily) have all shown early evidence of activity in the treatment of CRPC with deficient homologous recombination repair; olaparib and rucaparib are FDA approved for CRPC in the setting of homologous recombination repair gene defects. Common side effects of PARP inhibitors include gastrointestinal symptoms and fatigue.

Two additional systemic treatment approaches merit attention. First, for CRPC arising in the setting of DNA mismatch repair deficiency, like other cancers with DNA mismatch repair defects, the immune checkpoint inhibitor pembrolizumab ([Keytruda]<sup>1</sup> 200 mg every 3 weeks) can be effective at achieving significant and durable treatment responses. Major side effects include “autoimmune breakthrough events” such as colitis, pneumonitis, and hypophysitis. Immune checkpoint inhibitor therapy otherwise shows very little activity against prostate cancers. Second, for patients with CRPC manifest as small cell neuroendocrine cancer, treatment with chemotherapy doublet regimens like cisplatin or carboplatin and etoposide may be helpful.<sup>1</sup>Not FDA approved for this indication.

## Monitoring

Patients treated for clinically localized prostate cancer by surgery or radiation therapy are monitored for cancer recurrence principally by serum PSA testing every 6 to 12 months and by DRE yearly. A newly detectable or increasing serum PSA can trigger a more complete evaluation using abdominopelvic CT or MRI and nuclear medicine scanning with  $^{11}\text{C}$ -choline,  $^{18}\text{F}$ -fluciclovine,  $^{68}\text{Ga}$ -PSMA, or  $^{18}\text{F}$ -piflufolastat.  $^{18}\text{F}$ -deoxyglucose PET imaging is not helpful. If necessary, a prostate biopsy may be undertaken in the setting of disease recurrence after radiation therapy.

Metastatic prostate cancer treatment can be monitored using serial serum PSA determinations and repeated imaging at known and/or symptomatic sites of disease. In addition, whether used for nonmetastatic or metastatic prostate cancer, ADT carries a substantial risk of osteoporosis. As such, patients should be subjected to dual-energy x-ray absorptiometry (DEXA) scanning. For patients with a low fracture risk, calcium (1000 mg) and vitamin D (400 IU) supplements may suffice, but for patients facing a higher probability of bone fracture, treatment with agents such as denosumab ([Prolia] 60 mg every 6 months), zoledronic acid ([Reclast]<sup>1</sup> 4 mg no more often than monthly), or alendronate ([Fosamax]<sup>1</sup> 70 mg once weekly) should be considered along with calcium and vitamin D. Patients receiving ADT should also be

screened for diabetes and for cardiovascular disease, conditions that are common among men in the age range for prostate cancer.

## Management of Complications

Men who are survivors of prostate cancer face a number of health challenges that comprise long-term side effects of the treatment(s) they received. Surgery tends to disrupt urinary and sexual functions. Stress incontinence may be the most common urinary problem, though more severe incontinence can occur. Urinary symptoms, such as urgency, frequency, and nocturia can arise; sometimes these symptoms herald the appearance of a urethral stricture at the site of the anastomosis of the bladder neck to the urethra during surgery. Urethral strictures related to scarring can be distinguished from cancer recurrence and treated via dilation by a urologist. Sexual problems include difficulties achieving erections sufficient for intercourse and a change in sexual experience attributable to lack of ejaculation and to differences in orgasms. Frank discussions about sexual function after primary prostate cancer treatment can aid in sexual recovery. Some urologists have attempted to use phosphodiesterase type 5 inhibitors (sildenafil [Viagra]<sup>1</sup> 50 mg, vardenafil [Levitra]<sup>1</sup> 10 mg, and tadalafil [Cialis]<sup>1</sup> 5 mg) early after surgery to augment restoration of erectile function. These drugs have also been used successfully by some patients to improve erections months and years after surgery. Radiation therapy late effects can also include urinary and sexual difficulties, and they can involve the rectum in inflammation, pain, bleeding, and incontinence. Minor rectal symptoms can be alleviated using stool softeners, but more severe complications require the attention of a gastroenterologist or colorectal surgeon. Hyperbaric oxygen may help some patients with radiation proctitis as a late effect of prostate cancer treatment.

ADT causes a diverse collection of long-term side effects, including loss of libido, erection problems, hot flashes, weight gain and obesity, mood changes/depression, anxiety/distress, gynecomastia, anemia, osteoporosis (see previously), diabetes/metabolic syndrome, and decreased lean muscle mass. Increased physical activity and dietary changes appropriate for obesity can be helpful. Careful attention and screening for psychological stress and depression should be a routine aspect of prostate cancer survivorship care. Even patients likely cured of prostate cancer by surgery or radiation therapy frequently suffer with significant “PSA anxiety” around the time of follow-up vigilance to detect disease recurrence. Hot flashes, which occur in as many as 40% of patients on ADT, can be treated using selective serotonin reuptake inhibitors such as paroxetine ([Paxil]<sup>1</sup> 10 to 20 mg daily), serotonin and norepinephrine uptake inhibitors such as venlafaxine ([Effexor XR]<sup>1</sup> 75 mg daily), or the anticonvulsant gabapentin ([Neurontin]<sup>1</sup> 600 mg or more daily).

## PROSTATITIS

Method of  
Charles Powell, MD

### CURRENT DIAGNOSIS

- The workup for prostatitis begins with a thorough history and physical examination as well as a urinalysis and urine culture. Diagnosis is based on symptoms (Figure 1) and tenderness on digital rectal examination. There is a controversial role for prostate massage and culture of expressed prostatic secretions.
- Urinalysis and midstream urine culture are important to distinguish bacterial from nonbacterial causes, but it is not necessary for the diagnosis of prostatitis.
- Prostatitis is categorized as *acute* or *chronic*. It has been further grouped by the National Institute of Diabetes, Digestive, and Kidney disorders (NIDDK), part of the National Institutes of Health (NIH) into four categories: *acute bacterial*, *chronic bacterial*, *chronic pelvic pain syndrome* (also called *chronic nonbacterial prostatitis*), and *asymptomatic* (Table 1).
- Chronic prostatitis is defined as duration longer than 3 months and typically manifests with pelvic pain and lower urinary tract symptoms.

### CURRENT THERAPY

- The majority of prostatitis falls under the category of chronic prostatitis/chronic pelvic pain syndrome, and monotherapy has not proven effective.
- Fluoroquinolone antibiotics are the first-line therapy for acute and chronic *bacterial* prostatitis, which are thought to comprise <10% of all cases. Ciprofloxacin (Cipro) and levofloxacin (Levaquin) demonstrated cure rates of 73% to 75% in one randomized controlled trial (RCT) with culture-proven prostatitis.
- Trimethoprim/sulfamethoxazole (Bactrim)<sup>1</sup> can be considered first-line therapy, but local antibiotic resistance patterns should be considered before initiating empiric treatment.
- First-generation cephalosporins, doxycycline,<sup>1</sup> tetracycline<sup>1</sup> (not available in most areas), azithromycin (Zithromax),<sup>1</sup> and clarithromycin (Biaxin)<sup>1</sup> are all second-line agents.
- Acute prostatitis may require inpatient admission and intravenous (IV) antibiotics depending on severity and presence of sepsis. Urinary retention may require suprapubic tube urinary drainage as a Foley catheter may worsen prostate inflammation.
- The role of antibiotics in the treatment of *chronic pelvic pain syndrome* is less clear. Treatment directed at *specific phenotypes* has improved outcomes. The UPOINT treatment philosophy (urinary symptoms, psychosocial dysfunction, organ-specific findings, infection, neurologic/systemic, and tenderness of muscle) has garnered much interest in the urologic community and is used to phenotype subjects and to direct multimodal therapy.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

The prevalence of prostatitis is approximately 8.2% (range: 2.2% to 9.7%). It accounts for 8% of visits to urologists and up to 1% of visits to primary care physicians. In 2000, the estimated cost to diagnose and treat prostatitis was \$84 million, not including pharmaceutical spending.

### Risk Factors

The risk factors for prostatitis include urinary tract infection, elevated postvoid residual (urinary retention), recent history of prostate biopsy, urinary catheterization, unprotected anal intercourse, recent urethral instrumentation such as cystoscopy, and condom catheter use.

### Pathophysiology

Prostatitis is commonly associated with infection but can also describe non-infectious chronic pelvic pain as well as asymptomatic histologic evidence of sterile inflammation. The causes for acute and chronic *bacterial* prostatitis include prior genitourinary infections such as epididymitis/orchitis, infection resulting from prostate needle biopsy, and recent urinary tract infection. Other predisposing factors include obstruction of urine from urethral stricture, benign prostatic hyperplasia (BPH), or neurogenic causes. A causative organism can be found in <10% of prostatitis cases. The causative organisms include *Escherichia coli* (most common at 65% to 80% of infections), *Pseudomonas aeruginosa*, *Serratia* species, *Klebsiella* species, and *Enterobacter aerogenes*. Gram-positive organisms include enterococci. Organisms isolated from patients with a recent history of lower urinary tract instrumentation or manipulation exhibit more resistance to ciprofloxacin and cephalosporins. For these patients, ciprofloxacin is often inadequate. A combination of cephalosporins and aminoglycosides is appropriate. Patients with a history of HIV infection should prompt investigation for atypical pathogens. The cause of chronic pelvic pain syndrome/chronic nonbacterial prostatitis (NIH category 3) is less well understood, as is asymptomatic prostatitis (NIH category 4).

### Prevention

Prophylactic antibiotic dose is appropriate before urologic procedures, particularly prostate needle biopsy according to the American Urological Association Best Practice Statement for Urologic Surgery (<http://www.auanet.org>). Preprocedure rectal swabs to assess resistance patterns are now considered in select cases in which resistance is more likely.

### Clinical Manifestations

Figure 1 details some of the symptoms of prostatitis, separated by domain.

### Diagnosis

Diagnosis of acute and chronic bacterial prostatitis is primarily based on history, physical examination, urine culture, and urine specimen testing pre- and post-prostatic massage. If acute bacterial prostatitis is suspected, prostatic massage should not be performed as this might be harmful. Sexually active men younger

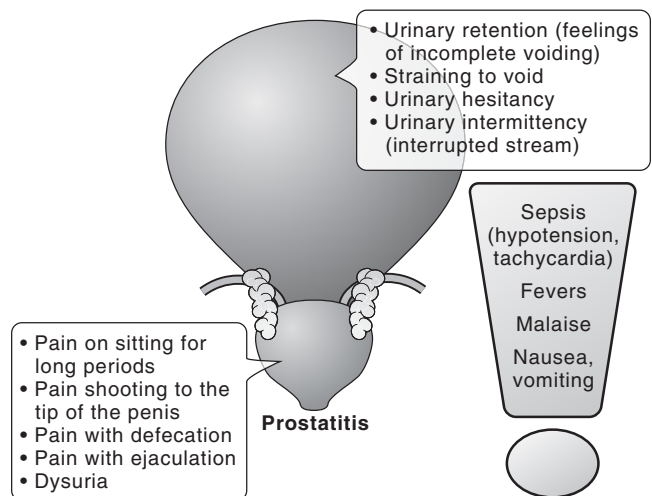

Figure 1 Symptoms associated with prostatitis.

**TABLE 1** National Institutes of Health Consensus Classification of Prostatitis

CATEGORY	DESCRIPTION
I. Acute bacterial prostatitis	Acute infection of the prostate gland with positive urine or semen cultures. Symptoms present for less than 3 months
II. Chronic bacterial prostatitis	Chronic infection of the prostate gland with positive urine or semen cultures. Symptoms present for longer than 3 months
III. Chronic pelvic pain syndrome	Chronic pelvic pain in the absence of bacterial infection localized to the prostate. Symptoms present for longer than 3 months
A. Inflammatory	Significant WBC count in the prostatic secretions, urine, or semen
B. Noninflammatory	Insignificant WBC count in the prostatic secretions, urine, or semen
IV. Asymptomatic prostatitis	WBC count elevated and/or bacteria in the prostatic secretions, urine, semen, or histologic specimens of prostate tissue

than 35 years of age and older men who engage in high-risk sexual behaviors should be tested for *Neisseria gonococcus* and *Chlamydia trachomatis* as well. The presence of leukocytes in the semen, first-void urine, midstream urine, expressed prostatic secretions, or post-prostatic massage urine did not correlate with symptoms when studied in a prospective manner. Bacterial localization studies, such as the Meares-Stamey four-glass test, are useful in subcategorizing type 3 chronic pelvic pain syndrome but have unclear significance in the acute clinical setting.

### Differential Diagnosis

The differential diagnosis of prostatitis includes acute cystitis, BPH, prostate cancer, urinary tract stones, bladder cancer, prostatic abscess, enterovesical fistula, foreign body within the urinary tract, voiding dysfunction, and inflammatory conditions of the bladder such as interstitial cystitis/painful bladder syndrome.

### Therapy (or Treatment)

Treatment depends on the NIH-NIDDK Prostatitis Classification Category. For those with acute prostatitis, oral ciprofloxacin (Cipro)<sup>1</sup> 500 mg orally, twice daily for 4 to 6 weeks or levofloxacin (Levaquin)<sup>1</sup> 500 mg orally, once daily for 4 to 6 weeks is appropriate for nonseptic-appearing patients. Trimethoprim/sulfamethoxazole (Bactrim, Septra),<sup>1</sup> 160 mg/800 mg orally twice daily for 4 to 6 weeks is also appropriate, depending on local antibiotic resistance patterns. Patients who appear septic (hypotension, tachycardia, high fevers) should be admitted to the hospital and started on broad-spectrum antibiotics such as ampicillin 2 g IV every 6 hours and an aminoglycoside such as gentamicin 1 mg/kg IV every 8 hours. Aminoglycosides should be monitored and adjusted based on serum peak and trough levels. Aminoglycosides should be used cautiously in patients with azotemia. Prostatic abscess should be considered if patients do not improve within 24 to 48 hours. Prostatic abscesses are urologic emergencies and can be drained with transurethral resection of

the prostate, ultrasound-guided transrectal needle drainage, or CT-guided needle drainage. Urinary retention should be treated with suprapubic catheter drainage in cases of acute prostatitis. Chronic bacterial prostatitis (CBP) is treated with the same oral agents as acute bacterial prostatitis. For the treatment of chronic pelvic pain syndrome (CPPS) antibiotics play a less clear role, but fluoroquinolone antibiotics used empirically for 4 to 6 weeks have been effective in previously untreated patients. There is little value to repeated courses of antibiotics if the first course is not effective. There is conflicting evidence for alpha blockers such as tamsulosin (Flomax 0.4 mg orally once per night)<sup>1</sup>. The interested reader is referred to a 2010 review by Nickel wherein a multidisciplinary approach is advocated, taking into account a more detailed six-domain phenotype with therapy directed at the relevant phenotype(s). This is known as UPOINT. These phenotype domains include urinary symptoms (divided into voiding and storage symptoms), psychosocial dysfunction (divided into depression and catastrophizing), organ-specific findings (divided into bladder and prostate), infection (noted in the urine or expressed prostatic secretions), neurologic (divided into focal and systemic), and tenderness (of muscle). Categorizing patients according to these domains may allow clinicians to personalize treatment using a multimodal approach involving physical therapy, psychiatry, and medication.

Other therapies have been described with low-quality evidence for efficacy. These are included here as an alternative treatment option for patients who do not respond to the interventions and strategies outlined earlier. The 5-alpha reductase inhibitors (finasteride [Proscar]<sup>1</sup>) have demonstrated slight improvement over placebo in two underpowered RCTs, but carry a 10% to 15% risk of adverse events including "partial impotence." Chronic opioid therapy (COT) is appealing to some, but as the U.S. Centers for Disease Control and Prevention (CDC) has noted, the harms outweigh the benefits for most causes of chronic pain, and its use should be discouraged. Celecoxib (Celebrex)<sup>1</sup> has demonstrated no benefit over placebo in one RCT utilizing the National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) as the validated endpoint. Allopurinol (Zyloprim)<sup>1</sup> has demonstrated a slight benefit versus placebo in an underpowered RCT that utilized a nonvalidated questionnaire as the clinical endpoint. Pentosan polysulfate (Elmiron)<sup>1</sup> has demonstrated a slight benefit in the NIH-CPSI quality-of-life domain compared with placebo, but not in other endpoints. In this study, 22 of 100 men (22%) withdrew from the study because of adverse events such as diarrhea, headache, and nausea. Transurethral microwave therapy (TUMT) of the prostate, a treatment for BPH, has been noted in one very small RCT ( $n = 20$ ) comparing sham treatment versus TUMT. This study reported 7 of 10 patients having at least 50% improvement, measured by a nonvalidated "global assessment" endpoint. Transurethral resection of the prostate (TURP) has also been discussed, but no RCT exists with the intent to treat men with chronic prostatitis. It is an untested option for men in whom all other treatment modalities have failed, but it has a long history of ameliorating obstructive and irritative lower urinary tract symptoms (LUTS) that often accompany CP/CPPS. Investigators have noted some non-randomized benefit to administration of 200 units onabotulinumtoxin A (Botox)<sup>1</sup> directly into the prostate. They report that 72% of 42 nonrandomized men responded at 3 months compared with 0% who underwent cystoscopy alone. The improvement decreased to 37% at 12 months, which is not surprising because the medication loses efficacy 6 to 12 months after administration.

### Monitoring

Monitoring is based on symptoms. In cases of acute prostatitis treated with appropriate antibiotics, persistent fevers should prompt a workup for prostatic abscess. The NIH-CPSI patient-reported questionnaire can be used to quantify symptoms over

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

time. It is available online at <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2736311>. PSA testing plays no role in the treatment or monitoring of prostatitis, but it should be considered if risk factors for prostate cancer are present such as a prostate nodule or family history. PSA testing is affected by acute inflammation and should be postponed until a few months after the symptoms of prostatitis have resolved.

### Complications

Acute prostatitis can progress to urosepsis and hypotension. Chronic bacterial prostatitis might have the ability to progress to chronic pelvic pain syndrome and become a source of pain for years.

## URINARY TRACT INFECTIONS IN THE MALE

Method of

Donald A. Neff, MD

### CURRENT DIAGNOSIS

- Urinary tract infection (UTI) can involve any portion of the urinary tract.
- Infection at any site in the urinary tract places the entire system at risk.
- UTIs can be broadly categorized as uncomplicated or complicated.
- Although uncommon, men can have uncomplicated UTI.
- Urologic evaluation is recommended for UTI in young boys.
- Detailed workup of uncomplicated UTI in the adult male is usually not needed.
- Urinalysis is useful to establish presumptive diagnosis.
- Urine culture with sensitivities is helpful to document infection and guide therapy.
- Repeat urine culture after treatment is unnecessary in uncomplicated infections.
- Screening urine cultures in asymptomatic individuals should be avoided.

### CURRENT THERAPY

- The goal of treatment is elimination of infection from the urinary tract.
- Prompt initiation of treatment can prevent the spread of infection to other portions of the urinary tract.
- Management of complicated UTI should include imaging of the upper urinary tract.
- Efforts should be made to control underlying risk factors in patients with complicated UTI.
- For complicated UTI, repeat culture after treatment may be helpful to document clearance of infection.

### Definitions

Standardized terminology is helpful for communications between providers.

**Bacteriuria:** Presence of bacteria in the urine. This may be symptomatic or asymptomatic. Asymptomatic bacteriuria may not require treatment.

**Pyuria:** Presence of white blood cells (WBCs) in the urine. Suggests infection or inflammatory response of the urothelium. Sterile pyuria is lack of bacterial growth in presence of WBCs in the urine and should warrant further investigation to determine the underlying cause.

**Urinary tract infection (UTI):** Inflammatory response of urothelium to bacterial invasion

**Uncomplicated UTI:** Infection in a healthy patient with anatomically and functionally normal urinary tract. These infections respond promptly to appropriate treatment.

**Complicated UTI:** Infection associated with an anatomically or functionally abnormal urinary tract. The host may be immunocompromised. Risk factors for complicated UTI include male gender, advanced age, diabetes, immunosuppression, recent antibiotic use, the presence of an indwelling urinary catheter, recent instrumentation, and recent hospitalization.

**Colonization:** Presence of bacteriuria in the urine and absence of inflammatory response. Often seen in patients with indwelling urinary catheters. Generally, colonization does not require treatment. Overtreatment of the colonized urinary tract will select for bacterial resistance.

**Isolated UTI:** Infection in patient with no or remote prior history

**Recurrent UTI:** Infection that occurs after successful treatment of a prior infection. May be bacterial persistence or reinfection. Persistence is suggested by growth of the same organism. Reinfection usually shows growth of different types of organisms.

**Unresolved UTI:** Generally due to bacterial persistence. Repeated infection with same organism with similar resistance profile.

## Introduction

Urinary tract infections (UTIs) are one of the most common bacterial infections in humans. UTI is defined as an inflammatory response of the urothelium to bacterial invasion. Infections of the urinary tract encompass a wide variety of diagnoses depending on the specific anatomic site of infection, the common denominator being bacterial invasion of genitourinary organs and tissues. Any site within the urinary tract may be involved including the kidney (pyelonephritis), ureters (ureteritis), bladder (cystitis), prostate (prostatitis), epididymis (epididymitis), and urethra (urethritis). Once any part of the urinary tract is infected, the remaining portions of the system are placed at risk for further bacterial invasion. Due in part to the relative rarity of UTI in adult males, evaluation and management of UTI in this population is hampered by lack of high-quality empirical data with which to guide treatment decisions.

## Incidence and Epidemiology

UTI in males is not a reportable disease. Therefore, true incidence is difficult to assess in the United States. For both sexes, UTI accounts for 7 million office visits and 400,000 hospitalizations annually. In men, UTI accounts for 0.6% of all office visits. During infancy, the incidence of symptomatic UTIs is higher in boys than in girls, primarily related to circumcision status. Bacteria adhere to the inner prepuce, allowing easier access to the meatus followed by ascending infection. Neonatal circumcision reduces the rate of UTI in boys by over 90%. After the neonatal period, symptomatic UTI is uncommon until middle age. The incidence then increases to approach 10% by age 61, 14% in ages 61 to 70, 26% in ages 71 to 80, and 42% over age 81.

## Pathophysiology

In the modern era most infections of the urinary tract occur via the ascending route. This begins with colonization of the perineum, most commonly with fecal bacteria. These bacteria then move from the perineal area to the urethra and to the bladder, ureter, and eventually the kidney. Fecal flora is a common source with *Escherichia coli* being the most common cause of UTIs. *E. coli* accounts for 85% of community acquired and 50% of hospital acquired infections. Hematogenous seeding does occur; however, this is much less likely in anatomically and physiologically normal individuals. The kidney may be secondarily infected by *Staphylococcus aureus* or *Candida fungemia* in this manner. In certain geographic areas, tuberculosis of the urinary tract is still seen and reaches these organs hematogenously. These types of infection are facilitated by prior renal damage or obstruction of the urinary tract.

Adherence of bacteria to the uroepithelium is an essential step in the pathogenesis of UTI. Bacterial virulence factors such as adhesins, type-1 pili, and P pili facilitate adherence to receptors on uroepithelial cells. Some individuals are genetically predisposed to infection, with increased uroepithelial receptivity to adherence of bacteria resulting in increased susceptibility to infection. Once within the bladder, uropathogenic bacteria are internalized into the intracellular space of superficial urothelial cells. In this space, the bacteria are more protected from the immune response and

form intracellular bacterial communities, eventually forming protective biofilms. Bacteria then escape from the intracellular space into the urinary lumen, where they readhere and reinvade the uroepithelium. Once the inoculum is sufficient, a host immune response occurs. This response involves multiple cell types including neutrophils, macrophages, and other immunocytes along with associated cytokines. This inflammatory response results in the symptoms of UTI. Indeed, the levels of certain inflammatory factors have been correlated with the severity of symptoms.

The urinary tract has natural defenses in place to resist adherence and ascension of bacteria. Normal urogenital flora form a barrier to colonization by uropathogenic bacteria. Inhibitory urinary factors include osmolality, urea, organic acid concentration, and pH. Uromodulin is a protein present in the urine that binds to type-1 pili, preventing binding of bacteria to the urothelium. Regular and complete emptying of the bladder helps to expel bacteria and keep bacterial inoculum low.

## Clinical Manifestations

The specific clinical symptoms of UTI depend on the anatomic site of infection. Urethritis presents with dysuria, urinary urgency and frequency, and penile discharge. The penis may be tender or swollen. Associated inguinal lymphadenopathy may be present. Epididymitis usually presents as unilateral testicular pain that is gradual in onset. The scrotum is swollen, warm, and erythematous. Scrotal cellulitis may be present. Acute prostatitis includes fevers, chills, dysuria, and pelvic pain. Urinary hesitancy and weak stream are often seen due to swelling of the prostate gland and increased resistance of flow through the prostatic urethra. Cystitis is associated with dysuria, urinary urgency, and urinary frequency. There may be associated suprapubic pain or gross hematuria. Pyelonephritis is associated with the classical triad of fevers, chills, and flank pain. In older adults, symptoms may not be as clear. Generalized abdominal pain, increased confusion, and altered mental status may be the presenting signs of UTI in these individuals.

An important consideration is the entity of asymptomatic bacteriuria. In this instance bacteria are able to be identified in a noncontaminated urine culture. However, there is no associated immune response, or the clinical symptoms mentioned above. Indeed, urine is not sterile as has been previously thought, with a normal urinary microbiome present that is difficult to detect on routine culture media.

Prevalence of asymptomatic bacteriuria increases with age and can be seen in up to 15% of men over age 75. In general, asymptomatic bacteriuria should not be treated. The 2019 guidelines of the Infectious Diseases Society of America (IDSA) recommend screening and treatment of men for asymptomatic bacteria only in patients undergoing invasive urologic procedures. Inappropriate treatment of asymptomatic bacteria contributes to antimicrobial resistance.

## Differential Diagnosis

The differential diagnosis of UTI should be focused on the anatomic location of symptoms. Urethritis can be caused by multiple organisms, and sexually transmitted diseases should be considered. Lower urinary tract symptoms (urgency, frequency) associated with cystitis can also be seen with bladder stones or bladder tumors. Flank pain may result from urinary tract obstruction due to stone, trauma, or musculoskeletal sources. Sterile pyuria should prompt investigation for stone, tuberculosis, and malignancy. Sterile pyuria may also be associated with nonurologic diagnosis such as appendicitis, diverticulitis, or autoimmune diseases.

## Clinical Evaluation

The foundation for evaluation of a patient with UTI remains a thorough history and physical examination. A detailed surgical history is helpful to determine risk factors for complicated

UTI. A urinalysis is essential in the evaluation of urinary symptoms and can provide information for a preliminary diagnosis. Normal urine should be free of bacteria and inflammation. False negatives can occur early in the clinical course or when a patient has taken antimicrobial therapy prior to obtaining the urine specimen. False positives may be caused by contamination or over-the-counter remedies such as phenazopyridine (positive nitrites). The decision to send a urine culture should be based on the overall clinical picture. For an uncomplicated UTI, a urine culture is helpful but not required unless the patient fails to improve with treatment. If symptoms fail to improve, or if the patient has risk factors for complicated UTI, a culture is strongly recommended to determine the underlying organism and antimicrobial sensitivities. Proper collection and storage of the urine specimen can minimize the potential for false results.

Localization of bacteria to differentiate the source of an infection within the lower urinary tract of males can be challenging. The Meares-Stamey four-glass urinary tract localization test has been well described. First, the patient is asked to void 5 to 10 cc into a sterile container (VB1). A second, midstream specimen is then obtained (VB2). A prostatic massage is then performed by digital rectal examination (DRE), and the expressed fluids are collected (EPS). Finally, the postprostate massage urine is collected. The four specimens are then sent separately for culture and sensitivity. VB1 represents urethral flora, VB2 represents bladder urine flora, EPS and VB3 represent prostatic flora. The four-glass test can be expensive, cumbersome, and is often of low diagnostic yield. An alternate approach is a modified Meares-Stamey two-glass test, which is easier and less costly to perform. This is performed by collecting a urine specimen premassage and then a second specimen post-massage. The premassage specimen represents bladder flora, and the post-massage specimen represents the prostatic flora.

Due to the rarity of urinary infection in boys outside of the neonatal period, urologic investigation is essential for the evaluation of UTI in the pediatric population to rule out structural abnormalities. These include vesicoureteral reflux, posterior urethral valves, congenital ureteropelvic junction obstruction, ureterocele, and megaureter. Referral to a pediatric urologist should be considered. Early diagnosis and therapy will help prevent scarring and preserve renal function. A history of constipation should be elucidated, as bowel-bladder dysfunction places boys at risk of UTI. The optimal imaging approach to the pediatric patient is controversial. The combination of renal-bladder ultrasound and voiding cystourethrogram (VCUG) has traditionally been used to assess both the upper and lower urinary tracts. In the modern era, provided the renal bladder ultrasound is normal, VCUG may be safely deferred. A nuclear medicine scan can be useful to determine differential renal function and identify the presence of obstruction of the upper urinary tract.

For adults, the use of radiographic investigations is again based on the unique clinical picture of a given patient. For uncomplicated UTI, particularly in otherwise healthy men whose infections resolve easily, detailed investigations, including imaging, are often not necessary. Complicated infections require further investigation to search for a nidus or anatomic abnormality. These include patients with a recurrent or unresolved infection or patients with aforementioned risk factors. Computed tomography (CT) urography is a complete study of the upper urinary tract and includes a noncontrast phase, a nephrographic phase, and delayed images to evaluate the upper urinary drainage system. This study allows for assessment of renal stones, masses, impaired or altered drainage, and is the imaging study of choice in patients with normal renal function. For patients with poor renal function, renal-bladder ultrasound is a reasonable alternative. Measurement of post-void residual is helpful to determine whether retention of urine is causing urinary stasis.

## Treatment

Elimination of the infecting organism from the urinary tract is the goal of therapy for UTI. There is limited data to guide duration of treatment of UTI in males, with many treatment strategies extrapolated from studies done in females. Although traditionally men have been considered to always have complicated UTIs, an afebrile man with a first UTI and no complicating factors can be considered to have an uncomplicated UTI.

In general, empirical selection of antimicrobial therapy should be selected to target the pathogen being treated, with local resistance patterns taken into consideration. Uncomplicated infections should be anticipated to resolve promptly with appropriate therapy. Duration of therapy for these types of infections in men is not well established, but 5 to 7 days of treatment is reasonable depending on the agent chosen. Prompt initiation of broad spectrum therapy in complicated UTIs will help prevent further dissemination of the infection and the development of sepsis. Treatment can later be tailored to the results of culture and sensitivities. These infections require longer duration of therapy, 10 to 14 days. In the setting of multidrug-resistant isolates, parenteral therapy may be required for the duration of treatment. For patients with bacterial persistence after treatment, a thorough urologic evaluation should be made, followed by an attempt to eliminate the source of bacteria if possible.

## Monitoring and Prevention

In most patients with UTI, routine repeat culture of urine after therapy is not indicated. However, if patients thought to have uncomplicated UTI do not improve as expected, a urine culture should be obtained to guide therapy. Similarly, rapid recurrence of symptoms after initial improvement should prompt repeat urine culture. Antibiotic prophylaxis in males is generally not warranted, and prevention should be directed at elimination or treatment of the underlying cause if possible. For example, initiation of medications in patients with incomplete bladder emptying due to BPH, or treatment of an infected urinary stone would be of higher yield than suppressive antibiotics.

## Management of Complications

Complications in patients with UTI should be managed according to the clinical setting. The decision to admit a patient to the hospital is dictated by multiple factors. Nontoxic patients who can take PO medications may be safely managed as outpatients. Immunosuppressed or diabetic patients may warrant admission for observation. These patients and those with other risk factors for complicated UTI may progress rapidly to sepsis, and admission to the intensive care unit (ICU) may be necessary. Patients who develop perinephric or prostatic abscess will require either percutaneous or surgical drainage.

## Special Considerations

Patients with chronic indwelling catheters will nearly always be colonized. Screening cultures are not indicated and should be avoided. In general, bacterial colonization of the urinary tract should not be treated unless symptoms develop. It is often counterproductive to attempt clearance of bacteria in this population as overtreatment will select for bacterial resistance. Further, elimination of benign colonizing bacteria from the urinary tract in these individuals often allows more virulent bacteria to establish residence. Antimicrobial prophylaxis is not indicated. Treatment strategies in these individuals should be focused on the underlying factors leading to the need for catheter drainage. These include institution of clean intermittent catheterization when possible, or more frequent changing of the catheter if necessary.

Another special consideration is the presence of a bacterial UTI in an obstructed urinary system. This most commonly occurs when a kidney stone causes ureteral obstruction in the setting of pyelonephritis. These patients can rapidly progress to sepsis.

Prompt drainage of the affected renal unit either by ureteral stent or by percutaneous nephrostomy tube, along with institution of appropriate antimicrobial therapy, is essential in the management of these patients.

## ABNORMAL UTERINE BLEEDING

Method of

Sarina Schrager, MD, MS

### CURRENT DIAGNOSIS

- Anovulation and pelvic structural abnormalities are the most common causes of abnormal vaginal bleeding in reproductive-age women.
- All women with abnormal bleeding should have a pregnancy test.
- A pelvic ultrasound will detect many structural causes of abnormal bleeding.
- Either a pelvic ultrasound or endometrial biopsy is appropriate for evaluation of postmenopausal bleeding.

### CURRENT THERAPY

- Unstable women with acute heavy vaginal bleeding should be admitted to hospital for intravenous (IV) estrogen therapy (Premarin) or surgical intervention.
- Treatment of anovulatory bleeding includes ovulation induction if a woman desires pregnancy and hormonal cycle control if she does not.
- Anovulatory women are at risk for endometrial hyperplasia or carcinoma due to unopposed estrogen and should have regular progesterone-induced withdrawal bleeds.
- Treatment of menorrhagia can include nonsteroidal antiinflammatory drugs (NSAIDs), tranexamic acid (Lysteda), or insertion of a levonorgestrel intrauterine device (IUD) (Mirena).

### Epidemiology

Abnormal vaginal bleeding is a common complaint in primary care. The prevalence of some type of abnormal bleeding is between 10% and 30% among women of reproductive age. Anovulatory bleeding is more common in women who are perimenopausal and who are overweight. The estimated direct and indirect costs of abnormal bleeding are \$1 billion and \$12 billion annually, respectively. Abnormal bleeding is also a common reason for women to be referred to gynecologists and is an indication for up to 25% of all gynecologic surgery.

### Pathophysiology

Normal menstrual bleeding is defined as regular vaginal bleeding that occurs at intervals from every 21 to 35 days. A normal menstrual cycle is ovulatory, with two distinct phases: the follicular phase and the luteal phase. The follicular phase is the first half of the cycle. The luteal phase occurs after ovulation, when the corpus luteum develops in anticipation of a possible pregnancy. [Table 1](#) defines vocabulary to describe different patterns of abnormal bleeding.

**TABLE 1** Causes of Abnormal Uterine Bleeding (ACOG)

PALM (structural causes)	COEIN (non-structural causes)
Polyp	Coagulopathy
Adenomyosis	Ovulatory dysfunction
Leiomyoma	Endometrial
Malignancy and hyperplasia	Iatrogenic
	Not yet classified

**TABLE 2** Signs and Symptoms of Ovulatory Cycles

Regular cycle length	Presence of premenstrual stress (PMS) symptoms
Dysmenorrhea	Mittelschmerz (pain at ovulation)
Changes in cervical mucus	Biphasic temperature curve
Premenstrual breast tenderness	Positive test result from luteinizing hormone (LH) predictor kit

The pathologic abnormality in anovulatory cycles is a lack of ovulation, which produces an unopposed estrogen state. The luteal phase of the menstrual cycle is dominated by progesterone, which is only produced after ovulation. This lack of progesterone contributes to irregular endometrial growth and nonuniform bleeding. In a normal cycle, the entire endometrium sloughs off during menstruation. In an anovulatory cycle, different sections of endometrium outgrow their blood supply at different times and bleed erratically. Anovulatory bleeding (also referred to as dysfunctional uterine bleeding) is unpredictable in timing and amount of bleeding.

The most common structural abnormalities that cause abnormal bleeding are endometrial polyps, leiomyomas, adenomyosis, and hyperplasia or malignancy.

Abnormal bleeding is also common in women who use hormonal contraception, usually due to endometrial abnormalities from exogenous hormones. Women who take combination estrogen/progestin contraception often have intermenstrual bleeding for the first 3 months of treatment. Missed pills are a very frequent cause of abnormal bleeding. In women using progestin-only methods, the abnormal bleeding usually is caused by progestin-induced endometrial atrophy.

### Diagnosis

All women with abnormal bleeding should have a thorough history and physical examination and a pregnancy test. If the pregnancy test is negative, the next step is to determine whether her cycles are ovulatory or anovulatory. [Table 2](#) describes characteristics of ovulatory cycles. Laboratory evaluation includes looking for causes of anovulation ([Table 3](#)), assessing for anemia with a hemoglobin and hematocrit level, and consideration of getting a pelvic ultrasound to look for structural abnormalities.

In menorrhagia, evaluation for a coagulation disorder (most commonly von Willebrand disease), liver failure, or chronic renal

In menorrhagia: <ul style="list-style-type: none"> <li>• Consideration of liver function tests, BUN/Cr, CBC, coagulation profile</li> <li>• Pelvic ultrasound to exclude uterine fibroids</li> <li>• Sonohysterogram to exclude polyps or adenomyosis</li> <li>• Endometrial biopsy (especially if age &gt;45) to exclude endometrial hyperplasia</li> </ul>	Laboratory studies: <ul style="list-style-type: none"> <li>• TSH</li> <li>• Prolactin</li> <li>• CBC (if acute bleeding episode or frequent heavy bleeding)</li> <li>• Consideration of endometrial biopsy (especially if age &gt;45) to exclude hyperplasia or malignancy</li> <li>• Evaluation for other symptoms of PCOS</li> </ul>
In intermenstrual bleeding: <ul style="list-style-type: none"> <li>• Pap smear, cervical cultures</li> </ul>	Screen for eating disorder, stress, female athlete triad

*Abbreviations:* BUN/Cr=blood urea nitrogen/creatinine; CBC=complete blood count; Pap=Papanicolaou smear; PCOS=polycystic ovary syndrome; TSH=thyroid-stimulating hormone.

failure is also indicated. Evaluation in an acute bleeding episode (usually due to anovulatory bleeding) should include a hemoglobin and hematocrit if the bleeding is heavy assessment of volume status, and an endometrial biopsy. Postmenopausal bleeding is related to an increased risk of endometrial hyperplasia and cancer and should be evaluated with a transvaginal ultrasound to look at the endometrial thickness (under 4 mm is reassuring) or an office endometrial biopsy. [Table 4](#) describes the steps in evaluation of a woman with abnormal bleeding.

### Treatment

If a woman presents with heavy bleeding and exhibits any signs or symptoms of hypovolemia, she should be admitted to the hospital and either treated with IV conjugated estrogen (Premarin) to stop the bleeding or have a surgical procedure (such as dilation and curettage). If the bleeding is heavy but the woman is stable and her hemoglobin and hematocrit are close to normal, outpatient treatment with high-dose oral contraceptive pills (OCPs), estrogen, cyclic progesterone, NSAIDs, or tranexamic acid (Lysteda) is indicated. Women with structural abnormalities causing menorrhagia should be referred for possible surgical treatment.

Treatment of women with ovulatory bleeding is indicated if the woman is anemic or is bothered by her bleeding pattern. However,

**TABLE 5** Treatment Options for Abnormal Vaginal Bleeding

**Anovulation:** cycle control with estrogen/progestin contraception, DMPA, levonorgestrel IUD (Mirena), or scheduled progestin-induced withdrawal bleeds, ovulation induction with clomiphene citrate (Clomid), and referral to gynecologist if pregnancy desired

**Acute bleeding episode—outpatient:** administration of high-dose OCPs (up to 4 per day) for 5–7 days with subsequent continuous cycling with OCPs for at least 1 month, administration of oral estrogen to acutely stop bleeding, or administration of oral progesterone to acutely stop bleeding

**Acute bleeding episode—inpatient:** IVF, supportive care, IV estrogen therapy, consultation for surgical intervention

**Menorrhagia—treatment with NSAIDs, tranexamic acid (Lysteda), insertion of levonorgestrel IUD, referral for endometrial ablation or surgical treatment of structural abnormality**

**On combination estrogen/progestin contraception:** supportive care for first 3 months, assessment of adherence to pill regimen, add supplemental estrogen, change to a method with a higher dose of estrogen or a different class of progestin

**On progestin-only contraception:** add supplemental estrogen or combination oral contraceptive pill and NSAID to decrease bleeding

*Abbreviations:* DMPA=depot medroxyprogesterone acetate (Depo-Provera); IUD=intrauterine device; IV=intravenous; IVF=in vitro fertilization; NSAID=nonsteroidal antiinflammatory drug; OCP=oral contraceptive pill.

treatment of anovulation with some type of progesterone is necessary to reduce the risk of endometrial hyperplasia or carcinoma. All women with chronic anovulation should have regular progesterone-induced withdrawal bleed. OCPs, monthly cycling of progesterone, and continuous administration of progestin contraception (e.g., depot medroxyprogesterone acetate [Depo-Provera] or levonorgestrel IUD [Mirena]) are all effective treatments ([Table 5](#)).

Treatment of women with abnormal bleeding on OCPs involves education and support to try to get them through the first 3 months on the pills. After that, consideration of supplemental estrogen, changing to a higher dose of an estrogen pill, changing to a pill with a different class of progestin, use of a supplemental NSAID to decrease the amount of bleeding, decreasing the hormone free interval, or changing to a nonhormonal type of contraception are all potential treatments.

## AMENORRHEA

Method of

Colleen Loo-Gross, MD, MPH

### CURRENT DIAGNOSIS

- In the absence of physiologic causes (e.g., pregnancy, lactation, and menopause), four conditions account for the majority of amenorrhea cases: polycystic ovary syndrome, hypothalamic amenorrhea, hyperprolactinemia, and primary ovarian insufficiency.
- Most causes of amenorrhea can be identified through a detailed history, physical examination, and laboratory evaluation.
- Müllerian agenesis is the most common cause of anatomic malformations associated with amenorrhea.
- In the evaluation of amenorrhea, it is important to exclude physiologic causes such as pregnancy and lactation, as well as potential iatrogenic causes (e.g., hormonal contraception, chemotherapy and radiation therapy, and medications that may cause hyperprolactinemia).
- Initial laboratory evaluation should include follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and prolactin levels.
- In amenorrheic women less than 40 years of age, an elevated FSH level in the menopausal range indicates primary ovarian insufficiency.
- A low or normal FSH value in amenorrhea without evidence of anatomic cause suggests chronic anovulation, most commonly attributed to hypothalamic amenorrhea or polycystic ovary syndrome.
- In cases of elevated prolactin level (with no evidence of thyroid disease), MRI is warranted to assess for a possible pituitary tumor.

### CURRENT THERAPY

- The underlying cause of amenorrhea should be treated accordingly.
- For those with an estrogen deficient state, cyclic hormone therapy may be indicated, and adequate calcium and vitamin D intake are essential to reduce the risk of osteoporosis.
- Fertility considerations should be addressed in all causes of amenorrhea.
- Psychosocial support, such as counseling services and peer support groups, is an important aspect of management.

Amenorrhea is defined as the absence of menses. Its prevalence, when not related to pregnancy or lactation, is approximately 3% to 4% among premenopausal women. Amenorrhea is further categorized into primary amenorrhea (prior to menarche) and secondary amenorrhea (following menarche). Evaluation for primary amenorrhea should be initiated when menarche has not occurred by 15 years of age, or sooner for females without onset of menses within 5 years of thelarche. Evaluation should also be considered when thelarche has not occurred by 13 years of age. Secondary amenorrhea is the lack of menses for 3 months in females with preceding regular cycles or 6 months in those with irregular menstrual cycles.

### Etiology

There are a number of potential etiologies of amenorrhea. In the absence of physiologic causes (e.g., pregnancy, lactation, and menopause), four conditions account for the majority of amenorrhea cases: polycystic ovary syndrome (PCOS), hypothalamic

amenorrhea, hyperprolactinemia, and primary ovarian insufficiency. The approximate frequency of common causes of primary and secondary amenorrhea are shown in [Tables 1 and 2](#). Other considerations may also include adrenal disease, adrenal hyperplasia, chronic disease, Cushing syndrome, androgen-secreting tumors, central nervous system infections, and a history of trauma (such as traumatic brain injury).

With primary amenorrhea, anatomic defects and chromosomal abnormalities (with associated primary ovarian insufficiency) are often causative factors. Anatomic abnormalities may cause amenorrhea due to obstruction along the genital outflow tract. With Müllerian agenesis, incomplete development of the Müllerian duct embryologically results in a range of defects due to agenesis or atresia of the uterus and/or vagina, though ovarian function is usually unaffected. Müllerian agenesis is a common cause of primary amenorrhea among females who present with normal signs of adrenarche and breast development. In primary ovarian insufficiency, amenorrhea occurs as the result of ovarian follicle depletion or dysfunction. It comprises 2% to 10% of cases of amenorrhea.

Excluding pregnancy, the most common causes of secondary amenorrhea are hypothalamic amenorrhea and PCOS. Functional hypothalamic amenorrhea occurs in the presence of hypothalamic-pituitary-ovarian axis suppression, without evidence of organic cause. In these cases, the regulatory pulsatile secretion of gonadotropin-releasing hormone (GnRH) is affected, leading to abnormally low levels of estrogen.

### Evaluation

Most causes of amenorrhea can be identified through a detailed history, physical examination, and laboratory evaluation. It is important to exclude physiologic causes of amenorrhea such as pregnancy and lactation, as well as potential iatrogenic causes (for example, hormonal contraception, chemotherapy and radiation therapy, and medications that may cause hyperprolactinemia such as antipsychotics, antidepressants, opiates, and metoclopramide [Reglan]). The incidence of amenorrhea is approximately 12% in women taking antipsychotic medications, due to the resultant increase in prolactin levels.

### History

Obtaining a detailed history is an important component in the evaluation of amenorrhea. The presence of vasomotor symptoms, such as hot flashes, may be indicators of primary ovarian insufficiency, whereas reports of headache or vision changes may prompt further evaluation for possible central nervous system tumor or empty sella syndrome. Women with anatomic causes of amenorrhea, such as transverse vaginal septum, imperforate hymen, and isolated absence of the vagina or cervix, may report cyclic pelvic pain, which occurs due to blood accumulation behind the outflow tract obstruction and in some cases, associated endometriosis. Anosmia may be an indication of the rare Kallmann syndrome, which presents with amenorrhea due to GnRH deficiency and is associated with abnormal development of the olfactory bulb.

Additional history details should include assessment of mood and stress, weight changes, nutrition and eating patterns, and exercise routines, with evaluation for a possible eating disorder or other cause of an overall energy deficit. Abnormal historical findings such as these may be suggestive of functional hypothalamic amenorrhea. It is also important to assess for signs or symptoms of thyroid disease and of other potential chronic medical conditions.

Family history may also provide useful information. A positive family history for delayed menarche may suggest constitutional delay of puberty as the cause of amenorrhea, though this is considered a diagnosis of exclusion. A family history of primary ovarian insufficiency is also worth noting, given the related genetic predisposition. Moreover, early menopause in family members is a risk factor associated with primary ovarian insufficiency.

### Physical Examination

About 15% of those with primary amenorrhea have an abnormality noted on genital examination. Both internal and external genitalia should be examined. A shortened vagina is associated with conditions such as Müllerian agenesis (which may present with a range of defects resulting from incomplete embryologic development of the Müllerian duct), imperforate hymen, transverse vaginal septum, cervical atresia, or other uterine anomalies. In some cases, the vagina may appear as no more than a small dimple.

Additional physical findings may also help guide the evaluation of amenorrhea. Dysmorphic features should be noted, such as a webbed neck or short stature, which may be suggestive of Turner syndrome. Galactorrhea may warrant evaluation for a pituitary tumor. Clinical evidence of self-induced vomiting may be suggestive of a hypothalamic etiology of amenorrhea.

The physical examination should further assess for secondary sexual characteristics, such as the presence of pubic hair and also breast development, which is an indicator of endogenous estrogen effect. Conversely, the presence of thin vaginal mucosa is a sign of low endogenous estrogen level. Signs of hirsutism, acne, and male pattern alopecia are indicators of androgen excess, which may suggest hyperandrogenic etiologies of amenorrhea such as PCOS. Body mass index (BMI) also helps to differentiate PCOS from other causes of amenorrhea (such as functional disorders of the hypothalamus) given its typical presentation with obesity.

### Laboratory Studies

When the etiology of amenorrhea is not evident after completing a thorough history and physical examination, additional assessment is warranted. Initial laboratory evaluation should include levels of follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and prolactin. Abnormal thyroid levels should be managed accordingly. An elevated prolactin level without apparent cause necessitates further investigation with diagnostic imaging of the pituitary gland.

In amenorrheic women less than 40 years of age, an elevated FSH level in the menopausal range indicates primary ovarian insufficiency. The FSH level should be repeated at least 1 month following the initial result for confirmation. For women less than 30 years of age with identified primary ovarian insufficiency, a karyotype should be obtained to assess for possible chromosomal abnormality. Karyotype analysis may be considered for those over 30 years of age as well. In cases when the cause is not identified, particularly in women who also have a family history of primary ovarian insufficiency, premutation carrier testing for the fragile X gene (*FMR1*) should be considered.

A low or normal FSH value in amenorrheic women without evidence of anatomic cause suggests chronic anovulation, most commonly attributed to hypothalamic amenorrhea or PCOS. In principle, hypothalamic amenorrhea would be associated with low estradiol levels, and PCOS would more often be associated with normal estradiol levels. However, estradiol levels fluctuate and testing is not recommended to help distinguish between these diagnoses. Similarly, the progesterone challenge test for withdrawal bleeding is not considered a reliable

indicator of estrogen levels, given both high false positive and false negative rates.

### Imaging Studies

In certain situations, further evaluation with imaging may be indicated, such as the use of ultrasound, magnetic resonance imaging (MRI), or hysteroscopy to assess for a potential anatomic abnormality. Examples include the absence of the uterus in primary amenorrhea, as may be seen with Müllerian agenesis and 46,XY conditions like androgen insensitivity syndrome, or the presence of intrauterine synechiae (Asherman syndrome) in those with prior procedural instrumentation of the uterus. In cases of an elevated prolactin level (with no evidence of thyroid disease), MRI is warranted to assess for a possible pituitary tumor, which is present in 50% to 60% of women with hyperprolactinemia.

## Diagnoses and Management

### Anatomic Causes

Müllerian agenesis is the most common cause of anatomic malformations associated with amenorrhea, comprising approximately 10% of primary amenorrhea cases. In addition to malformations along the genital tract, over half of Müllerian agenesis cases may also present with other congenital abnormalities, such as urinary tract or skeletal defects (e.g., scoliosis, vertebral arch anomalies, and wrist hypoplasia). Thus, it is important to assess for the presence of coexisting congenital anomalies in those with Müllerian agenesis. Renal ultrasound and spinal X-ray imaging should be considered in these women.

A less common cause of anatomical defects in the uterus or vagina is complete androgen insensitivity, which accounts for 5% of primary amenorrhea. Other anatomic defects leading to primary amenorrhea include transverse vaginal septum (2% of cases), imperforate hymen (1% of cases), and isolated absence of the vagina or cervix. In women with prior history of procedural interventions involving the uterus or cervix, intrauterine synechiae (Asherman syndrome) and cervical stenosis should also be considered as potential etiologies of amenorrhea. In cases of Asherman syndrome, treatment often involves hysteroscopy for lysis of the intrauterine adhesions.

Women with Müllerian agenesis typically present with normal secondary female sexual characteristics, in the setting of anatomic defects in all or some aspects of the uterus and vagina. Women with complete androgen insensitivity may also present with vaginal defects, though in addition they have a family history suggestive of androgen insensitivity, lack of pubarche, and may present with inguinal hernias or masses containing testes. Complete androgen insensitivity is an X-linked recessive condition and is confirmed by an elevated serum testosterone level in the male range and karyotype analysis (46,XY). Of note, complete androgen insensitivity confers an increased risk of gonadal malignancy, and treatment includes gonadal removal, typically after completion of growth and breast development. Hormonal replacement therapy is indicated following prophylactic gonadal removal for the maintenance of bone health.

The first-line treatment for Müllerian agenesis includes vaginal dilation to achieve elongation, a nonsurgical, patient-controlled therapy that has a success rate above 90%. Surgery to create a vagina is much less commonly required and reserved for rare cases. Psychosocial support is another important aspect of treatment for these individuals. Fertility considerations should also be addressed. In those with Müllerian agenesis who desire children, options may include assisted reproductive technology with gestational surrogacy or adoption. With regard to ongoing care, routine cervical cancer screening is not typically indicated given the absence of a cervix in these women.

### Primary Ovarian Insufficiency

Persistently elevated FSH levels in the menopausal range indicate impaired ovarian function, consistent with primary ovarian insufficiency. Other terms to describe this condition have been previously used, including premature ovarian failure, premature menopause, and primary ovarian failure. This condition may affect 1% to 5% of women, though the etiology is not always known.

Congenital causes are a factor in some cases of primary ovarian insufficiency, with certain chromosomal abnormalities leading to gonadal dysgenesis, an example being Turner syndrome (45,X). Chromosomal abnormalities are identified in 50% of adolescents without comorbidities who present with primary amenorrhea and in 13% of women 30 years of age or younger who present with secondary amenorrhea. With regard to management, it is important to remember that the incidence of gonadal malignancy is up to 25% for women with a Y chromosome. Accordingly, in 46,XY women with lack of gonadal function as evidenced by elevated FSH levels and absence of hormone secretion, gonadal removal is indicated at the time of diagnosis.

Primary ovarian insufficiency has shown associated genetic predisposition, and premutation carrier testing for fragile X syndrome should be considered in these women when another cause has not been identified. Among those with a normal karyotype, 6% of women with primary ovarian insufficiency are found to have premutation of the *FMR1* (fragile X) gene. Additionally, primary ovarian insufficiency may also be seen with various endocrinopathies, such as hypoparathyroidism and hypoadrenalism, or autoimmune disease. Specifically, approximately 4% of cases have adrenal or ovarian antibodies, and autoimmune disorders may be found in up to 40% of women with primary ovarian insufficiency, most commonly thyroid disease.

For women with primary ovarian insufficiency, infertility should be addressed, though up to 10% may have temporary remission with spontaneous conception. It is unclear whether oral contraceptives are as effective in this population, so alternative methods such as barrier contraception or intrauterine device options are more appropriate for pregnancy prevention. Genetic predisposition for this condition should also be addressed. Consultations with reproductive endocrinology and fertility specialists are indicated when pregnancy is desired, as options are limited beyond donor *in vitro* fertilization. Psychosocial counseling and support should be offered as well.

Annual visits are recommended in those with primary ovarian insufficiency. Given the increased cardiovascular risk associated with the early estrogen deficient state, steps should be taken to ensure optimized cardiovascular health, including routine screening for hypertension and a lipid panel at least every 5 years. Furthermore, hormonal treatment until the typical age of menopause is appropriate both to support bone health as well as to develop and maintain secondary sexual characteristics. The estrogen deficient state in this condition poses risk to the attainment of peak bone mass. Thus, weight-bearing exercise as well as adequate calcium (1300 mg per day) and vitamin D (400 to 1000 IU per day) intake are also important aspects of management to reduce the risk of osteoporosis. With regard to hormone therapy in these cases, additional potential benefits include decreased risk of ischemic heart disease, less cardiovascular mortality, and vasomotor symptom control. Of note, combined oral contraceptives provide higher levels of hormones than are necessary for this purpose and are not recommended in this setting. A more appropriate regimen would include daily estradiol (e.g., 100 µg dose in transdermal [Alora, Dotti, Minivelle, Vivel] or oral form [Estrace], though the latter confers a relatively higher thromboembolism risk), with 12 days of cyclic progesterone monthly (e.g., medroxyprogesterone acetate [Provera] 10 mg). For those still undergoing pubertal growth and maturity, specialized care is recommended, as hormone therapy should begin with estrogen before the introduction of progesterone, with the purpose of mimicking hormonal levels associated with development.

### Hyperprolactinemia and Pituitary Causes

Another potential etiology of amenorrhea or oligomenorrhea is an elevated prolactin level, which inhibits the release and thus the effect of gonadotropins. Specifically, the presence of hyperprolactinemia suppresses GnRH secretion. When hyperprolactinemia is identified, in the absence of other potential causes such as medications or thyroid disease, an MRI of the head is warranted for further evaluation. Among women who present with amenorrhea and elevated prolactin, 50% to 60% are associated with a pituitary tumor. Additionally, pituitary disorders including Sheehan

syndrome, pituitary gland necrosis, and empty sella syndrome may also be causes of anovulation and amenorrhea, as well as other pituitary or central nervous system tumors and organic diseases.

Regarding treatment for hyperprolactinemia, dopamine agonists may be used to aid in decreasing prolactin levels, regardless of the presence of pituitary tumor. This has an effect on the subsequent restoration of menses. In cases of pituitary adenoma, surgical resection may be warranted.

### Hypothalamic Amenorrhea

The most common cause of chronic anovulation is functional hypothalamic amenorrhea, often associated with stress, weight loss, poor nutrition, and strenuous exercise. In these cases, suppression of the normal hypothalamic-pituitary-ovarian axis occurs as a result of an overall energy deficit, though the exact pathophysiology remains unclear. A much less common cause of hypothalamic amenorrhea is isolated gonadotropin deficiency, such as that seen in Kallmann syndrome (primary GnRH deficiency).

Multidisciplinary care should be considered in the approach to treatment of functional hypothalamic amenorrhea. Appropriate nutrition rehabilitation and reduction of strenuous exercise are important aspects of management for these women, and restoration of menses usually occurs following correction of the energy deficit. Furthermore, treatment should address stress reduction and psychosocial health, which may also play a role in the resumption of menses. As for pharmacologic management, evidence suggests that the use of leptin may help restore GnRH pulsatility and thus ovulation and menses, given its regulatory role in hypothalamic dysfunction. For those with hypothalamic amenorrhea desiring pregnancy, treatment options for ovulation induction may be pursued, typically with GnRH or gonadotropin therapy.

Similar to primary ovarian insufficiency, hypothalamic amenorrhea is associated with an estrogen deficient state, so affected women are at increased risk for osteoporosis. Bone density screening may be considered. In addition to nutrition rehabilitation and a decrease of strenuous activity, it is important to ensure adequate calcium and vitamin D intake with supplementation. Cyclic hormone therapy at physiologic doses may be considered for optimizing bone health, such as in cases where correction of the underlying cause of hypothalamic amenorrhea is not easily achieved. However, the potential beneficial effects on bone density in these cases are limited in the absence of appropriate nutrition rehabilitation. Furthermore, the use of bisphosphonates in the premenopausal population is not recommended given the limited data available and concern for potential teratogenic risks. Thus, treatment should primarily focus on addressing the underlying cause of hypothalamic amenorrhea.

### Polycystic Ovary Syndrome

Chronic anovulation and amenorrhea may also occur with PCOS, though these women are more likely to present with oligomenorrhea. The presence of obesity and concomitant signs of androgen excess help distinguish PCOS from hypothalamic amenorrhea. Typically, a higher BMI is associated with PCOS, while normal or low BMI is more often associated with functional hypothalamic amenorrhea. According to the Rotterdam Consensus Criteria from 2003, the diagnosis of PCOS requires at least two of the following: (1) signs of androgen excess, (2) the presence of polycystic ovaries, and (3) ovulatory dysfunction. However, the 2006 Androgen Excess Society criteria for PCOS differ slightly from these guidelines, specifically requiring hyperandrogenism as one of the diagnostic conditions, along with ovarian dysfunction (oligo-anovulation and/or polycystic ovaries) and exclusion of other androgen excess or related disorders. The evidence of hyperandrogenism may be established by clinical findings (e.g., hirsutism, acne, male pattern alopecia) or laboratory measurement. Generally, serum androgen levels in those with PCOS do not exceed twice the upper limit of normal range, so further investigation for other etiologies of hyperandrogenism would be warranted in these cases.

The management of women with PCOS includes monitoring for insulin resistance and glucose intolerance, dyslipidemia, and cardiovascular risk, with subsequent interventions as indicated for any identified comorbidities. Treatment also involves healthy lifestyle modifications directed at dietary changes, exercise, and weight loss, given the association of PCOS with obesity. Furthermore, low-dose combined oral contraceptives are recommended to reduce the risk for endometrial cancer in the setting of chronic anovulation. Pharmacotherapy with metformin (Glucophage)<sup>1</sup> is another important treatment consideration, which may provide beneficial effects on ovulation, menstrual abnormalities, and androgen levels, in addition to its known effects on improving glucose tolerance.

<sup>1</sup>Not FDA approved for this indication.

## BACTERIAL INFECTIONS OF THE URINARY TRACT IN WOMEN

Method of  
Kinder Fayssoux, MD

### CURRENT DIAGNOSIS

- Acute cystitis is the most common urologic disorder in women.
- *Escherichia coli* and *Staphylococcus saprophyticus* are the causative agents for 80% of community acquired urinary tract infections (UTIs).
- *E. coli* is also the most common uropathogen in the nosocomial setting.
- Anatomic risk factors include short urethra, the proximity of the urethra to the anus, and the colonization of the periurethral mucosa with bowel flora.
- Other risk factors include previous UTI, sexual intercourse, and, separately, the use of spermicide, pregnancy, diabetes, incontinence, cystocele, and incomplete emptying of the bladder and dysfunctional voiding (defined as abnormal bladder emptying in the absence of neurologic disease).
- Postmenopausal women are also at increased risk if they are estrogen deficient.
- Acute cystitis typically presents with abrupt onset of dysuria, increased frequency, and/or urgency. Less frequently a patient will present with hematuria, suprapubic discomfort, or back/costovertebral angle pain. If a fever is present, it is usually less than 38.9°C (102°F).
- Acute pyelonephritis can evolve from either asymptomatic bacteriuria or from an ascending bladder infection.
- Symptoms usually include fever usually greater than 38.9°C (102°F) with chills, nausea/vomiting, dysuria, increased frequency, urgency, and costovertebral angle (CVA) tenderness (usually unilateral).
- *E. coli* is the major pathogen in acute pyelonephritis and treatment depends on severity and pregnancy status.

## CURRENT THERAPY

- Empiric therapy for uncomplicated UTIs should be dependent on the most recent antibiotic guidelines and the uropathogen resistance patterns in a community.
- In a community with >20% incidence of resistant *E. coli*, nitrofurantoin (Macrobid) 100mg bid for 7 days is the treatment of choice with quinolones as second-line therapy.
- In a community with <20% *E. coli* resistance, trimethoprim/sulfamethoxazole 160/800 (Bactrim DS) PO twice daily for 3 days is also acceptable as first-line therapy with quinolones still considered as second-line therapy.
- Phenazopyridine (Pyridium), a smooth muscle relaxant, can be prescribed for spasm relief.
- Fungal UTIs or candiduria should be treated with fluconazole (Diflucan) 200 mg daily for 2 weeks.
- Outpatient treatment guidelines for acute pyelonephritis are the same as for uncomplicated UTI except the duration of antimicrobial therapy is longer (10–14 days).
- Inpatient treatment for acute pyelonephritis is typically IV levofloxacin (Levaquin) (750 mg daily) or ampicillin (1 g every 6h).
- Acute pyelonephritis should resolve in 48 to 72 hours, if patients are not getting better, imaging should be undertaken with ultrasound or CT scan to assess for renal abscess or urethral obstruction.

### Acute Cystitis (Urinary Tract Infection)

Acute cystitis is the most common urologic disorder among women. It represents 4% of all outpatient visits. Of these visits, 52% present to a primary care clinic and 23% to the emergency department. The annual health care costs associated with urinary tract infections (UTIs) are roughly 1.6 billion and climbing. Antimicrobial prescriptions for UTIs account for 15% of all outpatient prescriptions. One-third of all women will have at least one symptomatic UTI by age 24, with more than half of all women having at least one during their lifetime.

Acute cystitis can be defined as uncomplicated or complicated. Uncomplicated cystitis is defined as a UTI in patients with normal urinary tract anatomy without a contributing medical condition such as diabetes mellitus, neurogenic bladder, pregnancy, renal insufficiency, immune deficiency, recent antibiotic use, recent genitourinary instrumentation, spinal cord injury, ureteral obstruction, or nephrolithiasis. Complicated cystitis is defined as a UTI in patients with abnormal urinary tract anatomy or with one of the aforementioned medical conditions. These patients generally require urine culture as part of the initial work-up to guide antimicrobial therapy and often additional condition specific evaluation and treatment.

Acute cystitis is caused by ascending bacteria of perineal/urethral/fecal origin through the urethra into the bladder and renal systems. *Escherichia coli* and *Staphylococcus saprophyticus* are the causative agents for 80% of community acquired UTIs (complicated and uncomplicated). *E. coli* is also the most common uropathogen in the nosocomial setting. Other known uropathogens include *Pseudomonas spp*, *Klebsiella spp*, *Proteus*, *Corynebacterium urealyticum*, and *Providencia*. Fungal UTIs caused by *Candida spp*, *Aspergillus spp*, and *Cryptococcus neoformans* are also increasingly encountered. These are usually caused by indwelling urinary devices and seen more frequently in diabetics. Other populations prone to fungal UTIs include patients who are immunocompromised, hospitalized, or elderly.

There are numerous risk factors for acute cystitis, several specific to women. Risk factors unique to women include several related to their anatomy. These anatomic differences are the primary reason for the increased incidence of UTI in women when compared to men and include the female's relatively short urethra

(when compared to the male counterpart), the proximity of the urethra to the anus, and the colonization of the periurethral mucosa with bowel flora.

Other risk factors include previous UTI, sexual intercourse, and, separately, the use of spermicide, pregnancy, diabetes, incontinence, cystocele, and incomplete emptying of the bladder and dysfunctional voiding (defined as abnormal bladder emptying in the absence of neurologic disease). Postmenopausal women are also at increased risk if they are estrogen deficient.

Dysfunctional voiding has an unknown etiology and results in increased external sphincter activity during voluntary voiding which results in reflux, increasing chances of UTI.

Commonly advised behavioral modifications thought to decrease the risk of UTI (e.g., postcoital voiding, increased fluid intake, avoidance of urinary holding, douching, front-to-back wiping, proper tampon/sanitary napkin use, and loose/cotton underwear) have been supported by the literature.

Acute cystitis typically appears as an abrupt onset of dysuria, increased frequency, and/or urgency. Less frequently a patient will present with hematuria, suprapubic discomfort, or back/costovertebral angle pain. If a fever is present, it is usually less than 38.9°C (102°F).

Obtaining a good history that assesses for risk factors and symptoms is important in diagnosing acute cystitis. In a woman who presents with one or more symptoms of UTI (dysuria, frequency, urgency, hematuria), the probability of infection is already 50%. A urine dipstick is a useful diagnostic test, with a positive (+) nitrite or leukocyte esterase result increasing the chances of infection. The combination of positive nitrite and leukocyte esterase results has the highest diagnostic correlation with UTI. Physical examination findings may include suprapubic tenderness or costovertebral angle tenderness, although these are unlikely in an uncomplicated UTI scenario.

The gold standard for diagnosis of acute cystitis is a culture that has 10<sup>2</sup> to 10<sup>3</sup> colony-forming units of a single uropathogen from a clean catch or catheterized urine specimen. However, research has shown that, for uncomplicated cystitis, ordering cultures and sensitivities makes little difference in treatment while increasing cost of care. Thus, it is reasonable to start empiric treatment without a culture and sensitivities in a patient presenting with uncomplicated UTI.

The differential diagnosis for an uncomplicated UTI includes:

- Vaginitis/vaginal infections: can cause dysuria
  - *Gardnerella*, *Candida albicans*, and *Trichomonas*
- Urethritis: can cause dysuria/frequency
  - STDs (*Chlamydia trachomatis*, gonorrhea, herpes simplex)
  - Pelvic floor spasm (leads to urethral spasm/irritability)
- Interstitial cystitis
- Malignancy
- Renal tuberculosis

Differentiating between sexually transmitted infections (STI), vaginal infections, and UTIs can be difficult because symptoms and signs commonly overlap. History elements that should prompt a pelvic examination and laboratory evaluation for pathogens are complaints of a vaginal discharge or vaginal irritation/pruritus. Persistent hematuria should raise the concern for underlying malignancy or renal tuberculosis, and further evaluation should be done.

Empiric therapy for uncomplicated UTIs should be dependent on the most recent antibiotic guidelines and the uropathogen resistance patterns in a community. In a community with >20% incidence of resistant *E. coli*, nitrofurantoin (Macrobid) 100mg bid for 7 days is the treatment of choice with quinolones as second-line therapy. In a community with <20% *E. coli* resistance, trimethoprim/sulfamethoxazole 160/800 (Bactrim DS) PO twice daily for 3 days is also acceptable as first-line therapy with quinolones still considered as second-line therapy. Phenazopyridine (Pyridium), a smooth muscle relaxant, can be prescribed for spasm relief and is usually only necessary for the first 24 hours after treatment is initiated. Fungal UTIs or

*candiduria* should be treated with fluconazole (Diflucan) 200 mg daily for 2 weeks.

For a complicated UTI, a culture must always be obtained and the patient should be evaluated in the context of his or her specific comorbid condition before treatment.

### Acute Pyelonephritis

Acute pyelonephritis can evolve from either asymptomatic bacteruria or from an ascending bladder infection. Although it can progress from an uncomplicated cystitis, it more commonly presents from a complicated cystitis in the setting of other medical conditions such as cholelithiasis, urinary obstruction, malformations, or pregnancy.

Symptoms usually include fever usually greater than 38.9°C (102°F) with chills, nausea/vomiting, dysuria, increased frequency, urgency, and CVA tenderness (usually unilateral). These symptoms can present on a spectrum from mild to severe. *E. coli* is the major pathogen, and treatment depends on severity and pregnancy status. Pregnant patients or patients with moderate to severe nausea/vomiting that would interfere with oral antibiotic treatment should be hospitalized and have blood cultures done in addition to urine culture. Patients with mild symptoms and the ability to tolerate oral antibiotics can be treated as an outpatient basis with a urine culture obtained before initializing treatment. Outpatient treatment guidelines are the same as for uncomplicated UTI, except the duration of antimicrobial therapy is longer (10–14 days). Inpatient treatment is typically IV levofloxacin (Levaquin 750 mg daily) or ampicillin (1 g every 6 h). Once the inpatient is able to tolerate oral antibiotics and the infection is felt to be controlled, he or she can be switched to oral antibiotics and discharged to complete a 14-day course of treatment as an outpatient.

Symptoms should resolve in 48 to 72 hours; if patients are not getting better, imaging should be undertaken with ultrasound or CT scan to assess for renal abscess or urethral obstruction.

### Urethritis

Urethritis usually has a gradual onset and is accompanied with milder symptoms of dysuria, frequency, urgency, or hematuria. It can also occur with a vaginal discharge and complaints of dyspareunia and vaginal pruritus depending on cause. Chlamydial, gonorrheal, candidal and trichomonal urethritis is usually accompanied by a vaginal discharge. Candidal urethritis can also be associated with pruritus and dyspareunia. If urethritis is suspected, a pelvic examination and further laboratory work-up is necessary.

### Asymptomatic Bacteruria

Asymptomatic bacteruria is defined as the presence of 100,000 microorganisms/milliliter of urine without any symptoms of cystitis.

No screening should be performed in healthy nonpregnant women, elderly living in the community, diabetic women, institutionalized elderly, or persons with spinal cord injury. Pregnant women are the exception. They should be screened; positive cultures need to be treated, as there is an increased likelihood of asymptomatic bacteruria turning into UTI or pyelonephritis because of vesicoureteral reflux and urinary stasis resulting from increased progesterone levels.

### Recurrent Cystitis

Recurrent cystitis is defined as at least three episodes of uncomplicated UTI with one or more documented positive (+) cultures in 12 months. It can be due to relapse or reinfection. Relapse is defined as infection occurring with the same organism as a

previous UTI. Reinfection is when symptoms return after treatment and a completely symptom-free interval along with a negative urine culture or when the second infection is caused by a different organism. Most recurrent cystitis tends to be caused by reinfection.

In patients presenting with recurrent cystitis, an age-based evaluation is a good place to start. Adolescents who are not sexually active should be evaluated for congenital abnormalities. Premenopausal females should be questioned about the temporal relationship of the onset of UTI to increased frequency/recent sexual intercourse, spermicide use (with or without condom or diaphragm), or renal stones. Postmenopausal females should be evaluated for decreased estrogen/vaginal atrophy, incontinence, incomplete bladder emptying, cysto-coles, and prolapse.

If a complete and thorough evaluation is done, complicating factors are ruled out, modifiable factors are treated, and recurrent cystitis still remains a problem, then treatment should be considered. Treatment options include continuous antibiotics, postcoital therapy, or self-initiated treatment at the first sign or symptom of an infection.

Gross hematuria or persistent microscopic hematuria should increase suspicion for an underlying malignancy. Also, recurrent cystitis symptoms in a setting of negative cultures may suggest mycobacterial infection or interstitial cystitis.

### Catheter Associated Urinary Tract Infection

Catheter-associated UTI is defined as a UTI in a patient who had an indwelling urethral catheter within 48 hours of onset of infection. Indwelling urinary catheters and clean intermittent catheterization are associated with the highest rates of bacteruria; after 1 month of either there is almost 100% risk of bacteruria. Formation of a bacterial biofilm on the catheter is thought to be the mechanism of infection in this setting.

No treatment is recommended for asymptomatic patients, and neither prophylactic antibiotics nor routine UA and culture are recommended for this population. For symptomatic patients, the first step is to determine whether the catheter can be removed. If it cannot, then it should be replaced. In addition, a blood and urine culture (taken from a new catheter) should be obtained. Initial treatment is the same as for an uncomplicated UTI as discussed earlier. Confirmation of susceptibility should be confirmed with culture results.

## BENIGN BREAST DISEASE

Method of  
Lauren Nye, MD

### CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Benign breast disease may present with an abnormality on screening breast imaging or with a breast symptom such as a breast mass or nipple discharge.
- Nonproliferative breast lesions are not associated with an increased risk of breast cancer.
- Proliferative breast lesions without atypia are associated with a slightly increased risk for breast cancer, whereas proliferative lesions with atypia are associated with a significantly increased risk for breast cancer.
- Factors contributing to a woman's breast cancer risk include family history, personal health history, and modifiable lifestyle factors.

### CURRENT THERAPY

- Some benign breast lesions do not need any further intervention after diagnosis; others may require surgical excision to rule out malignancy.
- Women at high risk for breast cancer may warrant additional breast screening or begin screening at an earlier age.
- Women at high risk for breast cancer should be counseled on risk reduction strategies, including lifestyle modification.
- Chemoprevention agents include tamoxifen, raloxifene (Evista), and aromatase inhibitors.

Breast health is an important aspect of women's health care; it includes breast cancer screening and evaluation of breast concerns. Benign breast disease can be identified on a biopsy done for an abnormal screening test, a palpable breast mass, nipple discharge, or other breast concerns. Benign breast disease may be associated with an increased risk for breast cancer. Women at high risk for breast cancer should be considered for additional breast cancer screening recommendations and risk reduction strategies.

### Presentation and Workup

Patients can present with benign breast disease after an abnormality detected on screening imaging or after workup for breast symptoms such as a palpable mass, breast pain, or spontaneous nipple discharge. In women who are considered at average risk for breast cancer based on medical and family history, screening includes history and physical examination by their health care provider, clinical breast examination, and breast imaging. Breast awareness should be encouraged, but formal breast self-examinations in average-risk women have not been shown to have a breast cancer mortality benefit, although in women who performed self-breast examinations, a greater number of benign breast lesions were detected.

### Breast Cancer Screening

Women at average risk for breast cancer should begin screening mammography between age 40 and 50. The 2016 updated recommendations of the US Preventive Services Task Force (USPSTF) recommend biennial screening mammography for women ages 50 to 74; the decision to start screening mammography prior to age 50 should be individualized. The 2015 American Cancer Society

(ACS) breast cancer screening guidelines for women at average risk include a strong recommendation to begin screening mammography at age 45 and a qualified recommendation to begin at age 40, continuing as long as the woman is in good overall health and life expectancy is 10 years or greater. The most updated recommendation from the National Comprehensive Cancer Network (NCCN) and the American College of Radiology (ACR) is for annual screening mammography beginning at age 40. The standard for breast cancer screening is the digital mammogram; however, in recent years digital breast tomosynthesis has become more prevalent and available to women at breast imaging centers. Digital breast tomosynthesis has both a higher breast cancer detection rate and a lower recall rate compared with the digital mammogram for breast cancer screening. In women with heterogeneously dense breast or dense breast tissue on screening mammogram, the risks and benefits of supplemental screening with bilateral breast screening ultrasound or breast MRI should be discussed as high breast density limits mammogram sensitivity.

Normal and abnormal findings on breast imaging are reported using the universal classification system by the ACR's classification: the Breast Imaging Reporting and Data System (BI-RADS). Table 1 includes the BI-RADS categories, the risk of malignancy, and the recommended follow-up. BI-RADS 0 indicates an incomplete assessment and that further workup is needed, typically with additional imaging recommendations. BI-RADS 3 lesions are considered probably benign based on appearance; a mammogram and/or ultrasound in 6 months is recommended for follow-up. BI-RADS 4 and BI-RADS 5 lesions are suspicious or highly suggestive of malignancy, respectively, and a biopsy of the lesion is recommended.

### Palpable Breast Mass

In patients who present with a palpable breast mass, workup is determined by patient age, menopausal status, and degree of suspicion of breast mass. Fig. 1 outlines the algorithm for evaluation of a woman with a breast mass. In women younger than age 30 with a mass of low clinical suspicion, it would be appropriate to consider observation over one to two menstrual cycles prior to moving on to ultrasound imaging if the mass persists. If no mass is detected on ultrasound, short-term clinical follow-up is recommended. Diagnostic mammography with ultrasound may be considered in women younger than age 30 who have a mass of high clinical suspicion or increased breast cancer risk. In postmenopausal women and women 30 years of age and older, a clinically palpable breast mass should be evaluated with a diagnostic mammogram and ultrasound. A clinically suspicious mass without a radiographic correlate on imaging should be evaluated for palpation-guided biopsy of the mass. A patient identified to have a simple cyst on imaging can return to age-appropriate breast screening. A solitary complicated cyst should be aspirated or be followed in short-term follow-up for stability. Multiple complicated cysts are considered a benign finding and do not require aspiration or short-term follow-up. Routine cytology of aspirated fluid is not recommended. If the mass persists after aspiration of a complicated cyst or if initial imaging shows a mass of high clinical suspicion or a complex cystic and solid mass, ultrasound-guided biopsy of the mass is recommended.

The sonographic description of a simple cyst is a round or oval circumscribed mass with acoustic enhancement and lacking any solid components or Doppler signals. A nonsimple cyst may be complicated or a complex cystic and solid mass. A complicated cyst is round or oval and circumscribed but may show low-level internal echoes without demonstrating vascular flow, whereas a complex cystic and solid mass may have thick septations, thick and irregular walls, and an internal solid component; it may display internal echoes, internal blood flow, and lack of posterior wall enhancement.

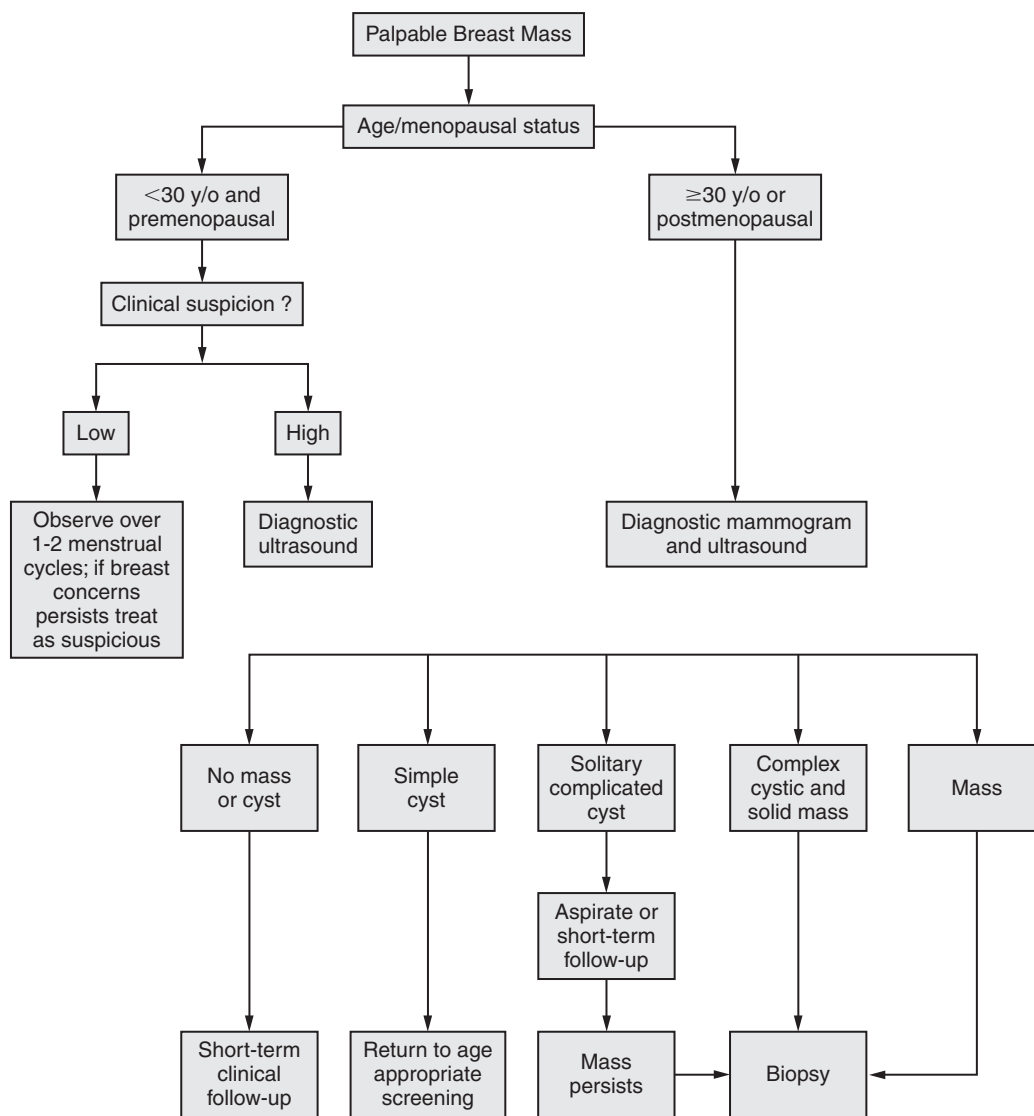

### Nipple Discharge

Some women may present with nipple discharge without a palpable mass. Concerning features for pathologic nipple discharge

**TABLE 1** Breast Imaging Reporting and Data System Mammography Classification

BI-RADS CATEGORY	DEFINITION	RISK FOR MALIGNANCY	RECOMMENDED FOLLOW-UP
0	Incomplete assessment	N/A	Further imaging
1	Negative study	N/A	Routine mammogram screening
2	Benign	N/A	Routine mammogram screening
3	Probably benign	≤ 2%	Repeat imaging in 6 months
4	Suspicious	>2%–95% depending on degree of suspicion	Biopsy recommended
5	Highly suggestive of malignancy	≥ 95%	Biopsy recommended
6	Known biopsy-proven malignancy	N/A	Appropriate action should be taken

BI-RADS, Breast Imaging Reporting and Data System.

**Figure 1** Algorithm for the evaluation of a woman with a breast mass.

include a spontaneous unilateral single-duct discharge that is reproducible on examination and discharge that is clear, serous, sanguineous, or serosanguinous. Nonspontaneous nipple discharge or multiduct discharge is likely physiologic and the most common cause is duct ectasia. Women should be educated on avoiding further breast compression to elicit the discharge, ensure that they are up to date on age-appropriate breast cancer screening, and review potential medications that could cause nipple

discharge. In women with spontaneous pathologic single-duct nipple discharge, the most common etiology is an intraductal papilloma. The most common malignant explanation would be ductal carcinoma in situ (DCIS). The workup should include diagnostic mammography and ultrasound for women 30 years of age or older and at least a diagnostic ultrasound in women younger than age 30. Suspicious or highly suspicious imaging findings warrant biopsy. If initial imaging does not explain the

**TABLE 2** Benign Breast Lesions

NONPROLIFERATIVE LESIONS	PROLIFERATIVE LESIONS WITHOUT ATYPIA	PROLIFERATIVE LESIONS WITH ATYPIA
Apocrine metaplasia	Fibroadenomas	Atypical ductal hyperplasia
Breast cysts	Microglandular adenosis	Atypical lobular hyperplasia
Columnar cell change	Moderate or florid usual ductal hyperplasia	
Duct ectasia	Papilloma	
Fibrosis	Radial scar	
	Sclerosing adenosis	

nipple discharge, a ductogram or magnetic resonance imaging (MRI) may be considered for further evaluation. In some cases duct excision may be recommended; otherwise the patient should have short-term follow-up with clinical breast examination and imaging.

### Benign Lesions

Benign breast diseases can be categorized as nonproliferative, proliferative without atypia, proliferative with atypia, and miscellaneous other conditions such as fat necrosis, various types of mastitis, pseudoangiomatous stromal hyperplasia, fibrous mastopathy, amyloid deposits, and dermatologic conditions. [Table 2](#) outlines the benign breast lesions. A study by Dupont and Page in the 1980s and a review by Hartmann et al. in 2005 found that nonproliferative breast disease was not associated with an increased risk for breast cancer. Proliferative breast disease without atypia is associated with a slightly increased risk for breast cancer but less than two times the average population risk. Proliferative breast disease with atypia is associated with a significantly increased breast cancer risk that can be four to five times higher than the average population risk.

### Nonproliferative Lesions

Nonproliferative breast lesions are also known as fibrocystic disease or change and include duct ectasia, fibrosis, and apocrine metaplasia. In women without a significant family history of breast cancer, nonproliferative breast lesions are not associated with an increased breast cancer risk. In the study by Dupont and Page including 3303 patients with benign breast disease, only 2.2% of the patients with nonproliferative lesions had breast cancer at a mean follow-up of 17 years. The Hartmann study of 9087 women followed for a median of 15 years found that the strength of family history was an independent risk factor; in women with nonproliferative lesions, the relative risk of breast cancer was 1.27. No increased risk was found in women with no family history.

Ductal ectasia and breast cysts are common findings. Occasionally the ectatic ducts are surrounded with periductal inflammation, which can occur in nonlactating women when the duct becomes congested with debris. This can lead to periductal mastitis that requires treatment with antibiotics. Breast cysts are most common in perimenopausal women but can occur in premenopausal women and postmenopausal women on hormone replacement therapy. Breast cysts may present in women with fibrocystic breast disease, which women may report as nodular breast tissue and is caused by microcystic formation and stromal proliferation of the breast. Apocrine metaplasia, in which acini and cysts are lined with large columnar cells that resemble the apocrine sweat glands, is not an uncommon finding. The individual cells are large, with abundant granular eosinophilic cytoplasm. The apical aspects of these cells have a rounded protrusion into the cyst

spaces. Columnar cell change is characterized by enlargement of the terminal duct lobular units and dilated acini without atypia.

### Proliferative Lesions Without Atypia

Proliferative breast lesions without atypia include fibroepithelial lesions such as fibroadenomas, moderate or florid usual ductal hyperplasia, microglandular and sclerosing adenosis, papillomas, and radial scars. Proliferative breast lesions without atypia are associated with a slightly increased risk of breast cancer compared with the average risk of the population, with the relative risk estimated between 1.8 and 1.9. These lesions are not currently considered to put a woman at high risk for breast cancer unless other risk factors are present, such as family history.

Fibroadenomas are benign processes containing glandular and fibrous tissue. Fibroadenomas were originally classified as nonproliferative lesions (including in the Hartmann study) but are now typically considered proliferative breast lesions. Simple fibroadenomas without associated proliferative disease are not associated with an increased risk for breast cancer, while complex fibroadenomas and those with coinciding proliferative disease are associated with a slight increase in breast cancer risk. Fibroadenomas are most common in young premenopausal women and can fluctuate in size with changes in hormones. They do not routinely need to be excised unless they are enlarging or have associated symptoms, such as tenderness.

The normal number of epithelial linings within the breast is two. Epithelial hyperplasia has a spectrum of changes from mild to severe, presenting with an escalating scale of complexity. Usual ductal hyperplasia (UDH) is an increased number of cells within the duct that will vary in size and shape but will appear benign and without atypia. Microglandular adenosis and sclerosing adenosis are lesions with an increased number of glandular elements within fibrous stroma. Microglandular and sclerosing adenosis may be associated with microcalcifications and/or a mass on mammography.

Classic papillomas are masslike lesions that occur within large ducts close to the subareolar area. Histologically, they are composed of arborizing fronds of fibrovascular stroma lined by epithelial cells with a stalk attaching the mass to the wall of the cyst within which they arise. They can appear as a mass on mammography or present with unilateral nipple discharge. Papillomas can be associated with hyperplasia with and without atypia or DCIS; in those cases, surgical excision is recommended to rule out malignancy.

Radial scars or complex sclerosing lesions are a pathologic diagnosis but can cause abnormalities on breast imaging including mass, nonmass enhancement, or architectural distortion. Histologically, they have a central fibroelastic core with radiating and branching ducts and lobules at the periphery. The etiology of these lesions is unknown. Depending on the size and presentation, surgical excision may be recommended to rule out underlying malignancy.

### Proliferative Lesions with Atypia

Proliferative lesions with atypia include atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH). These atypical hyperplasia lesions are characterized by an abundance of monotonous-appearing epithelial cells partially filling a duct and/or lobule. The presence of atypical hyperplasia is a risk factor for future breast cancer and is associated with a relative risk of breast cancer between four and five times the general population risk. The risk of breast cancer over the 25 years following a biopsy demonstrating atypical hyperplasia is estimated at 30%. The number of foci of atypia present in the specimen can stratify the risk, with one focus being a lower risk compared to three or more foci of atypia. These patients should be managed in a multidisciplinary fashion to include assessment of concordance between radiology and pathology. The standard management for atypical hyperplasia including ADH and ALH is surgical excision to rule out underlying malignancy; however, select patients who have concordance with imaging may be appropriate for screening in lieu of surgical excision.

### Miscellaneous Benign Breast Conditions

Pseudoangiomatous stromal hyperplasia (PASH) is a lesion of a stromal proliferation with anastomosing spaces, with the dense hyalinized stroma intermixed with glandular components. These spaces could appear as vascular structures to the untrained pathologist. PASH may appear similar to an angiosarcoma but can be differentiated by the lack of atypia and mitosis. PASH can present with a palpable mass, with a mammogram abnormality, or as an incidental finding. Historically this lesion commonly underwent excision; however, depending on the size of the lesion, concordance with imaging, and other risk factors, PASH may be appropriately monitored with follow-up imaging.

Fat necrosis is secondary to trauma or injury to the breast. Fat necrosis typically presents with a painless breast mass and appears as an ill-defined dense mass on breast imaging. A biopsy is recommended to rule out malignancy; however, no further treatment is necessary.

### High-Risk Evaluation and Management

The lifetime risk of breast cancer for women in the United States is approximately one in eight. There are elements of a woman's personal or family history that may increase her risk for breast cancer and potentially warrant additional screening and management. Risk factors that contribute to a woman's lifetime risk of breast cancer include family history of breast and/or ovarian cancer, genetic mutations associated with hereditary breast cancer, reproductive history, personal history of multiple breast biopsies or a breast biopsy showing atypical hyperplasia or lobular carcinoma in situ (LCIS), and dense breast tissue on mammography. Women who received thoracic radiation prior to age 30 are also at an increased risk for breast cancer. Modifiable risk factors for breast cancer include increased body mass index, sedentary lifestyle, alcohol intake, and hormone replacement therapy with estrogen and progesterone. Breast cancer risk assessment tools are available to estimate a woman's risk and include the Breast Cancer Risk Assessment Tool (previously referred to as the Gail model) and family history-based models such as, BRCAPRO, and Tyrer-Cuzick. In 2019, the USPSTF updated recommendations for BRCA-related cancer risk and recommended women with a family history of breast, ovarian, tubal, or peritoneal cancer and previously treated survivors of any of those cancers should be assessed for genetic risk.

Women considered at high risk for breast cancer include those with a Gail Model 5-year breast cancer risk of greater than or equal to 1.7%, a lifetime risk of breast cancer of greater than 20% based on a family history-based model, or a history of thoracic radiation prior to age 30, as well as women harboring a deleterious genetic mutation associated with breast cancer or a personal history of atypical hyperplasia or lobular carcinoma in situ. Women at high risk for breast cancer may be eligible for additional screening including earlier age at initiation of screening/imaging and consideration of an annual breast MRI.

Women at high risk for breast cancer should be counseled on screening recommendations and risk reduction strategies. Lifestyle modifications associated with decreased breast cancer risk include breastfeeding, achieving a healthy body mass index, limiting alcohol consumption, and exercising regularly. Some women may be considered for risk-reducing surgery. Chemoprevention may also be an option for women at high risk for breast cancer.

### Chemoprevention

Risk-reducing agents, also known as chemoprevention, are appropriate to consider in women with atypical hyperplasia, LCIS, or a 5-year breast cancer risk of greater than or equal to 1.7%. Risk-reducing agents include tamoxifen, raloxifene (Evista), and the aromatase inhibitors (exemestane [Aromasin]<sup>1</sup> and anastrozole [Arimidex]<sup>1</sup>). Chemoprevention is taken daily for 5 years and

associated with a potential risk reduction of 40% to 65%. No survival benefit has been demonstrated in women who take chemoprevention, and the risks and benefits of each therapy should be discussed. Tamoxifen is a selective estrogen receptor modulator (SERM) and is the only agent available for premenopausal women. Tamoxifen should not be recommended to women who are currently pregnant or considering future pregnancy owing to potential teratogenic effects. The National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (NSABP P-1) of tamoxifen 20 mg daily for 5 years versus placebo included both pre- and postmenopausal women at high risk for breast cancer and demonstrated a reduced risk of invasive breast cancer of 49%. In this study tamoxifen was associated with an increased rate of endometrial cancer, deep vein thrombosis, pulmonary embolism, and stroke, and these events were more frequent in women over the age of 50. Raloxifene is a second-generation SERM. The STAR trial (NSABP P-2) randomized postmenopausal women at high risk for breast cancer to 5 years of tamoxifen 20 mg daily versus raloxifene 60 mg daily. Raloxifene was demonstrated to be as effective as tamoxifen at reducing the risk of invasive breast cancer but not noninvasive breast cancer. Raloxifene was associated with a lower rate of venous thromboembolic events and endometrial cancer. Aromatase inhibitors were studied in postmenopausal women for breast cancer prevention in the MAP.3 (exemestane) and IBIS-II (anastrozole) trials. Exemestane 25 mg daily for 5 years was associated with a 65% relative reduction in annual incidence of breast cancer compared with placebo. Anastrozole 1 mg daily for 5 years reduced the incidence of estrogen receptor-positive breast cancers by over 50% compared with placebo with a hazard ratio (HR) of 0.47. In both trials, musculoskeletal complaints and vasomotor symptoms were more common in the aromatase inhibitor groups. Vaginal dryness and decreased libido are also common side effects of aromatase inhibitors. There is potential for a decrease in bone mineral density while taking an aromatase inhibitor; however, no increased fracture rate was seen in either trial. In postmenopausal women, age and comorbidities along with bone health should be considered when a risk-reducing agent is being selected.

## BREAST CANCER

Method of  
Lauren Nye, MD

### CURRENT DIAGNOSIS

- Mammography is used for breast cancer screening, and it is recommended to begin screening in women at average risk for breast cancer between ages 40 and 50.
- Women with an elevated risk for breast cancer may be considered for additional high-risk screening that can include breast magnetic resonance imaging (MRI) or other supplemental screening in addition to annual mammography.
- Individuals with a palpable breast mass or breast symptom concerning for malignancy and those with an abnormal screening mammogram need diagnostic breast imaging.
- Women with diagnostic breast imaging that is suspicious or highly suggestive of malignancy should undergo core needle biopsy.

### CURRENT THERAPY

- Breast cancer is a heterogeneous disease and requires a multidisciplinary approach and multimodality therapy.
- The treatment of early-stage breast cancer may include local therapy such as surgery and radiation as well as systemic therapy including chemotherapy, endocrine therapy, and biologic therapy.
- Metastatic breast cancer is treated with systemic therapy; the goal of treatment is disease control and preserving quality of life.
- Breast cancer survivors may have multiple long-term complications of therapy that need to be addressed, including vasomotor symptoms, osteoporosis, lymphedema, and increased cardiac risk factors as well as psychosocial distress and financial toxicity.

### Overview

Breast cancer is the most common cancer and the third leading cause of death among women in the United States. It is a heterogeneous disease for which a personalized approach is important in the evaluation and treatment of each individual. Furthermore, the multidisciplinary team is vital in the management of breast cancer and can include a medical oncologist, surgical oncologist, plastic surgeon, radiation oncologist, pathologist, supportive services, and the patient's personal physician. At the conclusion of treatment and active surveillance, the patient typically returns to his or her primary care physician for continued survivorship care.

### Epidemiology

It is estimated that there were 281,550 new cases of breast cancer in 2021. The estimated deaths from breast cancer in the same year were 43,600, accounting for 6.8% of all cancer deaths. Female breast cancer is most commonly diagnosed among women from 55 to 64 years of age, with the median age at diagnosis of 62. Although rare, male breast cancer comprises 1% of all breast cancer cases in the United States. The incidence of breast cancer has risen slowly by 0.3% annually, whereas the mortality rate has been falling by 1.8% each year. The 5-year relative survival rate improved by 16% over 30 years, from 74% in 1980 to 90.9% in 2010. Despite the improvement in mortality for most individuals, there remains a breast cancer mortality disparity for African American women diagnosed with breast cancer.

### Risk Factors

Well-recognized risk factors for breast cancer include older age, female sex, white race, obesity, high exposure to hormones (either exogenous or endogenous), personal and family history of breast cancer, inherited genetic mutations, benign breast disease (e.g., atypical hyperplasia and LCIS), previous history of radiation therapy to the chest, as well as lifestyle factors such as alcohol consumption and obesity.

Individuals who carry a *BRCA1* or *BRCA2* mutation are at a significantly higher risk for developing breast cancer. In a 2017 case-control study by Couch et al. of more than 65,000 women with breast cancer, genetic mutations associated with an increased risk of breast cancer were identified in 10.2% of cases. The most common gene mutations identified included *BRCA1*, *BRCA2*, *ATM*, *CHEK2*, *PALB2*, *BARD1*, and *RAD51D*. Individuals with a strong family history of cancer should be considered for genetic counseling and testing for appropriate risk stratification.

### Risk Reduction

For women at an average risk for breast cancer, lifestyle modifications including regular aerobic exercise, maintaining a healthy weight, and limiting alcohol are most important for breast cancer risk reduction. In addition, complying with breast cancer screening recommendations provides an opportunity for early detection and decreased mortality. Women at average risk for breast cancer should begin screening mammography between age 40 and 50. The US Preventive Task Force (USPSTF) updated recommendations in 2016 recommend biennial screening mammography for women aged 50 to 74 years. The decision to start screening mammography prior to age 50 should be individualized. The 2015 American Cancer Society (ACS) breast cancer screening guidelines for women at average risk include a strong recommendation to begin screening mammography at age 45 and a qualified recommendation to begin at age 40 and continue as long as the patient remains in good overall health and has a life expectancy of 10 years or greater. The most updated recommendations from the National Comprehensive Cancer Network (NCCN) and the American College of Radiology (ACR) are for annual screening mammography beginning at age 40. The standard for screening breast imaging is the digital mammogram; however, in recent years digital breast tomosynthesis has become more prevalent and available to women at breast imaging centers. Digital breast tomosynthesis has both a higher breast cancer detection rate and lower recall rate compared with the digital mammography for breast cancer screening.

Women who are at an increased risk for breast cancer may be considered for additional screening and risk reduction measures. Factors that increase a woman's risk include having a known genetic mutation associated with hereditary breast cancer, having a family history of breast cancer in a first- or second-degree relative, especially premenopausal breast cancer or male breast cancer, having a personal history of a breast biopsy with atypical hyperplasia or lobular carcinoma in situ, having a personal history of chest radiation before age 30, or having a high breast density. Several breast cancer assessment tools are available for the evaluation of personalized breast cancer risk (e.g., Breast Cancer Risk Assessment Tool, Tyrer-Cuzick, BRCAPRO models). Women with a lifetime risk of breast cancer greater than 20% on a family history-based model or women with a genetic mutation or prior chest radiation may be eligible for additional annual screening with breast MRI. Certain high-risk populations may benefit from risk-reducing therapies such as chemoprevention and risk-reducing mastectomy, especially for carriers of high-penetrance mutations.

### Clinical Manifestations

Women with ductal carcinoma in situ (DCIS) and early-stage breast cancer may be asymptomatic. The most common symptoms of breast cancer include the following:

- New palpable mass in the breast or axilla
- Skin changes such as dimpling, erythema, irritation, edema, thickening, peau d'orange (Fig. 1)
- Nipple retraction

**Figure 1** Peau d'orange of the breast.

- Abnormal nipple discharge
- New asymmetric appearance of breast

### Differential Diagnosis

Differential diagnoses include benign conditions such as fibroadenoma, papilloma, breast cyst, and mastitis as well as malignant conditions such as breast lymphoma, sarcoma, neuroendocrine tumors, leukemia, and skin metastasis from breast or other primary tumors.

### Diagnosis

Once breast malignancy is suspected clinically, either by palpation or breast imaging (Fig. 2), further evaluation is warranted. Women with an abnormal mammogram should undergo further diagnostic imaging, which may include diagnostic mammography, ultrasonography, or breast MRI. Normal and abnormal findings on breast imaging are reported using the universal classification system of the American College of Radiology (Breast Imaging Reporting and Data System [BI-RADS]). BI-RADS 0 indicates an incomplete assessment and that further workup is needed, typically with additional imaging. BI-RADS 1 and BI-RADS 2 lesions are negative or benign, respectively. BI-RADS 3 lesions are considered probably benign based on appearance; a mammogram or ultrasound scan in 6 months is recommended for follow-up. BI-RADS 4 and BI-RADS 5 lesions are suspicious or highly suggestive of malignancy, respectively, and a biopsy of the lesion is recommended. Core needle biopsy is the recommended approach for tissue sampling. The pathology report from a biopsy of a primary breast cancer will typically include the histology and tumor prognostic markers. These histologic subtypes of breast cancer include ductal, lobular, mixed, metaplastic, as well as the more favorable histologic subtypes of tubular, mucinous, and papillary.

Once breast cancer has been diagnosed, appropriate clinical staging is done, directed by a medical oncologist or surgical oncologist. This may include further breast imaging to characterize the extent of the tumor, axillary staging with ultrasound to assess for abnormal-appearing lymph nodes, and clinical examination with consideration of whole-body staging with computed tomography (CT) scan of the chest, abdomen, and pelvis depending on the size and lymph node involvement of the primary lesion. Bone scanning or positron emission tomography (PET/CT) may also be considered in some circumstances. Staging of the breast cancer is done in accordance with the American Joint Committee on Cancer (AJCC) staging system. The most updated version, the *AJCC Cancer Staging Manual*, Eighth Edition, was published in December 2017 and includes anatomic stage groups, clinical prognostic stage groups, and pathologic prognostic stage groups. All patients should have a clinical prognostic stage documented as part of their treatment plan, and those with surgery as initial treatment may also have a pathologic prognostic stage. The

**Figure 2** Breast cancer on mammogram.

updated staging guidelines also include biomarker testing results within the staging system.

### Pathophysiology

Breast cancer is a heterogeneous disease. Malignant cells arise from neoplastic proliferation of epithelial cells in the ducts or lobules of the breast. If neoplastic cells are confined within the duct or lobule, the lesion is termed *ductal* or *lobular in situ*, respectively. DCIS is a precursor lesion that can potentially develop into invasive carcinoma. Invasive carcinoma is classified into four distinct molecular subtypes: luminal A, luminal B, basal-like, and HER2 enriched. More frequently we use the tumor receptor markers of the breast cancer to guide therapy, namely estrogen receptor (ER), progesterone receptor (PR), and HER2 overexpression. Hormone receptor–positive breast cancer (meaning progesterone- or estrogen receptor–positive) is the most common type of breast cancer, comprising more than 65% of all breast cancers. In general it has a less aggressive course with a long survival, even in the metastatic setting. In contrast, hormone receptor–negative and HER2-negative breast cancer—also known as triple negative breast cancer (TNBC)—tends to be more aggressive and has a much poorer outcome, especially in the advanced setting. Although the natural course of HER2-overexpressed disease tends to be aggressive, HER2-positive breast cancer now has a longer survival time since the advent of effective HER2-directed therapies.

### Treatment

Breast cancer is a complex disease that requires multidisciplinary management as well as a tailored therapy plan depending on the stage, histologic subtype, and prognostic tumor marker status. Current modalities for treating breast cancer include local therapy such as surgery and radiation therapy as well as systemic therapy including chemotherapy, endocrine, and biologic therapy.

Early-stage breast cancer is treated with surgery (lumpectomy or mastectomy) with or without radiation therapy. Women who undergo lumpectomy and radiotherapy have equivalent survival outcomes to those receiving mastectomy. Axillary lymph nodes are typically evaluated by sentinel lymph node biopsy and/or axillary lymph node dissection depending on initial clinical findings and lymph node involvement with metastases on pathologic review. For selected cases, preoperative (neoadjuvant) treatment with chemotherapy or endocrine therapy are used. Neoadjuvant chemotherapy is indicated for inoperable or locally advanced breast cancer such as inflammatory breast cancer, extensive primary tumor extending to the chest wall or skin, bulky or matted axillary lymph nodes, and extra-axillary lymph node involvement. In the setting of operable breast cancer, neoadjuvant systemic

treatment may be recommended to optimize surgical outcomes or to allow for assessment of tumor response on surgical pathology to guide adjuvant systemic therapy.

After definitive surgical management, adjuvant systemic therapy may be offered to reduce the risk of local and distant recurrence. Chemotherapy is considered for those at high risk for recurrence, characterized by large tumor size, positive lymph nodes, high-grade histology, or a triple negative (hormone receptor–negative, HER2–negative) breast cancer. For hormone receptor–positive, HER2–negative, axillary node–negative breast cancer, the 21-gene recurrence score is widely used to evaluate for the potential benefit of adjuvant chemotherapy. HER2–positive breast cancer is treated with HER2–directed biologic agents along with chemotherapy followed by maintenance therapy with anti-HER2 agents such as trastuzumab (Herceptin), pertuzumab (Perjeta), and ado-trastuzumab emtansine (Kadcyla). When an anthracycline chemotherapy or HER2 antibody therapy is indicated, baseline cardiac function evaluation by either echocardiogram or multigated acquisition scan must be obtained before treatment and will be regularly monitored during the treatment with HER2–directed therapies. In high-risk triple negative breast cancer, chemotherapy may be combined with immunotherapy for systemic treatment. Radiation therapy, if indicated, is typically offered after chemotherapy.

After local treatment of hormone receptor–positive breast cancer with or without chemotherapy, adjuvant endocrine therapy is recommended for a minimum of 5 years with either a selective estrogen-receptor modulator (SERM) such as tamoxifen (Nolvadex), an aromatase inhibitor such as anastrozole (Arimidex), letrozole (Femara), or exemestane (Aromasin). In general, the choice of endocrine therapy agents is based on the menopausal state and side-effect profiles. Aromatase inhibitors need to be combined with ovarian suppression in premenopausal women. Adjuvant endocrine therapy is associated with an approximate 50% reduction in breast cancer recurrence.

Locally recurrent disease without distant metastasis can be managed with a curative intent. Combination of local therapies and systemic treatment may be used depending on the clinical scenario. Metastatic (stage IV) breast cancer with distant metastasis is not curable and is managed with the intent of disease control while maintaining quality of life and requires systemic therapy. Local therapies such as surgery and radiation therapy are indicated for palliative purposes when appropriate. Hormone-positive metastatic breast cancer can be treated with endocrine therapy as first-line treatment if there is no evidence of visceral crisis. Cyclin-dependent kinase (CDK4/6) inhibitors have emerged as promising agents for hormone receptor–positive, metastatic disease. In combination with endocrine therapy, CDK inhibitors demonstrated longer progression-free survival, and in some cohorts an overall survival benefit. In patients with a somatic (tumor) PIK3CA mutation, the PI3K $\alpha$  inhibitor, alpelisib (PIQRAY), is approved in combination with fulvestrant (Faslodex) for individuals after an endocrine-based regimen. An mTOR inhibitor can be also used in this setting in combination with endocrine therapy. The mTOR inhibitor is known to overcome endocrine resistance, although toxicity (e.g., mucositis and gastrointestinal side effects) may limit its use.

Metastatic HER2–positive breast cancer is treated with HER2–directed agents and chemotherapy. Additional strategies include drug antibody conjugates (ado-trastuzumab emtansine [Kadcyla], fam-trastuzumab deruxetecan-nxki [Enhertu]) or dual HER2 blockade such as trastuzumab (Herceptin) and pertuzumab (Perjeta) or lapatinib (Tykerb) or neratinib (Nerlynx) with chemotherapy, which demonstrate superior progression-free survival compared with a single HER2 agent added to chemotherapy. Biosimilars for trastuzumab are now available. For HER2–positive and hormone receptor–positive disease, dual HER2–targeted therapy combined with an aromatase inhibitor may be beneficial.

In the setting of metastatic triple negative breast cancer, systemic therapy can include the immunotherapy drug pembrolizumab (Keytruda) combined with chemotherapy, chemotherapy alone, antibody drug conjugates such as sacituzumab govitecan-hziy (Trodelvy), or targeted agents. Immunotherapy overall is better

tolerated than chemotherapy but has a unique profile of potential toxicities including colitis, pneumonitis, dermatologic reactions, and endocrinopathies along with less common immune mediated adverse events.

Although single chemotherapy is preferred for metastatic disease, combined chemotherapy may be indicated for diseases with high tumor burden or in visceral crisis. Management of metastatic breast cancer may also include germline genetic testing for a *BRCA1* or *BRCA2* mutation and/or genomic testing of the tumor to identify potential molecular targets unique to the individual or tumor. In 2018, the US Food and Drug Administration (FDA) approved olaparib (Lynparza) and talazoparib (Talzenna), which are a poly-ADH ribose polymerase inhibitors, for the treatment of metastatic HER2–negative, *BRCA*-associated breast cancer. Further targeted therapies may be explored in the setting of a clinical trial.

For patients with bone metastasis, bone-targeted therapies such as denosumab (Xgeva) and intravenous bisphosphonates are given to reduce skeletal-related events, such as pathologic fractures. Patients with poor dentition or oral hygiene who need future dental procedures during treatment are at increased risk for osteonecrosis of the jaw; thus dental evaluation is important before bone-directed therapy is initiated.

### Monitoring and Survivorship

The majority of breast cancer patients are treated with curative intent and gain long-term survival. The risk of recurrence, however, is a realistic concern for many years after definitive therapy, especially for women with locally advanced or node-positive disease. Once the patient has completed definitive treatment, careful history taking and physical examination become the most important aspects of surveillance. Patients are advised to schedule an office visit up to four times yearly for the first 5 years and then annually. Monitoring for recurrence by laboratory and radiologic tests should be kept minimal in the nonmetastatic setting unless clinically indicated otherwise.

Women should continue to undergo annual screening mammography for their remaining breast tissue. If they were receiving high-risk screening with a breast MRI based on a genetic mutation, this may also be continued after breast cancer treatment. Annual gynecologic assessment is recommended for women on tamoxifen because of the associated increased risk of uterine cancer, which typically presents with abnormal bleeding in postmenopausal women. Patients on an aromatase inhibitor should have a bone mineral density completed at baseline and then annually while receiving treatment. Bone-modifying agents such as intravenous bisphosphonates or RANK ligand inhibitors may be used for management or prevention of osteoporosis while on aromatase inhibitor therapy.

In addition, women receiving adjuvant endocrine therapy may experience menopause-related symptoms such as vasomotor symptoms, vaginal dryness, and sexual dysfunction. Patients are encouraged to discuss these symptoms with their physicians because they can frequently be managed with nonhormone-based approaches. Venlafaxine (Effexor)<sup>1</sup>, oxybutynin (Ditropan)<sup>1</sup>, and gabapentin (Neurontin)<sup>1</sup> have demonstrated efficacy in management of hot flashes, as well as cognitive behavioral therapy acupuncture and avoiding triggers. Vaginal moisturizers and lubricants can be applied to help alleviate symptoms of vaginal dryness. Laser therapy may also be considered in some circumstances.

Long-term complications after definitive treatment may include lymphedema and self-image issues after surgery, skin changes after radiation therapy and persistent neuropathy, prolonged hair loss, fatigue, cognitive impairment, and a small risk of developing leukemia and myelodysplastic syndrome after chemotherapy.

Heart disease remains the leading cause of death among US women. Those who have undergone treatment for breast cancer may be at a higher risk for myocardial events depending on their baseline risk factors and the treatment they received. Accumulating evidence suggests that lifestyle modifications including regular exercise, achieving a healthy body mass index, limiting alcohol intake, and abstaining from tobacco products lead to optimal outcomes for breast cancer survivors.

## CANCER OF THE ENDOMETRIUM

Method of

Locke Uppendahl, MD; and Boris Winterhoff, MD

### CURRENT DIAGNOSIS

- The high incidence of uterine cancer in developed countries reflects increased obesity rates.
- The progression from atypical hyperplasia to adenocarcinoma is a consequence of prolonged, unopposed estrogen exposure.
- Approximately 90% of women with uterine cancer report abnormal uterine bleeding, with postmenopausal bleeding the most common.
- Over 95% of uterine cancers are diagnosed in women 40 years or older.
- In most uterine cancer cases, the tumor is confined to the uterine corpus at the time of diagnosis and portend a good prognosis.
- Uterine carcinomas are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

### CURRENT THERAPY

- Comprehensive surgical staging with total hysterectomy, bilateral salpingo-oophorectomy, and bilateral pelvic and para-aortic lymphadenectomy is a critical component for the diagnosis and management of all endometrial cancers.
- The utility and extent of lymph node dissection in endometrial cancer is controversial.
- The decision for adjuvant therapy is based on the risk of relapse and persistent disease.
- Surgery alone is usually curative for women with early-stage, low-risk disease.
- Adjuvant vaginal brachytherapy is recommended for early-stage endometrial cancers that demonstrate pathologic features known to increase risk of vaginal cuff recurrence, such as high-grade, deep myometrial invasion, cervical involvement, or presence of lymphovascular space invasion.
- Women with advanced-stage (stage III or IV) or recurrent endometrial cancer are frequently treated with systemic, platinum-based chemotherapy

## Epidemiology

In the United States, uterine cancer is the most common gynecologic malignancy of the female genital tract, with an estimated 65,620 new cases and 12,590 deaths expected for 2020. Approximately 1 in 35 women will develop invasive cancer over their lifetime, with an average age of diagnosis of 62 years. The high incidence observed in developed countries is attributable to increased obesity rates and other risk factors.

Uterine cancer is one of the few malignancies where survival has not improved since the mid-1970s. In fact, death rates for uterine cancer rose in 2011 through 2015 by 2% per year. The 5-year survival rate for all stages is 22% lower for black women compared to white women. This large disparity likely reflects a delay in diagnosis in this population.

## Classification

Uterine cancers arising from the lining of the uterus are called endometrial carcinoma and are classified into two broad histologic categories: the estrogen related endometrioid (Type I) and nonestrogen related (Type II) tumors.

### Type I tumors

Type I tumors are the predominant form of endometrial cancer, comprising approximately 80% of new diagnoses. They include tumors of endometrioid histology and often arise in the background of atypical endometrial hyperplasia. Type I tumors are more indolent, diagnosed at earlier stages, occur in younger women, and overall portend a favorable prognosis. Patients with high-grade (grade 3) endometrioid adenocarcinoma have a less favorable prognosis. The average age at diagnosis is approximately 62 years old, with nearly 70% of the tumors confined to the uterus at time of diagnosis.

Recent, comprehensive genomic characterization has identified a number of genetic alterations associated with type I tumors. The loss of function in the DNA mismatch repair (MMR) enzymes MLH1, MSH2, MSH6, and PMS2 results in the inability to properly detect and repair abnormal DNA sequences. This leads to mutations in genes that have microsatellite repeats. Microsatellite instability (MSI) is found in approximately one-third of type I tumors and can be as a result of germline or sporadic mutations. Other commonly mutated genes include *PTEN*, *CTNNB1*, *PIK3CA*, *ARID1A*, and *KRAS*.

### Type II tumors

In contrast to type I tumors, other endometrial cancers are unrelated to unopposed estrogen exposure. Type II cancers include clear cell and serous histology tumors. They are diagnosed more frequently among older, non-obese, non-white women and portend an unfavorable prognosis due to the later stage in diagnosis and the aggressive nature of the tumor.

Serous carcinoma of the endometrium represents ~10% of endometrial carcinomas but accounts for 40% of all endometrial cancer-related deaths. They often invade deep into the myometrium and demonstrate the ability for early peritoneal spread. Uterine serous carcinomas are molecularly distinct and are characterized by high genomic instability (high copy number alterations), low mutational burden, and *TP53* mutations. Newer evidence demonstrates dysregulation of the *Her2/neu* oncogene in 27% of cases. Clear cell carcinomas, another rare but aggressive subtype, represent ~5% of endometrial carcinomas. The 5-year overall survival rates for serous and clear cell carcinomas are 41% and 65%, respectively. Recently, genomic characterization identified approximately 25% of grade 3 endometrioid tumors cluster with serous carcinomas, with very high somatic copy-number alterations. Nearly 90% of these tumors have *TP53* mutations. Novel mutations in *TAF1* have been implicated in a subset of clear cell carcinomas.

## Risk Factors

Type I tumors are strongly linked to long-term, unopposed exposure to estrogen. Therefore risk factors include any excessive exogenous (hormonal therapy, tamoxifen [Nolvadex]) or endogenous (obesity, chronic anovulation, estrogen-secreting tumors) estrogen exposure to the uterine lining. In the United States, the high prevalence of obesity has increased the incidence of uterine cancer over the past two decades. A BMI 25 to < 30 kg/m<sup>2</sup> confers a relative risk of 1.5 to develop endometrial cancer, compared to 7.1 for BMI > 40 kg/m<sup>2</sup>. Other risk factors for type I tumors include nulliparity, diabetes mellitus, and hypertension.

Tamoxifen (Nolvadex) is a selective-estrogen receptor modulator (SERM) used in the treatment and prevention of breast cancer. The drug functions as an antagonist in the breast but has agonist effects on the endometrium. The risks of endometrial cancer associated with tamoxifen, although very low, are well documented in the literature.

Lynch / Hereditary Non-Polyposis Colorectal Cancer (HNPCC) syndrome is caused by mutations in DNA mismatch-repair genes *MLH1*, *MSH2*, *MSH6*, and *PMS2*. The lifetime risk of developing colorectal and endometrial cancer is 25–50% and 15–71% (depends on mutated gene), respectively.

## Pathophysiology

The World Health Organization (WHO) has recently clarified the classification of endometrial hyperplasia, differentiating between only two categories: (1) hyperplasia without atypia and (2) atypical hyperplasia / endometrioid intraepithelial neoplasia. Multiple studies have demonstrated the progression of atypical hyperplasia to adenocarcinoma is a consequence of prolonged, unopposed estrogen exposure.

## Prevention

Over 95% of uterine cancers are diagnosed in women 40 years or older. Therefore abnormal uterine bleeding in these women should prompt evaluation with endometrial biopsy or dilatation and curettage (D&C). Depending on age and reproductive desire, women with endometrial hyperplasia may be treated with removal of estrogen stimulus, the periodic use of progestins, or by hysterectomy to prevent the onset of uterine cancer. For women with atypical hyperplasia, hysterectomy is the treatment of choice, because coexistent adenocarcinoma may be present in 40% of cases. In addition, this group of women carries a 30% risk of developing invasive carcinoma later in life. Finally, women with a uterus should never receive estrogen-only hormone replacement therapy (HRT). The addition of a progestin to HRT can prevent endometrial hyperplasia and subsequent endometrial cancer.

Despite no current scientific evidence, women diagnosed with Lynch syndrome should consider annual screening with endometrial sampling and transvaginal ultrasound, beginning between ages of 30 and 35 years. Hysterectomy with or without oophorectomy is an option after childbearing to deter the risk of endometrial cancer.

## Clinical Manifestations

Abnormal uterine bleeding is often the only presenting symptom in women diagnosed with endometrial cancer. Upwards of 90% of women diagnosed with endometrial cancer report abnormal uterine bleeding, with postmenopausal bleeding the most common. However, postmenopausal bleeding has many etiologies, and only ~15% of these women will have endometrial cancer.

For pre- and perimenopausal women, the diagnosis is more challenging and often delayed. For this group of women, intermenstrual bleeding, prolonged, heavy bleeding, or the absence of menses for several months interrupted with episodes of bleeding warrants investigation.

Finally, Papanicolaou smears demonstrate malignant cells in only ~50% of women with underlying endometrial cancer. This highlights the ineffectual screening method of indirectly sampling

the endometrium. To date, no screening method for the general population is recommended.

## Diagnosis

Diagnosis of endometrial cancer is confirmed with a histological specimen. All women suspected of having uterine cancer due to abnormal uterine bleeding should have their endometrium sampled via biopsy. Most often, this can be done in the clinic with a rigid or flexible catheter. With this technique, reported detection rates for postmenopausal and premenopausal are 99.6% and 91%, respectively. However, there is approximately a 10% false-negative rate with endometrial biopsy. Therefore a negative biopsy result in women highly suspicious for endometrial cancer should undergo exam under anesthesia and curettage. Finally, transvaginal ultrasound demonstrating an endometrial thickness of 5 mm or more in a postmenopausal woman requires endometrial sampling.

Women taking tamoxifen should be counseled about the increased risk of endometrial cancer and to report any abnormal vaginal bleeding so they can be thoroughly evaluated. However, no evidence supports the screening of asymptomatic women with ultrasound or serial endometrial sampling.

## Staging

Due to the high incidence of lymph node metastases, the Cancer Committee of the International Federation of Gynecology and Obstetrics (FIGO) replaced a clinical staging system with a surgical staging system in 1988. The current, updated in 2009 FIGO staging system is detailed in [Table 1](#).

## Treatment

Comprehensive surgical staging with exploration of the abdominal cavity, total hysterectomy with bilateral salpingo-oophorectomy, and bilateral pelvic and para-aortic lymphadenectomy are critical components for the diagnosis and management of all endometrial cancers. For type II tumors, meticulous surgical staging with the addition of collection of peritoneal washings for cytology, omentectomy ± peritoneal biopsies is required, since metastatic disease is often only identified microscopically. In cases with gross metastatic disease, cytoreductive surgery may be required. Surgical staging can be performed by laparotomy, laparoscopy, or robotically assisted procedure.

**TABLE 1** Carcinoma of the Endometrium

### Stage I: Tumor confined to uterine corpus

IA	Tumor limited to endometrium or < 50% myometrial invasion
IB	≥50% myometrial invasion

### Stage II: Extension to cervical stroma

II	Cervical stromal invasion
----	---------------------------

### Stage III: Local and/or regional spread

IIIA	Tumor invades serosa and/or adnexa
IIIB	Vaginal and/or parametrial extension
IIIC1	Pelvic lymph node involvement
IIIC2	Para-aortic lymph node involvement

### Stage IV: Distant spread

IVA	Tumor invades bladder and/or rectal mucosa
IVB	Distant metastases, including abdominal spread and/or inguinal lymph nodes

Tumor grade, cell type, and presence/absence of malignant cytology in pelvic washings should be reported along with stage.

The utility and extent of lymph node dissection in endometrial cancer is controversial. Different strategies, including universal, selective, and sentinel lymph node mapping, are currently used. The universal method performs uniform comprehensive surgical staging for nearly all patients with endometrial cancer. This method allows for the most complete information postoperatively to make adjuvant decisions, but a significant percentage of women will develop lymphedema secondary to the nodal dissection. A common selective approach involves avoiding lymph node dissection in patients who have grade 1 or 2 endometrioid histology with < 50% myometrial invasion and tumor size < 2 cm, since these patients have < 1% risk of nodal metastases. Finally, an alternative approach utilizing sentinel lymph node mapping with indocyanine green dye is becoming more popular. Early studies have demonstrated promising results in decreasing morbidity while optimizing the pathological assessment of nodes in these women. Regardless the strategy, the presence of pelvic or para-aortic lymph node metastases remains one of the most important prognostic factors for endometrial cancer.

Following surgery, women are stratified by age and pathologic features to determine their risk for recurrence and the need for adjuvant therapy.

### Adjuvant Therapy

The decision for adjuvant therapy is difficult and is based on the risk of relapse and persistent disease. In general, women with stage IA, grade 1 or 2 endometrioid adenocarcinoma have a favorable prognosis, and no adjuvant radiation is necessary following surgery. Early-stage endometrial carcinomas with risk factors for recurrence, stage II-IV cancers, and all serous and clear cell carcinomas often require adjuvant therapy in the form of radiation, chemotherapy, or a combination of both.

### Early-Stage Disease

Surgery alone is usually curative for women with early-stage, low-risk disease. Women with early-stage, high-risk or high-intermediate risk factors are often recommended adjuvant radiation. The treatment can be in the form of external beam radiation therapy or vaginal brachytherapy. All serous and clear cell carcinomas of the uterus are recommended to receive adjuvant platinum-based combination chemotherapy regardless of stage. Adjuvant systemic therapy in patients with high-risk, early-stage endometrioid carcinoma remains controversial.

### Metastatic Disease

Approximately 10–15% of patients will present with metastatic disease at presentation. Surgical cytoreduction is the preferred treatment approach if complete resection is achievable because it is associated with improved progression-free and overall survival. This would be followed by adjuvant platinum-based combination chemotherapy. The most common regimens are carboplatin (Paraplatin)<sup>1</sup> plus paclitaxel (Taxol)<sup>1</sup> or the triple drug combination of cisplatin (Platinol)<sup>1</sup>, doxorubicin (Adriamycin)<sup>1</sup>, and paclitaxel.

Patients who are not candidates for surgical cytoreduction either due to grossly metastatic disease or too poor a surgical candidate have a poor prognosis, with 5-year relative survival of < 20%. These patients should be offered systemic chemotherapy generally with palliative intent. Radiation therapy to achieve local control in the pelvis to palliate bleeding, discharge, and pain is often performed.

### Recurrent Disease

Local recurrences, distance metastases, and simultaneous local and distant metastases are found in 50%, 29%, and 21%, respectively. Isolated vaginal recurrences are often salvaged with either surgery or radiation.

Distant recurrent endometrial cancer portends a poor prognosis. Systemic chemotherapy is given with a palliative intent,

with the most active agents including platinum, taxanes, and anthracyclines.

**Combination Chemotherapy and Radiation Therapy.** Several studies have evaluated combining chemotherapy and radiation therapy in advanced-stage endometrial cancer. Most recently, a randomized phase III trial compared cisplatin and tumor volume directed irradiation followed by four cycles of chemotherapy (experimental arm) against six cycles of chemotherapy (control arm). While the overall survival is immature, the study reported no increase in recurrence-free survival in optimally debulked, stage III or IV endometrial cancer.

Our experience involves using a “sandwich” method of irradiation between rounds of chemotherapy for advanced or recurrent endometrial cancer. The phase II trial demonstrated an overall 5-year survival of 79% with acceptable toxicity. The optimal sequencing of chemotherapy and radiation warrants further development.

### Hormone Therapy

Prior to endometrial cancer, the risk of endometrial hyperplasia and the development into carcinoma can be significantly reduced with administration of a progestin. After the development of carcinoma, patients whose tumors test positive for estrogen receptor (ER) and progesterone receptor (PR) are associated with longer survival, with PR being a stronger predictor than ER. However, the role of adjuvant progestins in stage I or II endometrial cancer has not been demonstrated to be of value and may worsen cardiovascular disease. Progestins are commonly used in advanced or recurrent well-differentiated endometrial cancers. Oral megesterol acetate (Megace) and medroxyprogesterone acetate (Provera)<sup>1</sup> are two of the most commonly used progestins.

The SERM tamoxifen<sup>1</sup> has been used to treat patients with recurrent endometrial cancer, with response rates seen in ~22% of patients. The aromatase inhibitors anastrozole (Arimidex)<sup>1</sup> and letrozole (Femara)<sup>1</sup> were investigated in recurrent and metastatic endometrial cancer and demonstrated minimal activity.

### Targeted Therapy

Multiple novel agents are being evaluated in clinical trials for use in treatment against endometrial cancer. Bevacizumab (Avastin)<sup>1</sup> is a monoclonal antibody directed against vascular endothelial growth factor (VEGF) that is active in endometrial cancer. Recent randomized trials demonstrated a benefit with the addition of bevacizumab to carboplatin and paclitaxel in first-line and second-line treatment of advanced, metastatic, and recurrent endometrial cancer. Results from phase 3 trials are needed prior to adopting as standard of care.

Pembrolizumab (Keytruda) is an immune checkpoint inhibitor that has FDA approval for the use in advanced solid tumors demonstrating MMR deficiency or MSI. In patients with endometrial cancer, it is often used following progression on platinum-based chemotherapy in women with MMR or MSI tumors. In the fall of 2019, the FDA approved two new therapeutic agents, lenvatinib (Lenvima), a combination of the inhibitors of VEGFR1, VEGFR2, and VEGFR3 kinases, and a humanized monoclonal antibody, pembrolizumab (Keytruda), for microsatellite-stable (MSS) tumors.

Trastuzumab (Herceptin)<sup>1</sup> and lapatinib (Tykerb)<sup>1</sup> are anti-human epidermal growth factor 2 (HER2) are investigational agents being tested as single agents and in combination with chemotherapy in some endometrial cancers, although the results thus far are not encouraging. The mechanistic Target of Ramamycin (mTOR) inhibitors everolimus (Zortress)<sup>1</sup> and ridaforolimus (MK-8669)<sup>5</sup> have been used to treat advanced-stage and recurrent endometrial cancers, with mixed response.

### Monitoring

Surveillance recommendations for endometrial cancer are stratified by risk of recurrence, and most women diagnosed and treated

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Not available in the United States.

for endometrial cancer will fall into the low-risk category. High risk for recurrence is defined as advanced stage or grade 3 endometrioid, serous, or clear cell histology. Follow-up recommendations for low-risk women involve a history and physical examination, including a speculum and pelvic examination, scheduled every 6 months for the first 2 years, then yearly. Women with high risk of recurrence should have the same follow-up recommendations at intervals of 3 months for the first 2 years, every 6 months in years 2–5, then yearly. Pap test/cytology, CA 125, and routine radiographic imaging are not recommended. Women suspected of recurrence should have imaging performed.

## CANCER OF THE UTERINE CERVIX

Method of

Lucybeth Nieves-Arriba, MD; and Peter G. Rose, MD

### CURRENT DIAGNOSIS

- New recommendations for cytology screening recommend starting screening at 21 years of age.
- Initial workup must include a biopsy.
- Imaging techniques including magnetic resonance imaging and positron emission tomography–computed tomography can assist in treatment planning.

### CURRENT THERAPY

- Despite recent availability of human papillomavirus (HPV) vaccination (Gardasil<sup>2</sup>, Gardasil 9, Cervarix<sup>2</sup>) and advances in screening, cervical cancer remains a significant global health problem, especially in underserved populations.
- Improved understanding of the disease has allowed more conservative treatment of selected patients with early-stage disease.
- For advanced and high-risk cervical cancer, chemoradiation has had a significant impact on survival.

<sup>2</sup>Not available in the United States.

## Epidemiology

Worldwide, cervical cancer is the fourth most common cancer in women. It is the greatest cancer killer of young women and the most common cause of death from cancer in women in the developing world. Worldwide in 2020, among the 604,237 new cases of cervical cancer, the highest incidence rates were

in Africa, Central and South America, and Asia. In the United States, it is estimated that approximately 14,100 new cases were diagnosed and 4280 patients died from cervical cancer in 2022. Significant disparities in incidence and stage at time of diagnosis have been identified among different ethnic groups—African Americans, Asian Americans, European Americans, and Latin Americans—in the United States. Factors that increase the risk of cervical cancer include early age at first coitus, multiple sexual partners, history of sexually transmitted diseases, low socioeconomic status, cigarette smoking, immunosuppression, and Fanconi syndrome.

## Pathophysiology

Cervical cancer occurs secondary to viral transformation of the surface (epithelial) cells by high-risk types of the human papillomavirus (HPV), and it is the only gynecologic cancer that can be prevented by regular screening. Persistent infection with high-risk HPV has been identified as the essential factor in the pathogenesis of the majority of cervical cancers. The virus’s ability to transform human epithelium has been associated with the expression of two viral gene products, E6 and E7, which interact with p53 (a tumor-suppressor protein) and retinoblastoma protein (pRB), respectively, and affect control mechanisms of the cell cycle.

The prevalence of genital HPV infection in the world is estimated to be 400 million. Data from the National Health and Nutrition Examination Survey (NHANES) estimate the prevalence of HPV infection among girls and women in the United States aged 14 to 59 years is 26.8%. In about 90% of cases, the high-risk HPV infection is cleared by the immune system within 16 months. HPV infections in girls and younger women are more likely transient and therefore less likely to be associated with significant cervical lesions.

## Prevention and Screening

Advances in molecular biology have allowed the development of viral-like particles using the L1 protein (major immunogenic capsid protein) of the HPV virus. Currently approved HPV vaccines include: Gardasil (2006)<sup>2</sup>, Cervarix (2009)<sup>2</sup>, and Gardasil 9 (2014). These vaccines are approved to use in girls/boys and women/men between the ages of 9 and 26 years. The FDA expanded its approval in 2018 to include men and women between 27 and 45 years old. Awareness of the importance of HPV vaccination has increased but vaccination rates for US adolescents are still not at goal with only 58.6% vaccinated as of 2021.

The current standard screening algorithm in the United States for preventing cervical cancer is presented in [Table 1](#). Women with abnormal cytology are referred for a colposcopic examination. The colposcopic examination is used to guide biopsies of the exocervix, and in most cases an endocervical biopsy is also performed. The biopsy results then determine the type of follow-up and or therapy required.

## Staging

The International Federation of Gynecology and Obstetrics (FIGO) defined the most commonly accepted staging of cervical cancer. This staging is based on a careful clinical examination and the results of specific radiologic studies and procedures. FIGO’s latest update (2018) is summarized in [Table 2](#).

In cervical cancer, primary lesions initially progress to lymphatics in the parametrium and pelvic nodes and then extend laterally to the pelvic side wall, bladder, and rectum. The two major spread patterns identified in cervical cancer include direct extension and lymphatic spread.

<sup>1</sup>Not available in the United States.

**TABLE 1** Cervical Cytologic Screening Guidelines from the American College of Obstetricians and Gynecologists

AGE (YEAR)	RECOMMENDATION FOR CYTOLOGIC SCREENING	COMMENTS
Younger than 21	Avoid screening	
21 to 29	Screen every 3 years	
30 to 65 or 70	May screen every 3 years	This recommendation applies only to women with 3 consecutive cytologic tests; exceptions include women with HIV infection, compromised immunity, a history of cervical intraepithelial neoplasia grade 2 or 3, or exposure to DES in utero.
	Screen every 5 years	Pap + HPV co-testing use
Between 65 and 70	May discontinue screening	This recommendation applies only to women with $\geq 3$ consecutive negative cytologic tests and no abnormal tests in the preceding 10 years; exceptions include women with multiple sexual partners.

DES, Diethylstilbestrol.

### Diagnosis

The initial workup for cervical cancer depends on whether a cervical lesion is visible. Patients without a visible cervical lesion require a cone biopsy to diagnose stage IA1 or IA2 tumor. Patients with a cervical lesion are assessed by history and physical examination and possibly by examination under anesthesia for biopsy, cystoscopy, sigmoidoscopy, and conventional imaging (chest x-ray, intravenous pyelogram). Other imaging modalities including computed tomography (CT), magnetic resonance imaging (MRI), and fluorodeoxyglucose positron emission tomography (FDG-PET) are useful in evaluating nodal or other metastatic sites. MRI performed significantly better than CT in detecting parametrial invasion, presence of bladder or rectal invasion, and identification of women suitable for fertility-preserving surgery. PET-CT is the most sensitive modality in identifying nodal metastasis or metastatic disease assisting with radiotherapy planning and evaluation of metabolic response to therapy. A 3-month posttherapy PET scan is highly predictive of long-term survival outcome.

### Treatment

Multiple factors including tumor stage, size, histologic features (lymphovascular space invasion [LVSI], nonsquamous components, and depth of cervical stromal invasion), and evidence of lymph node metastasis influence the choice of treatment for cervical cancer. Patients with stage IA1 cervical cancer have undergone a cone biopsy, and pathology demonstrates stromal invasion greater than 3 mm in depth and extension of less than 7 mm., no LVSI, and negative margins. Patients with this extent of disease can safely be treated with a less-radical hysterectomy, an

**TABLE 2** Revised FIGO Staging for Carcinoma of the Cervix

STAGE	CRITERIA
<b>Stage I</b>	
I	The carcinoma is strictly confined to the cervix
IA	Invasive carcinoma, which can be diagnosed only by microscopy, with deepest invasion $\leq 5$ mm and largest extension $\geq 7$ mm
IA1	Measured stromal invasion of $\leq 3$ mm in depth and extension of $\leq 7$ mm
IA2	Measured stromal invasion of $>3$ mm in depth and extension of $>7$ mm
IB	Clinically visible lesions limited to the cervix or preclinical cancers greater than stage IA
IB1	Lesion $>5$ mm depth of stromal invasion and $<2$ cm greatest dimension
IB2	Lesion 2 cm to $<4$ cm in greatest dimension
1B3	Lesion $>4$ cm in dimension
<b>Stage II</b>	
II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion $\leq 4$ cm in greatest dimension
IIA2	Clinically visible lesion $>4$ cm in greatest dimension
IIB	With obvious parametrial invasion
<b>Stage III</b>	
III	The tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
IIIC1	Pelvic lymph node metastasis only
IIIC2	Para-aortic lymph node metastasis
<b>Stage IV</b>	
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum; a bullous edema, as such, does not permit a case to be allotted as stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

extrafascial hysterectomy. Pelvic lymphadenectomy is not recommended owing to the low risk of pelvic node metastasis ( $<1\%$ ). In patients who desire to retain fertility, a cone biopsy may be considered. Wright and colleagues reported on 1409 women from the SEER database who were younger than 40 years and had stage IA1 cancer. The 5-year survival was 98% among 568 who underwent cone biopsy alone versus 99% among 841 who underwent hysterectomy.

Patients with stage IA2 to IB1 are generally treated with radical hysterectomy; in patients who are not candidates for surgery

owing to comorbidities, radiation therapy is used. In patients with high-risk criteria after surgery—positive surgical margin, parametrial involvement, and positive pelvic nodes—cisplatin-based<sup>1</sup> chemoradiation, based on a positive randomized trial, is recommended. Those with intermediate risk factors including tumor size, cervical stromal invasion, and lymphovascular invasion had an improved progression-free survival with adjuvant radiation.

Radical trachelectomy—laparoscopic, vaginal, or open—in conjunction with lymphadenectomy is a reasonable alternative treatment for select young patients with stage IA2 and IB1 who desire to maintain their childbearing capacity. The criteria used for patient selection include early-stage cervical cancer with a lesion less than 2 cm, no lymphovascular invasion, and no lymph node metastasis. Reports comparing radical trachelectomies with matched controls identified increased complications (25% vs. 3%) and overall less-radical dissection.

Treatment of stage IB2 cancer of the cervix varies depending on the bulkiness and shape of the lesion. Surgery and chemoradiation therapy have advantages and disadvantages. Finan and

colleagues reported that up to 72% of patients with stage IB2 disease who were treated with surgery received adjuvant radiation owing to high-risk factors identified in pathologic evaluation of specimens. In a randomized Gynecologic Oncology Group trial, 94% of patients with IB2 cervical cancer who underwent radical hysterectomy had high or intermediate risk factors warranting adjuvant radiation.

In 1999 the National Cancer Institute (NCI) initiated a clinical alert recommending that concurrent cisplatin-based chemotherapy be given with radiotherapy to women with cervical cancer based on five randomized studies, and this established a new standard of care (Table 3).

It is estimated that approximately 35% of patients with invasive cervical cancer will have recurrent or persistent disease, with most recurrences occurring in the first 2 years following primary therapy. Recurrence can be expected in 10% to 20% of patients treated with radical hysterectomy in contrast to 30% to 50% treated for more-advanced disease primarily with radiation plus concurrent chemotherapy. The site of the recurrence can direct further treatment. Patients with central pelvic recurrences after surgery are candidates for curative radiation; after primary treatment with radiation therapy patients may be candidates for

curative radical surgery (exenteration). Prognosis is more favorable for patients undergoing exenteration when there is a small (<3 cm) central recurrence, no sidewall involvement, and longer than 2 years of disease-free interval. Those with small recurrences limited to the cervix or upper vagina can occasionally be treated with radical hysterectomy and upper vaginectomy.

However, most recurrences are distant, involving the lung, bone, abdominal cavity, and supraclavicular lymph nodes. Recurrences within irradiated areas have a poor response to therapy

(0% to 5%). Recurrences in the nonirradiated areas respond better to chemotherapy, with response rates of 25% to 70%. The use of chemotherapy in the treatment of recurrent cervical cancer is challenging because agents are only moderately active and patients can present with renal impairment secondary to obstructive uropathy, resulting in altered excretion with increased toxicity from chemotherapeutic agents. Table 4 compares results of randomized chemotherapy trials for the treatment of recurrent cervical cancer.

New treatment strategies for recurrent disease include immunotherapy with multiple ongoing trials at this time.

## Conclusion

Adherence to current screening guidelines should allow early cervical cancer or precancerous detection. However, most patients with cervical cancer have not participated in regular screening and present with a variety of disease extents.

## CONTRACEPTION

Method of

Rachel A. Bonnema, MD, MS

## CURRENT THERAPY

- Long-acting reversible contraception (LARC) such as an implant or intrauterine device (IUD) is safe and extremely effective and should be considered in all women, including nulliparous women.
- Combined estrogen and progesterone methods (e.g., pills, patch, ring) are effective and commonly used. They provide excellent cycle control and decreased rates of ectopic pregnancy, pelvic inflammatory disease, and endometrial and ovarian cancer, and they can be used in extended-cycle methods for patients who desire fewer than 12 periods per year.
- The use of estrogen has been associated, albeit rarely, with the development of deep venous thrombosis, myocardial infarction, and stroke; estrogen should not be used in smokers older than 35 years of age and in patients with diabetes with end organ damage, coronary artery disease, migraines with aura, or a known hypercoagulable condition.
- For women with a contraindication to estrogen, progestin-only methods are safe to use.

Nearly one-half of all pregnancies in the United States are unplanned, a rate higher than the rate in other developed countries. Primary care physicians need up-to-date knowledge on contraceptive counseling for women to provide the best match between patient and contraceptive method, in part because providers frequently need to supply contraceptives to women who have particular medical comorbidities. Newer contraceptive preparations are now available, including a vaginal ring that can be reused for up to 1 year and a progestin-only pill (POP) with a wider window for missed doses.

## Nonhormonal Methods

Nonhormonal methods of contraception include barrier methods and the copper intrauterine device (IUD). These methods are safe, easily available, inexpensive, and reversible. Common barrier methods include male and female condoms, spermicides, vaginal sponges, diaphragms, and cervical caps (Table 1). Only condom use has been consistently found to protect against sexually transmitted infections (STIs) including HIV, and condom use may reduce the risk of cervical cancer as well. Of note is a novel pH-buffering spermicide, Phexxi, that is available by prescription only. Although it is not more effective than non-oxynol-9 spermicides, further studies are planned to evaluate Phexxi as a novel STI prevention method. Barrier methods have the lowest efficacy rates of all contraceptive methods, and users should also be counseled about emergency contraception (EC). The copper IUD is an extremely effective form of long-acting reversible contraception (LARC) and is a particularly attractive option for women who have contraindications to hormone use and desire effective contraception.

## Combined Hormonal Contraception

Combined hormonal contraception (CHC) contains estrogen and a progestin and work primarily by preventing the surge of luteinizing hormone and thereby preventing ovulation. The majority of CHCs contain ethinyl estradiol (EE), though a new contraceptive has been approved with a novel endogenous estrogen, estetrol (E4). CHC can be delivered as an oral contraceptive pill (OCP), as a vaginal ring (NuvaRing, Annovera), or as a transdermal patch (Xulane, Twirla). Risks, benefits, side effects, and contraindications of CHC are thought to be largely similar across delivery methods.

**TABLE 1** Nonhormonal Contraception

	BARRIER METHODS				INTRAUTERINE DEVICE
	CONDOM (MALE/FEMALE)	DIAPHRAGM OR CERVICAL CAP	SPONGE	SPERMICIDE	COPPER IUD
Duration	Female condom can be inserted up to 8 h before intercourse; male condoms must be changed with each act of intercourse	Can be placed up to 6 h before intercourse and should be removed within 6 h after	Can be left in for 30 h and through multiple acts of intercourse	Placed 30–60 min before intercourse; proper instructions should be followed according to product directions	Approved for up to 10 years
Typical-use failure rate*	15%	15%	15%	10%–22%†	Less than 0.1%
Side effects and considerations	High failure rates: condom can break or slip Acceptability by partner may be limited	Requires expert fitting Must be refitted after childbirth Requires dexterity and self-placement by patient Use with spermicide increases efficacy but can lead to risk of UTIs, increased risk of toxic shock syndrome, and potential increased risk of HIV transmission	May increase risk of UTIs Use with spermicide increases efficacy but can lead to risk of UTIs, increased risk of toxic shock syndrome, and potential increased risk of HIV transmission	Vulvovaginal burning/itching can occur Phexxi is a novel spermicide available only with prescription; nonoxynol-9 formulations are commonly available over the counter	Bleeding and cramping with menses initially Low risk of ectopic pregnancy, premature delivery, perforation, or expulsion Avoid with active infection, undiagnosed genital bleeding, cervical cancer, or Wilson disease
Consider in:	Patients at risk for STIs Patients without access to medical care and who are looking for nonhormonal, reversible, and convenient methods of contraception	Women who are looking for nonhormonal, reversible, and convenient methods of contraception	Women who are looking for nonhormonal, reversible, and convenient methods of contraception Patients without access to medical care	Women using other barrier methods or looking for moderately effective contraception	Women with contraindication to hormones or who desire hormone-free, long-acting, reversible contraception Women in need of EC followed by long-term effective contraception

\*Trussell J. Contraceptive failure in the United States. *Contraception*. 2011;83(5):397–404.

†Varies according to product, Wong JC, Creinin MD. 2021 update on contraception. *OBG Manag*. 2021;33(10):23–25, 30–32, 34, e1.  
EC, Emergency contraception; HIV, human immunodeficiency virus; IUD, intrauterine device; UTI, urinary tract infection.

There are many noncontraceptive benefits to CHC, including first-line treatment for dysfunctional uterine bleeding, dysmenorrhea, and menorrhagia. Benefits in addition to menstrual control include reduction in the risk for and symptoms of endometriosis, ovulatory pain, ovarian cysts, benign breast disease, premenstrual syndrome, and premenstrual dysphoric disorder. CHCs also reduce the risk of ovarian and endometrial cancers; these risk reductions extend for years after discontinuing CHC. The most common side effects of CHC are outlined in Table 2. The risk of venous thromboembolism (VTE) may be higher in obese patients, smokers, and those who use certain progestins such as desogestrel or drospirenone. This risk is lower, however, than the risk of VTE associated with pregnancy, and the absolute risk of VTE among CHC users remains small. The novel OCP with E4 (E4 plus drospirenone [Nextstellis]) has demonstrated more neutral effects on the liver, with preliminary findings suggesting lower VTE risk compared with other CHC.

CHCs can be used safely by those with a range of medical conditions, including well-controlled hypertension, uncomplicated diabetes, migraines *without* aura when younger than 35

years of age, and a family history of breast cancer, to name a few. CHC use is contraindicated in patients who have a history of migraine headache with aura at any age or in those older than 35 years of age with any migraine because of an elevated risk for stroke. CHC is also contraindicated in patients with diabetes with end organ damage, those with known cardiovascular disease, and individuals who smoke after 35 years of age because of an elevated risk for cardiovascular disease. Other contraindications include a personal history of breast cancer, an estrogen-dependent tumor, unexplained vaginal bleeding, stroke, known thromboembolic disorder, or known VTE. Elevated risk of VTE and negative effect on lactation restrict the use of CHC in the first 6 weeks after delivery.

### Combined Oral Contraceptive Pills

There are dozens of formulations of OCPs that differ by their estrogen type and dosage, progestin type and dosage, and hormone delivery schedule. OCPs can be monophasic in which each pill contains the same amount of hormones, or multiphasic in which pills contain different amounts of hormones throughout

**TABLE 2** Hormonal Contraception

	COMBINATION ESTROGEN-PROGESTIN		PROGESTIN-ONLY			
	TRADITIONAL (OCPS, PATCH, SA/EE RING)	EXTENDED CYCLE (OCPS, ENG/EE RING)	PILL		INJECTION	IMPLANT/IUD
			NORETHINDRONE	DROSPIRENONE		
Duration	Daily pill	Daily pill or monthly ring	Daily pill with no hormone-free interval	Daily with 4 day hormone-free interval	3 months	3–6 years
Reversibility	Immediate	Immediate	Immediate	Immediate	Variable	Immediate
Typical-use failure rate*	9%	9%	9%		6%	0.05%–0.8%
Side effects†	Spotting, nausea, headache, breast tenderness, VTE, stroke, MI	Similar to traditional with increased risk for unpatterned bleeding	Unpatterned bleeding, or absence of bleeding; headaches, nausea, mood changes, breast tenderness		Unpatterned bleeding or absence of bleeding; weight gain, depression, reversible decrease in BMD	Unpatterned bleeding, or absence of bleeding
Consider in:	Women with dysmenorrhea, menorrhagia, irregular menstrual periods, acne, hirsutism, or polycystic ovary syndrome	Women who do not desire monthly periods. Offers particular benefit for women with estrogen withdrawal symptoms, dysmenorrhea, or endometriosis	Women with contraindication to estrogen, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding		Women with contraindication to estrogen, seizure disorder, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding	Women with contraindication to estrogen, seizure disorder, hypercoagulable states, dysmenorrhea, migraine with aura, or breast-feeding

\*Trussell J. Contraceptive failure in the United States. *Contraception*. 2011;83(5):397–404.

†Note: For all combination methods, must have no contraindication to estrogen.

BMD, Bone mineral density; IUD, intrauterine device; MI, myocardial infarction; OCP, oral contraceptive pill; VTE, venous thromboembolism.

the monthly cycle. The different formulations offer patients options in cycle length, hormone levels, duration of withdrawal bleeding, and side-effect profile. Education should include taking the pill at the same time each day. If a pill is missed, it should be taken as soon as remembered. If 2 days of pills are missed, the regimen includes two pills daily for 2 days in a row with a backup method utilized. If 3 days of pills are missed, the pill pack should be discarded and a backup method utilized. At that point, it should be discussed whether to start a new pack or to change contraceptive methods.

For those who desire fewer days of menses or fewer than 12 menses per year, extended-cycle OCP regimens can be offered that offer a placebo week every 4 months or eliminate the placebo week altogether. Extended-cycle regimens have other benefits, including decreased hormone withdrawal symptoms such as headaches, tiredness, bloating, excessive bleeding, or menstrual pain. In addition to estrogen dose and scheduling, it is also important to consider the progestin component, which theoretically may affect libido, weight gain, acne, and hirsutism.

### Contraceptive Patch

Norelgestromin/EE (Xulane) is a thin transdermal patch delivering a daily dose of 35 µg/day EE and 150 µg/day norelgestromin. Levonorgestrel/EE (Twirla) is a newly approved patch delivering a daily dose of 30 µg/day EE and 120 µg/day levonorgestrel. Both patches are administered similarly: changed weekly for 3 weeks on “patch change day” followed by a patch-free week during which menses occur. Only one patch should be worn at a time, and no more than 7 days should pass during the patch-free week. Both have decreased efficacy in obese women and are contraindicated in patients with a BMI >30 kg/m<sup>2</sup>. Most of the noncontraceptive benefits, side effects, cardiovascular risks, and

contraindications are similar to those of other forms of CHC, but there may be an increased risk of VTE in patch users compared with OCP users, though studies are controversial as to the actual increase in associated risk. Of note, the VTE risk associated with patch use is lower than that associated with pregnancy.

### Vaginal Ring

Contraceptive vaginal rings (CVRs) deliver hormones directly through the vaginal epithelium for highly effective contraception without the need for daily dosing. There are currently two CVRs that are approved by the U.S. Food and Drug Administration (FDA) for use in the United States. Etonogestrel/EE (NuvaRing) is a soft plastic ring that is inserted vaginally by the patient, usually for 3 weeks and then removed for 1 week, at which time menses occur. A new ring is inserted 7 days after the last one was removed, even if bleeding is not complete. The ring releases 15 µg of ethinyl estradiol and 0.12 mg of etonogestrel daily for 3 to 5 weeks, so it can be kept in longer than 3 weeks for those desiring the benefits of extended-cycling use discussed previously. Each ring releases approximately one-half the level of hormones as the average OCP without affecting efficacy. If the ring falls out (as occurs rarely), it can be rinsed and reinserted without a change in efficacy. Most find the ring easy to insert and remove and comfortable to retain during intercourse.

A newer ring containing a year’s contraception with segesterone acetate (SA) and EE is now available. The SA/EE ring (Annovera) is used for 21 days followed by a 7-day use-free interval for up to 13 consecutive cycles. Unlike the NuvaRing, no data are available on extended periods of continuous use with the same SA/EE ring; during counseling, special emphasis should be placed on the increased pregnancy risk for patients

who remove the ring for more than 2 hours. Both rings available are highly effective, similar to other combined hormonal methods, and have excellent cycle control. The vaginal ring has been associated with an increase in leukorrhea. Otherwise, its noncontraceptive benefits, side effects, cardiovascular risks, and contraindications are similar to those of other forms of CHC.

### Progestin-Only Contraceptives

Progestin-only contraceptives are particularly beneficial for those with a contraindication to estrogen because progestin-only methods have decreased associated medical risks, including no increased risk of stroke, myocardial infarction, or VTE. All progestin-only methods have a similar method of action: Ovulation is variably inhibited, cervical mucus is thickened, and the endometrial lining undergoes histologic alterations, making implantation less likely. Because many of the progestin-only methods are long acting, they tend to have lower failure rates as opposed to CHCs (see Table 2). All progestin-only methods are appropriate for breast-feeding.

#### Pill

There are now two POPs available in the United States. Norethindrone pills are taken without a hormone-free interval, and fertility returns immediately on discontinuation. In fact, most experts believe fertility can return in as little as 3 hours after a missed dose; thus patients should be counseled to use a backup method if 3 or more hours late in taking her dose. Given this small window for error, this method should be prescribed only to patients who can adhere closely to a daily pill schedule. Additionally, counseling should include that while taking norethindrone pills, normal menstrual patterns may include anything from amenorrhea to menometrorrhagia. This unpatterned bleeding is likely one of the greatest obstacles to wider use of progestin-only oral contraception.

A new POP contraceptive contains drospirenone 4 mg (Slynd) and is available in a 24-day supply of hormone and a 4-day supply of placebo, allowing for a timed withdrawal bleed. The drospirenone-only pill maintains contraceptive efficacy, even with 24-hour delayed or missed-pill errors; patients can be counseled to take a missed pill as soon as remembered if within 24 hours or with the next scheduled dose if more than 24 hours late. Although intermenstrual bleeding rates are still high, the menstrual profile may be more tolerable compared with other POPs.

Because POPs have demonstrated no significant negative effects on breast-feeding, POPs can be prescribed immediately postpartum. POPs may have similar effects as other progestin-only methods in decreasing the frequency of sickle cell crises; however, unlike depot medroxyprogesterone acetate (DMPA, Depo-Provera) injections, certain anticonvulsants may lower the effectiveness of the POP, so other methods may be more beneficial in patients with seizure disorders.

#### Injectable

The intramuscular DMPA injection (Depo-Provera 150 mg) is given every 12 weeks and has a typical-use failure rate of 6%. A lower dose of DMPA (104 mg in Depo-SubQ Provera) has been approved for subcutaneous injection. Patients with seizure disorders are particularly good candidates for DMPA injections because, unlike other forms of contraception, the efficacy of DMPA is not affected by enzyme-inducing antiepileptic drugs. Depo-Provera may also decrease seizure frequency, providing additional benefit. DMPA reduces serum estradiol levels, which can adversely affect bone health. There is a clear association between DMPA use and decreased bone mineral density (BMD); however, data have shown the BMD loss to be reversible with discontinuation of use, and there is no increased risk of fracture with the use of DMPA. The World Health Organization has recommended that there be no restriction on the use of Depo-Provera in patients who are 18 to 45 years of age. According to recent

consensus guidelines, clinicians should advise patients about the risk for BMD loss but can reassure them about reversibility with discontinuation.

### Intrauterine System

The levonorgestrel intrauterine system (LNG-IUS) is a highly effective contraceptive method long considered to be reversible sterilization because of its excellent efficacy in preventing pregnancy and quick return to fertility after its removal. There are now multiple formulations of LNG IUS that prevent pregnancy for 3 to 6 years (Skyla, Kyleena, Mirena, Liletta), categorized by the amount of levonorgestrel that they contain: 52 mg in Mirena and Liletta, 19.5 mg in Kyleena, or 13.5 mg in Skyla. The LNG-IUS is ideal for those who require highly effective contraception and is particularly beneficial for patients requiring a progestin-only contraception. Its relatively low cost over time is another factor for patients to consider. Numerous studies have confirmed the effectiveness of the LNG-IUS for reduction of menstrual blood loss in menorrhagia, leiomyomas, and pain caused by endometriosis; Mirena received FDA approval for the indication of menorrhagia and has been shown to decrease menorrhagia for those on anticoagulation. Insertion of the LNG-IUS requires a trained provider. At the time of placement, cramping and pain may occur; a rare complication of placement is uterine wall rupture. Many will likely develop amenorrhea, though they may experience initial irregular bleeding and spotting.

### Implant

There is one single-rod subdermal implant available in the United States called Nexplanon that is a highly effective long-term contraceptive containing the progestin etonogestrel (ENG). The rod is implanted in the upper arm and remains active for 3 years. ENG does not cause a hypoestrogenic state and thus is not considered to have any significant effect on BMD. ENG implantation can be done as a simple procedure by a trained provider under local anesthesia with a preloaded, disposable applicator. Patients experience a quick return to normal cycles after implant removal, and there have been no reports of infertility after removal. Similar to other progestin-only forms of contraception, irregular bleeding is the major side effect of the ENG implant. The most common bleeding pattern associated with the implant is infrequent, irregular bleeding. This remains an important counseling point because the highest rate of discontinuation is during the first 8 to 9 months of use, primarily as a result of frequent bleeding.

### Permanent

Permanent birth control methods include vasectomy and female sterilization by various procedures. These methods are highly effective (typical failure rate 0.15% to 0.5%); however, they are permanent. Each sterilization procedure has advantages and disadvantages that should be considered by the patient before choosing which one to use.

### Emergency Contraception

Familiarity with EC is critical both for those having unprotected sex and for those who are using methods with higher failure rates. EC use has not been shown to reduce compliance with other first-line methods. EC primarily acts by inhibiting or delaying ovulation and works before implantation; if a fertilized egg has already implanted, EC will not work. EC includes pills (composed of estrogen plus progestin, progestin only, and antiproggestins) and copper IUD placement (inserted up to 5 days after unprotected intercourse); EC pills are most effective when taken in the first 12 hours but have gradually decreasing effectiveness for up to 120 hours after intercourse. The most accessible form of EC in the United States contains levonorgestrel only (Plan B One Step) and is available over the counter without age restrictions.

## Counseling

When counseling patients about their contraceptive choices, it is important that providers are aware of their role in giving information and allowing patients to make informed decisions. The only effective contraceptive is one that a patient is willing to use consistently and correctly, and the choice of contraception is ultimately the patient's decision. Providers must educate patients regarding the advantages and disadvantages of each method that is medically appropriate for them. Discussing patient preferences for menstrual frequency and tolerance for scheduled and unscheduled bleeding is important in deciding which contraceptive best fits a patient's needs. Providers should counsel patients on expected side effects as well as expectant management strategies. Every effort should be made to remove barriers to initiation, including having no requirement for a pelvic examination or Pap smear before initiation. Using the conversation about contraceptives to also discuss safe sex is ideal.

## DYSMENORRHEA

Method of

Linda Speer, MD

## CURRENT DIAGNOSIS

- Primary dysmenorrhea (painful menses without underlying pathology) is common among adolescents and young women. It usually begins shortly after menarche.
- Diagnosis of primary dysmenorrhea can be made based on typical history of crampy pelvic pain during the first 1 to 3 days of the menstrual cycle. Pelvic examination is not required.
- Secondary dysmenorrhea (with underlying pathology) should be considered in cases that do not match the typical history, begin later in life, and/or are refractory to treatment.
- The most common cause of secondary dysmenorrhea is endometriosis. The clinical standard for diagnosis of endometriosis is laparoscopic confirmation. Ultrasound imaging is useful in some cases.

## CURRENT THERAPY

- Nonsteroidal antiinflammatory drugs (NSAIDs) are well-established first-line therapy for treatment of primary dysmenorrhea. None has been confirmed as superior to others.
- Cyclooxygenase-2 (COX-2) inhibitors are effective and have fewer gastrointestinal side effects but may be less effective than NSAIDs.
- Oral contraceptives and the levonorgestrel intrauterine system (Mirena)<sup>1</sup> reduce dysmenorrhea.
- Other effective therapies include topical heat, high-frequency transcutaneous electrical nerve stimulation (TENS), and several herbal preparations.
- Treatments for endometriosis as a secondary cause of pelvic pain and dysmenorrhea include hormonal suppression of the endometrial tissue, conservative laparoscopic surgical debulking, and hysterectomy in selected cases.

<sup>1</sup>Not FDA approved for this indication.

Dysmenorrhea is defined as painful menses. Primary dysmenorrhea occurs without underlying pathology, typically beginning soon after menarche. It is common in adolescent girls, with prevalence ranging from 20% to 90% depending on measurement methods; about 15% of adolescents describe their dysmenorrhea as severe. The median duration of each episode is 2 days beginning with the onset of menses. During adolescence, dysmenorrhea leads to high rates of school absence and activity nonparticipation. According to representative national survey data in the United States, 14% of adolescent girls aged 12 to 17 years frequently miss school because of menstrual cramps.

A prospective cohort study showed that the prevalence and severity of dysmenorrhea was lower at 24 years of age than at 19 years of age. At 24 years of age, 67% of the women still experienced dysmenorrhea, and 10% reported pain severity that limited daily activity. The prevalence and severity of dysmenorrhea were reduced in women who were parous at 24 years and nulliparous at 19 years, but they were unchanged in women who were still nulliparous or women who had had a miscarriage or abortion.

There is a significant correlation between the severity of dysmenorrhea and the amount of menstrual flow. Survey data demonstrate that depression and anxiety are associated with menstrual pain and suggest that loss of social support is a significant contributor to menstrual symptoms. The severity of dysmenorrhea is not associated with height, weight, or regularity of the menstrual cycle. A relationship to smoking has been found inconsistently.

Secondary dysmenorrhea typically starts later in life after the onset of an underlying causative condition, most often endometriosis. The association between dysmenorrhea and endometriosis is uncertain for women with minimal disease. However, based on a study of more than 1000 women with laparoscopically confirmed endometriosis, chronic pelvic pain, dyspareunia, and dysmenorrhea are in fact related to the extent of endometriosis.

## Diagnosis

For adolescents who present with complaints typical for primary dysmenorrhea, treatment may be started empirically without a pelvic examination or diagnostic studies. Sexually active adolescents and young women should be screened for chlamydia and gonorrhea, which can be done with either urine or a genital sampling.

For adolescents and women who do not have a history consistent with primary dysmenorrhea or who are refractory to treatment, endometriosis may be suspected. The gold standard for diagnosis is laparoscopy and biopsy. Ultrasound may also be useful, especially to identify endometriomas.

## Treatment

### Nonsteroidal Antiinflammatory Drugs

A Cochrane review of randomized, controlled trials (RCTs) concluded that among women with primary dysmenorrhea, NSAIDs were significantly more effective for pain relief than placebo or acetaminophen (Tylenol). No specific NSAID was shown to be superior to others for either pain relief or safety. However, the available evidence had little power to detect such differences, because most individual comparisons were based on few small trials. In one study in which diclofenac (Voltaren) 100mg was compared with placebo for treatment of primary dysmenorrhea, the authors found that leg strength and aerobic capacity were maintained at the level found during luteal phase when women took diclofenac for dysmenorrhea, but they were reduced during menses in the placebo group.

### COX-2 Inhibitors

Several COX-2 inhibitors have been evaluated for treatment of dysmenorrhea in RCTs. Celecoxib (Celebrex) 200mg was compared with naproxen sodium (Naprosyn) 550mg and placebo for treatment of dysmenorrhea and found to be superior to placebo but not as effective as naproxen. Etoricoxib (Arcoxia)<sup>5</sup> 120mg daily was found to be better than placebo and equivalent to mefenamic acid (Ponstel) for treatment of primary dysmenorrhea with less nausea and epigastric pain than mefenamic acid.

### Oral Contraceptives

In a systematic review of NSAIDs and oral contraceptives (OCs) for treatment of dysmenorrhea that included 10 placebo-controlled RCTs of NSAIDs, two RCTs of OCs and six prospective observational studies of OCs, the authors concluded that both are effective. In a study of women with laparoscopically proven endometriosis, low-dose ethinyl estradiol and norethisterone (norethindrone) decreased dysmenorrhea associated with endometriosis as compared with placebo (with pain assessment on a verbal rating scale from 0 to 3). There was also a significant reduction in volume of endometriomas with OCs but not placebo.

### Levonorgestrel Intrauterine System

The levonorgestrel intrauterine system (LNG-IUS), Mirena, reduces menstrual bleeding and dysmenorrhea, which can be a desirable side effect for women desiring long-term contraception. In an uncontrolled case series of women treated with LNG-IUS for adenomyosis, dysmenorrhea diminished continuously during the 3-year study from a mean 78mm to a mean 12mm on a 100-mm visual analog scale. Overall satisfaction with treatment was 73%. Depot medroxyprogesterone acetate<sup>1</sup> (Depo-Provera) is similarly effective, but it is less likely to be well tolerated owing to unpredictable bleeding, weight gain, and mood changes.

### Transcutaneous Electrical Nerve Stimulation

In a study comparing transcutaneous electrical nerve stimulation (TENS) with interferential current for treatment of dysmenorrhea, each group received application of the modality for 20 minutes while experiencing dysmenorrhea. Both groups improved significantly from baseline without significant difference between them. High-frequency TENS has been found to be effective for the treatment of dysmenorrhea in a number of small trials. Low-frequency TENS does not appear to be effective.

### Topical Heat and Infrared Light

Two meta-analyses have concluded that topical heat is likely an effective therapy based on several small low-to-moderate-quality studies. In a trial comparing far-infrared emitting belt versus placebo belt for treatment of primary dysmenorrhea, both with concurrent application of topical heat, both groups improved, and

the duration of the analgesic effect was significantly longer in the group treated with the infrared belt.

## Complementary and Alternative Medicine Approaches

### Herbal

Several herbal remedies have been studied in RCTs for treatment of dysmenorrhea and found to be effective as compared with placebo or NSAIDs. They include *Psidium guajava* extract<sup>7</sup> 6mg/day, French maritime pine bark extract (pycnogenol),<sup>7</sup> ginger root powder<sup>7</sup> 250mg 4 times daily, salix extract<sup>7</sup> (willow bark) 400 mg daily, turmeric<sup>7</sup> 500 mg, fennel,<sup>7</sup> and cinnamon<sup>7</sup> one 1000 mg capsule daily. A pilot study of oral lactobacillus capsules (probiotic)<sup>7</sup> suggests that it may also be helpful.

### Acupressure and Acupuncture

The evidence for the effectiveness of acupuncture is not conclusive. In unblinded studies women experience clinically relevant reduction in pain scores, a mean of more than 10 points on a 100-point scale, which could be due to placebo effect. In fact, in a well-designed RCT of electro-acupuncture at the Sanyinjiao point (the point expected to be related to uterine pain) compared to an unrelated nonacupoint or no acupuncture, the only significant differences were with the no-acupuncture group as measured with a visual analogue rating scale.

Adequate blinding is also an issue among studies of acupressure. For example, in an RCT comparing auricular seed acupressure versus adhesive tape only for treatment of primary dysmenorrhea the acupressure group (but not the tape only group) had instructions to massage the seed 15 times, three times daily for 20 days. Menstrual pain decreased significantly in the acupressure group. Several other studies suggest that acupressure at the Sanyinjiao point or Taichong point is more effective than no intervention or inadequately blinded control groups. Because acupressure is a low-cost and harmless intervention, it may be worth considering even if the pain reduction is a placebo response. It appears to be less effective than analgesics.

### Yoga and Other Physical Activity

Yoga is another alternative approach with low cost and little risk that may be worth considering despite weak evidence for effectiveness. In one unblinded RCT, three yoga poses (cat, cobra, and fish) were studied for treatment of primary dysmenorrhea. Participants randomized to the intervention group were told to do the yoga poses during luteal phase and complete a questionnaire regarding menstrual characteristics. The control group was asked to complete the questionnaire only. There was significant reduction in intensity and duration of pain in the yoga group compared with baseline and with the control group.

Two meta-analyses have concluded limited quality evidence suggests that physical activity interventions reduce the duration and intensity of primary dysmenorrhea, perhaps more than oral analgesics. Further study is needed to determine what physical activity regimens are most beneficial.

### Spinal Manipulation

Overall there is no evidence to suggest that spinal manipulation is effective in the treatment of primary and secondary dysmenorrhea.

### Surgical Treatment

Surgical treatment may be considered in severe and refractory cases of pelvic pain including dysmenorrhea. Laparoscopic uterosacral nerve ablation (LUNA,  $n=35$ ) alone has been compared with LUNA plus presacral neurectomy ( $n=32$ ). There were no differences between groups for relief of dysmenorrhea at 3-, 6-, and 12-month follow-up, but more surgical complications were experienced with neurectomy.

<sup>5</sup>Investigational drug in the United States.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

## Treatment of Endometriosis

Treatment of endometriosis may start with use of NSAIDs, hormonal contraceptives, and/or LNG-IUS.<sup>1</sup> However, often endometriosis is diagnosed after those first-line therapies have failed. Debulking of the ectopic endometrial tissue during laparoscopy can relieve pain.

Other treatments involve hormonal suppression of endometrial tissue. Danazol is a 19-nortestosterone derivative with a long history of use for treatment of endometriosis pain at a dosage of 400 to 800 mg daily for 6 months, but it is often poorly tolerated owing to androgenic side effects. Progestin regimens (medroxyprogesterone acetate<sup>1</sup> [Depo-SubQ Provera 104]) 104 mg SQ every 3 months or norethindrone ([Aygestin] up to 15 mg PO daily) may be used to suppress menses for a 6-month course. Other accepted therapies include gonadotropin-releasing hormone (GnRH) agonist analogues such as leuprolide (Lupron). Aromatase inhibitors have been shown to be effective in a systematic review of several small RCTs. Etonogestrel subdermal implant<sup>1</sup> (Nexplanon) has been evaluated in an uncontrolled case series and found to be associated with pain relief.

In severe refractory cases, hysterectomy may be considered.

<sup>1</sup>Not FDA approved for this indication.

## ENDOMETRIOSIS

Method of

Zachary Kuhlmann, DO

### CURRENT DIAGNOSIS

- Clinical symptoms associated with endometriosis include chronic pelvic pain, dysmenorrhea, dyspareunia, and infertility.
- A pelvic sonogram may be helpful to aid in diagnosis of endometriosis. Care should be taken to exclude other gynecologic and non-gynecologic etiologies of pain.
- Diagnostic laparoscopy may reveal powder burn–like lesions, adhesions, endometriomas, or other signs of endometriosis on inspection.
- The gold standard to make a pathologic diagnosis of endometriosis requires a tissue biopsy of a suspected lesion.

### CURRENT MANAGEMENT

- Initial therapy for endometriosis includes NSAIDs, progestones, combined OCPs, danazol (Danocrine), GnRH agonists, and GnRH antagonists.
- Diagnostic laparoscopy with excision or ablative techniques are often used to treat endometriosis.
- It is reasonable to consider empiric medical therapy with a GnRH agonist before surgery in some situations.
- Hysterectomy with bilateral salpingo-oophorectomy is definitive surgical treatment for endometriosis.

Endometriosis is a common and benign gynecologic condition diagnosed when endometrial tissue is found outside the uterus. Common places for endometrial tissue to implant include the peritoneum and ovaries, although endometriosis can occur outside the pelvis as well. Other locations for endometriosis to be found include the rectovaginal septum, bowel, bladder, pleura, abdominal wall, and even the brain in rare cases. Endometriosis is an estrogen-dependent, inflammatory disorder.

### Epidemiology

Endometriosis affects between 5% to 10% of women of reproductive age. Women who experience infertility may have a prevalence of endometriosis of up to 50%, and women with chronic pelvic pain may experience a prevalence of endometriosis well over 80%.

### Risk Factors

There appears to be an inheritable component for endometriosis. Women who have a first-degree relative affected by endometriosis may have a 6 to 7 times higher incidence than women without an affected relative. Other risk factors for endometriosis include menarche before age 11 and extremes of cycle length (either short or long cycles). Women who breastfeed for long durations, women who have more children, and women who exercise regularly may see a reduction in their risk of endometriosis.

### Pathophysiology

There are many theories regarding the origin of endometriosis. Perhaps the most popular hypothesis proposes that retrograde menstruation allows for endometrial tissue to be passed back through the fallopian tubes and implant into the pelvis. Another theory suggests that coelomic metaplasia occurs. In this theory, it is thought that the differentiation of mesothelial cells into endometrial cells results in endometriosis lesions. It is

also thought that hematogenous or lymphatic spread is a plausible explanation for endometriosis. Endometrial cells may be deposited from the vascular or lymphatic vessels onto tissues outside the uterus. One final theory for the etiology of endometriosis involves bone marrow. Cells originating from the bone marrow may differentiate into endometrial tissue outside the uterus.

No matter how endometriosis originates, the immune system plays a pivotal role in the disease process. Endometriosis is associated with an overproduction of estrogen, prostaglandins, and cytokines. Estrogen is overproduced by an increase in aromatase activity. Cyclooxygenase-2 (COX-2) activity is also increased, which stimulates prostaglandin production. Endometriosis is also associated with progesterone resistance, and that magnifies the effect of estrogen in an already estrogen-rich environment. This inflammatory cascade leads to an increase in cytokines and macrophages. The cytokines increase the presence of macrophages and lymphocytes in the peritoneum.

The chronic inflammation identified in endometriosis may cause pain by stimulating the nerve endings or affect the neural innervations of the uterus. Fallopian tube function and sperm function may be adversely affected by the inflammatory cytokines. Also, the fallopian tubes may be completely blocked in some cases of endometriosis.

### Clinical Manifestations

Many clinical symptoms have been associated with endometriosis. Cyclical pain is often described with endometriosis. Some of the more commonly recognized symptoms include dysmenorrhea, chronic pelvic pain, dyspareunia, and infertility. Dysmenorrhea can be described as primary or secondary. The dysmenorrhea with endometriosis is classically described as secondary dysmenorrhea because it is associated with a pathologic diagnosis. Primary dysmenorrhea is when there is painful menstruation in the absence of pelvic pathology. Examples of chronic pelvic pain with endometriosis may include other visceral symptoms such as dyschezia or dysuria. Hematuria, diarrhea, constipation, and chronic back pain may all be symptoms associated with endometriosis.

Interestingly, the extent of disease may not necessarily correlate with the severity of symptoms. Some women with a small foci of endometriosis may have excruciating symptoms, whereas others with extensive endometriosis may only experience mild symptoms.

Exam findings consistent with a diagnosis of endometriosis may include uterosacral ligament nodularity/tenderness and presence of an adnexal mass. Tenderness in the cul-de-sac with a fixed and immobile uterus may also indicate presence of endometriosis. Cyclical hemoptysis has been reported with endometriosis. Endometriotic implants have also been located in scars, so the presence of cyclical pain in an abdominal incision may lead to suspicion of endometriosis.

### Diagnosis/Differential Diagnosis

The diagnosis of endometriosis is made surgically. The gold standard to make a diagnosis of endometriosis is to have a pathologic specimen from a tissue biopsy of a suspected lesion. Histology will reveal endometrial glands and stroma and inflammation. If a biopsy is not performed, surgical findings consistent with an endometriosis diagnosis include lesions that look like black powder burns and nonclassical red or white lesions. Endometriomas have also been described as a classic surgical finding of endometriosis. Endometriomas are an ovarian structure filled with endometriosis and are colloquially described as chocolate cysts because when they rupture, it appears as though chocolate syrup flows out of the cyst. Endometriomas appear on sonographic imaging as cysts with homogenous internal echoes. Although rare, endometriosis can sometimes be found in the bladder. If bladder involvement is suspected, such as the case of cyclical hematuria, a cystoscopy may be of benefit for diagnosis. Although surgery remains the mainstay of diagnosis for endometriosis, some studies suggest

**TABLE 1** Differential Diagnosis for Chronic Pelvic Pain Based on Organ Systems

GYNECOLOGIC	GASTROINTESTINAL	URINARY	MUSCULOSKELETAL
Endometriosis	Irritable bowel syndrome	Urinary tract infection	Fibromyalgia
Adenomyosis	Diverticuli	Interstitial Cystitis	Ankylosing spondylitis
Cervicitis	Crohn's	Malignancy	Arthritis
Leiomyoma	Ulcerative Colitis	Renal lithiasis	Muscle strains
Ovarian cysts	Gastroenteritis		
Pelvic adhesive disease	Hemorrhoids		
Hydrosalpinx/tubal disease			
Pelvic congestion syndrome			

there is a low correlation between the severity of symptoms, the amount of endometriosis visualized on surgical inspection, and diagnostic histologic findings.

Pelvic imaging may be helpful in the evaluation of endometriosis, especially in the presence of an adnexal mass. In patients with pelvic pain or disorders of menstruation, a sonogram is usually the preferred imaging modality for the pelvis. Computed tomography (CT) may help delineate the size and characteristic of an adnexal mass and is likely most useful to rule out other pathology or surrounding organ involvement. The usefulness of magnetic resonance imaging (MRI) is limited in the evaluation of endometriosis and should be reserved for extreme cases where specific organ involvement such as the bladder or bowel is suspected. MRI may also be useful in evaluating specific musculoskeletal conditions.

There is no good serum marker to make the diagnosis of endometriosis. CA-125 levels may be elevated in endometriosis, but there are many other inflammatory conditions that cause an elevation in CA-125 levels.

When initially evaluating for endometriosis, one should consider a thorough differential diagnosis for causes of chronic pelvic pain. Table 1 lists the differential diagnosis for chronic pelvic pain. A basic approach to the patient with chronic pelvic pain should include a detailed history and physical, urinalysis, gonorrhea/chlamydia cultures, consideration of pelvic sonogram, and serum or urine beta human chorionic gonadotropin (Bhcg). If after careful evaluation, endometriosis is at the top of the differential diagnosis for the patient's pelvic pain, then discussion with the patient regarding empiric treatment or diagnostic workup should occur.

### Medical Therapy

The goal of medical intervention for endometriosis is the treatment of pain. A reasonable approach to treating the patient with suspected endometriosis is to give a trial of empiric medical therapy. Although endometriosis is a surgical diagnosis, some patients with suspected endometriosis may wish to avoid surgery. Medical therapy is usually preferred for those patients who would like to preserve fertility and who are interested in delaying childbearing while managing their symptoms.

The combined oral contraceptive pill (OCP) is a usual first-line therapy for the treatment of suspected or diagnosed endometriosis. A 3- to 6-month trial with empiric treatment with OCPs is a reasonable time frame to assess effectiveness of medical treatment. OCPs should be avoided in patients that have contraindications to OCPs including pregnancy, history of thrombosis, liver disease, migraine with aura, uncontrolled hypertension, and those patients that smoke and are over the age of 35 years.

Other medications used to treat endometriosis include danazol (Danocrine), nonsteroidal anti-inflammatory drugs (NSAIDs), progestins, and gonadotropin releasing hormone (GnRH) agonists and antagonists. NSAIDs may improve the pain and dysmenorrhea associated with endometriosis. Danazol is an effective treatment for endometriosis. The side effect profile for danazol limits its use. Danazol has been associated with masculinizing

symptoms, which can include acne and hair growth. Danazol should be avoided in pregnancy because the masculinizing effects could be detrimental to a female infant.

Physicians commonly prescribe progestins in three different ways to treat endometriosis: injectable, oral, or intrauterine. Injectable medroxyprogesterone (Depo-SubQ Provera 104) is approved by the Food and Drug Administration (FDA) for the treatment of endometriosis. Depo-Provera's side effects may include weight gain, bleeding, amenorrhea, and slow return to fertility. Patients using Depo-Provera may initially experience irregular bleeding but often develop amenorrhea after the second dose is administered. Return to fertility after Depo-Provera is discontinued can also pose a problem. Oral agents such as norethindrone acetate (Aygestin) have also been approved by the FDA for the treatment of endometriosis. The levonorgestrel-containing intrauterine device (IUD) (Mirena)<sup>1</sup> is approved only for contraception and the treatment of menorrhagia, but it may still be an effective treatment for endometriosis.

The GnRH agonists are among the most effective medications available to treat endometriosis. The side effects of GnRH agonists include menopausal-like symptoms such as vaginal dryness, hot flashes, and osteopenia. The addition of add-back therapy may help ameliorate some of the GnRH agonist symptoms. Typically, add-back therapy involves the use of progestins concurrently with a GnRH agonist. Practice patterns vary; some providers may start add-back therapy immediately when a patient is started on a GnRH agonist. It is recommended that add-back therapy be initiated after 6 months of GnRH agonist use if it was not started previously. In addition to progestins, the combination of progestins and estrogen have been used for add-back therapy. The maximum duration of GnRH agonist treatment is typically 12 months. Another class of medication to treat endometriosis is the GnRH antagonist, currently available as elagolix (Orilissa). Advantages to this medication are that it is in an oral form and available in multiple doses. Studies showed estradiol suppression in a dose dependent manner. Common side effects include hot flashes, headaches, and nausea. Although add-back therapy is widely used in GnRH agonists, it has not been studied with the GnRH antagonists. When using this medication, consideration of a nonhormonal contraception would be recommended.

### Surgical Therapy

The goal of surgery for endometriosis is to relieve pain and/or infertility. One of the first questions the provider must answer is when to perform surgery. Surgery may be indicated if medical treatment has failed. Other times, the severity of symptoms or presence of large endometriomas may direct a provider to consider surgery sooner.

Laparoscopy is a common surgical approach for patients with confirmed or suspected endometriosis. At the time of laparoscopy, the surgeon can assess the uterus, ovaries, and surrounding

<sup>1</sup>Not FDA approved for this indication.

viscera for pathology. When endometriosis is encountered on laparoscopy, common approaches are to excise or ablate the lesions. Excision of endometriosis allows for a pathologic diagnosis. If the provider elects to ablate the lesions, this can be performed through electrocautery or laser. In addition to diagnosing and treating endometriosis, further evaluation of patients with infertility can be done at the time of laparoscopy. Tubal function can be assessed through a chromotubation where dye is passed through the fallopian tubes to prove the tubes are patent. Although laparotomy allows for thorough evaluation of the pelvis, it is usually reserved for cases of confirmed endometriosis where the extent of adhesions and distorted anatomy makes laparoscopy unsafe.

Endometriomas present an array of challenges when noted at the time of surgery. The decision to drain the cyst versus perform a cystectomy during surgery must be made by the surgeon. A general approach is to use a "3-centimeters (cm) rule" to help guide management decisions. Patients with an endometrioma greater than 3 cm may benefit from cystectomy, whereas endometriomas less than 3 cm may be managed by drainage and ablation. Although removing the endometrioma through cystectomy may confer a decreased risk or recurrence, the risk of damaging healthy ovarian tissue is ever present. Other confounders to consider are future fertility plans of the patient, severity of symptoms, and previous treatments for endometriosis.

In a patient who has completed childbearing or has no desire for future fertility, hysterectomy with a bilateral salpingo-oophorectomy (BSO) may be considered for treatment of endometriosis. Studies suggest that hysterectomy alone is less effective at curing pain than hysterectomy with a BSO. Although hysterectomy with BSO offers definitive treatment for endometriosis, surgery does not guarantee resolution of pain. Many routes may be considered for surgery, including laparoscopic, robotic-assisted laparoscopic, or laparotomy with a total abdominal hysterectomy/BSO. Although vaginal hysterectomy is a common and preferred route of surgery, the distorted anatomy and presence of adhesions often associated with endometriosis tends to discourage many surgeons from performing vaginal hysterectomies for endometriosis.

### Monitoring

Patients diagnosed with endometriosis may require frequent monitoring of symptoms. Routine visits with a physician may help determine the effectiveness of current treatment regimens. Physicians should consider what the patient's goals of treatment are: Does the patient want resolution of pain or infertility or both? Individualized plans may help each patient achieve their goals of treatment. As with any diseases involving chronic pain, care should be taken to regularly assess patients with endometriosis for depression.

## FEMALE SEXUAL DYSFUNCTION

Method of

Melissa Hague, MD

### CURRENT DIAGNOSIS

- Sexual pain is a common cause of distress for women and their partners, with up to 50% of women experiencing distress at some point in their lifetime.
- Women may present with a complaint of decreased libido, but on further questioning may have significant pain with sex that is causing or contributing to decreased desire.
- Always ask about relationship stress, pain, and ability to achieve climax when discussing sexual distress with female patients.
- Many medications interfere with libido, as does a patient's lifestyle and overall health status.
- Like many medical concerns, female sexual dysfunction is a complex, multifactorial problem that should be addressed with a holistic multidisciplinary approach.

### CURRENT THERAPY

- You cannot treat decreased libido in a patient who is having sexual pain without addressing the source of the pain.
- Determine the cause of sexual pain; once this has been adequately addressed, you may consider a treatment plan for decreased libido.
- Consider the approach to sexual pain from the outside working in. Start with skin or vulvar causes, such as lichen sclerosis, atrophy, or herpes. Work in toward the pelvic floor and consider muscle or nerve pain as a cause. Once you have considered these as a source of pain and not found a problem, you can consider a bimanual exam and see if pain occurs with cervical or uterine motion, or if there is evidence of pelvic mass.
- Realize that patients who have suffered sexual trauma, such as abuse or rape, will need a multidisciplinary approach that may include a physician, physical therapist, and counselor or sex therapist to help them with pain and libido concerns.
- Physical therapists trained in the treatment of pelvic floor dysfunction are an essential part of the team approach to treatment of patients with neuromuscular pelvic floor pain or dyspareunia.
- Mindfulness is a tool used by therapists to help patients struggling with anorgasmia to improve the sexual experience.
- Engaging the partner in developing a treatment plan for sexual pain or decreased libido is important to obtain endorsement from the patient. This is especially the case if you are recommending abstaining from sex for a period of time to allow for healing.

### Epidemiology

The prevalence of female sexual function concerns in the primary care clinic is difficult to quantify. Depending on which article you read, the prevalence is between 30% and 100% throughout the lifespan of a woman. The emotional toll that low libido, sexual pain, and anorgasmia take on women and their partners is significant. Patients experiencing sexual pain may be hesitant to discuss their concerns, or may have had a negative experience with a health care provider in the past when they tried to discuss concerns. On average, patients see more than six health care providers before the source of their sexual pain or libido concerns are adequately addressed. The occurrence of sexual concerns is

higher in patients with depression, chronic pain, cancer diagnosis, bowel or bladder problems, and arthritis, as well as in the postmenopausal years.

The general topic of female sexual function can be difficult to address in the primary care setting. When a patient presents for an annual exam, for example, and she says she is having pain with intercourse, it can cause anxiety on the part of the practitioner. This is often not a visit that can be accomplished in a 10-minute slot, so do not hesitate to tell the patient that you want to make sure you have adequate time to address her concerns. If this was not the reason for her visit, consider asking her to schedule a visit when you have more time available so that you can best help her. Having a basic knowledge about a systematic approach to female sexual pain can help the practitioner have confidence in discussing this area of distress with women and their partners. We will approach this from two different areas of concern: decreased libido and sexual pain.

### Pathophysiology, Diagnosis, Treatment: Decreased Libido

If a patient comes in complaining of decreased sex drive, you must consider many issues and life concerns that can impact intimacy. At the heart of hypoactive sexual desire disorder (HSDD) is an imbalance between excitatory (dopamine and norepinephrine) and inhibitory (serotonin) neurotransmitters in key regions of the brain. The difficulty in women is that libido is impacted by psychosocial factors, such as relationship concerns; physical concerns, such as obesity or arthritis; medical conditions; and medications. In research that includes women complaining of decreased libido, 30% may improve with placebo alone. This tells us how important addressing the psychosocial problems can be. The first question to consider is very simple and very powerful, “Do you like your partner?” This sole question can open up lines of communication and help sort out the cause of decreased desire (Box 1). If the patient indicates that her relationship is not currently rewarding or that she does not get along well with her partner, there is no pill that will solve desire concerns. Help the patient see that intervention in the form of counseling from a qualified provider may provide the best treatment for sexual concerns, or at least offer a good starting point. Make sure to follow your first question with the next question, “Does sex hurt?” If a woman has sexual pain, she may avoid sexual encounters. Helping the patient understand that sexual pain is not normal and is treatable may help her open up to you about the other important considerations for diagnosis, including onset, duration, circumstances in which the pain occurs, and associated factors. You may also need to assess her willingness and desire to address the problem of pain. Some women are resistant to discussing their pain due to a history of poor medical encounters

#### BOX 1 Decreased Libido Diagnosis

**Psychological:** Do you like your partner?

If they do not have a good relationship, you have an opportunity to point them to resources in your community to help them. Consider referral to a local marriage and family therapist or sex therapist to intervene.

**Physical:** Does sex hurt?

If a woman is experiencing sexual pain she will also suffer from low libido, as her brain is trying to protect her body from further trauma. Once you discover there is pain, work toward diagnosis or referral to a specialist. Set the expectation that until her pain has been addressed you do not expect her to have an improvement in libido.

**Neurologic:** Are you able to achieve climax?

If a woman is unable to orgasm, she may have lower desire. Acknowledging her lack of climax and the distress it is causing is the first step in helping her decide if she wishes to explore this area further with a specialist.

with physicians, previous trauma, or a foundational religious and/or cultural belief system surrounding sex. As stated previously, treatment for this condition is best guided by a careful history and discussion with the patient. If libido has been a concern for a significant period of time, encourage the patient to see a qualified counselor. Creating a list of resources available in your area is helpful to have on hand. If the patient previously had what she considers a good sex drive and this is a new problem, consider new medications, trauma, or recent events that may have triggered the onset of pain. See the list of medications impacting libido (Box 2). Although this is not exhaustive, if the patient is on more than one medication that affects sex drive, you may need to work with her to adjust medications. If she is premenopausal and not on any medications, treatment for HSDD includes psychosocial intervention, lifestyle adjustment, and medications. Lifestyle adjustments may include changing her schedule so there is time for intimacy, as many patients are too busy to allow for adequate time for arousal and a positive sexual experience. Also keep in mind the positive effect exercise has on sex drive—both directly, by increasing norepinephrine; and indirectly, by improving stamina and self-image. Dietary considerations are also important, as women who are overweight or obese may suffer from low libido due to self-image, fatigue from hyperinsulinemia or diabetes, and gastrointestinal or other issues. Currently, there are two FDA-approved treatments for HSDD: flibanserin (Addyi), which is a daily medication, and bremelanotide (Vyleesi), which is an episodic injectable medication. Both need to be prescribed by physicians experienced with the medication, indications, and potential side effects. Many other medications have been used to improve libido (see Box 2). Another consideration in women being treated for depression is to switch them from an inhibitory medication to one that may have a positive effect on libido. Encouraging patients to have open communication with their partners about what leads to pleasure and what does not is essential when addressing desire and arousal.

#### BOX 2 Treatment of Decreased Libido

##### May inhibit desire or arousal

- SSRIs
- Antipsychotics
- Benzodiazepines
- TCAs
- Lithium
- Phenytoin (Dilantin)
- Trazodone (Desyrel)
- OCP
- Narcotics
- Beta blockers
- Digoxin
- Spironolactone (Aldactone)
- Antihistamines
- Anticholinergics

##### May improve desire or arousal

- Flibanserin (Addyi)
- Bremelanotide (Vyleesi)
- Buspirone (BuSpar)
- Bupropion (Wellbutrin)
- Naltrexone/bupropion (Contrave)
- SNRIs
- Transdermal testosterone
- Topical (vulvar/vaginal) estrogen
- Topical (vulvar) testosterone
- Hormonal therapy in postmenopausal women

OCP, Oral contraceptive pill; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

## Pathophysiology, Diagnosis, Treatment: Sexual Pain

Dyspareunia can have many origins. The layered approach described by Dr. Coady is a systematic way to consider evaluation and also helps us understand the pathophysiology of this often complex problem (Box 3). Consider that the pain can be due to skin concerns or changes, neurologic problems, muscle pain, bowel conditions, bladder pain, medications (such as chemotherapy), and medical problems, such as endometriosis or enlarged uterus. A careful history and exam are the most important diagnostic tools when helping discern the cause for sexual pain.

There are many different ways to evaluate a patient for pain with sex, and specifically, pain with intercourse. When you take a history in a patient complaining of sexual pain it is important to glean from her the duration, inciting factors, alleviating factors, previous treatment, and what she thinks is causing the pain. Understanding if she has primary (never had a sexual encounter without pain) or secondary (new onset, previous pain-free encounters) dyspareunia is also important. Primary sexual pain can be caused by a history of sexual trauma, tight hymenal ring, skin-level concerns such as atrophy, herpes, or lichen sclerosis, pelvic floor muscle pain, or internal pain such as endometriosis, ovarian cysts, or other pelvic organ pathology. Secondary sexual pain can include the same causes but may be easier to treat depending on the sequence of events that led to the patient's onset of pain. When taking a history of the patient's pain, it is important to ask her if the pain is only on penetration or if it occurs through the entire encounter. Pain that only occurs with deeper penetration may more likely be pelvic floor muscle pain or endometriosis, whereas pain that occurs with any touch points you toward vulvar causes such as lichen sclerosis or atrophic changes.

Once you have gathered a careful history, it is important to perform a careful exam. Start with a very careful inspection of the vulva. Note the presence of labia minora—if absent or blunted, this may be consistent with atrophy. Note the clitoral hood—if it is retracted or adhesions are noted, the patient may have lichenification. A bright light and magnification (such as a colposcope) are often helpful in careful visualization. If no abnormalities are noted on careful inspection, look at the introitus. Patients with localized provoked vestibulodynia (LPV) may have an area of erythema at the 6 o'clock position of the introitus, just external to the hymenal ring. Show the patient a cotton swab and tell her you are going to touch areas on the vulva and you want her to tell you if anything hurts. With light pressure (depressing about 1 mm), touch the patient's thigh, slowly working inward to the labia. Touch the clitoris, the area around the urethra, and the area just external to the hymenal ring. Lastly, touch the area around the anus, as the rectal branch of the pudendal nerve could be the cause of the pain. If she has significant pain on palpation with the swab along Hart line, note the location of the pain and consider referral to a specialist who can address LPV. If the exam is normal and her pain does not appear to be external, do a careful exam of the pelvic floor. One way to do this is to insert one finger and gently palpate the muscles of the pelvic floor one at a time. A careful review of the anatomy of this area is helpful. If you are not comfortable evaluating for pelvic floor pain, referral to a sexual pain specialist or pelvic floor physical therapist is appropriate. If the patient does not seem to have pain on palpation of the pelvic floor muscles, performing a

bimanual exam can be helpful; however, great care must be taken to avoid further trauma. I do not often do a bimanual exam on patients with a complaint of sexual pain as their pain is often elicited by the previously described exam. A speculum is rarely useful for these patients and should be avoided if they are complaining of pain with intercourse, as you may cause her more pain and further discourage the patient from seeking medical help.

Your treatment plan for sexual pain must be guided by the differential diagnosis you develop following a careful history and exam. For skin concerns, clobetasol topical is the treatment for lichenification that includes lichen sclerosis and lichen simplex chronicus. If nerve or pelvic floor muscle pain is noted, sending the patient to a qualified physical therapist is a good first step. If this fails, or if the patient desires medication to help with the discomfort while working with a therapist, vaginal diazepam (Valium) can be utilized. The patient uses 10 mg at HS and is encouraged to use this as needed to help with more severe discomfort, as many of the patients who have dyspareunia also have generalized pelvic floor pain that may interfere with sleep or daily living activities. If physical therapy does not provide relief, a sexual medicine specialist may perform dry needling or trigger point injections to help with the pain. If the cause does not seem to be related to either skin or pelvic floor pain, an ultrasound may help to identify ovarian masses or uterine enlargement and the patient may need referral to a gynecologist for surgical intervention. In cases of gastrointestinal dysfunction, such as constipation or diarrhea, consider treatment of this dysfunction as it could lead to improvement in dyspareunia.

### A Note About Atrophy

When considering atrophic or hypoestrogenic changes many clinicians think of a postmenopausal woman. When it comes to sexual pain, however, do not forget that atrophy can be seen in premenopausal women in the setting of cancer treatment, postoophorectomy patients, and patients who have been on combined oral contraceptive pills for a period of time. Each of these patients may require a unique approach to treatment. For instance, if a woman is experiencing atrophy due to treatment of a nonhormonal cancer, such as leukemia, treating her with systemic or local hormonal therapy is likely the most appropriate approach. If she is currently being treated for breast cancer, discussing a treatment plan with her oncologist is important. Keep in mind that vaginal estrogen has a long-established safety record in breast cancer patients due to the low absorption. If you do not have experience in this area, helping your patient connect with a gynecologist or sexual medicine physician who *does* treat cancer survivors is essential. In the meantime, encourage her to use adequate vaginal lubrication and moisturizers. Lubrication that is water based is not often sufficient for a severely atrophic patient and oil-based lubrication, such as coconut oil, olive oil, or a commercially available product meant for sensitive tissues, is much superior. Encourage women to use moisturizers not just for intercourse, but also post-bathing, swimming, or exercising. Be aware that many patients who are breastfeeding or are taking combination oral contraceptives may also experience atrophic changes that cause pain during sexual encounters. For these patients, a small amount of topical vulvar hormones applied to the introitus is often quite effective in relieving symptoms.

### BOX 3 Sexual Pain Pathophysiology

#### Causes of Sexual Pain: The Layered Approach

Surface layer: lichen sclerosis, herpes, atrophy

Nerve layer: localized provoked vestibulodynia, pudendal neuralgia

Myofascial layer: chronic pain or acute, secondary to injury

Organ layer: ovarian cyst, endometriosis

Body-wide systems: gastrointestinal, psychological (history of trauma or abuse)

## INFERTILITY

Method of

Michael P. Diamond, MD; and Jessica Rachel Kanter, MD

### CURRENT DIAGNOSIS

- Infertility is defined as the inability to conceive with regular intercourse after 12 months in couples in which the female partner is younger than 35 or after 6 months in couples in which the female partner is 35 or older.
- The incidence of infertility is increasing.
- Consideration should be given to expedited evaluation, including possible referral to a reproductive endocrinologist in couples in which the female partner is 40 years of age or older.

### CURRENT THERAPY

- Assisted reproductive technologies are being used with increasing frequency and with increasing success rates.

### Epidemiology

Infertility is defined as the failure to conceive after 12 months of regular, unprotected intercourse. In couples where the female partner's age exceeds 35 years, evaluation may begin after just 6 months of infertility, and in those over 40 years, more immediate evaluation may ensue, owing to the time-sensitive nature of the problem. In some circumstances, diagnostic evaluation and therapeutic intervention are warranted at an earlier time. Infertility affects approximately 15% of couples. Many of these patients present to their primary care physician. Timely evaluation and potential referral to an infertility subspecialist are prudent.

### Risk Factors

There are numerous risk factors that contribute to infertility. The most common is age. However, it is necessary to evaluate other potential contributing factors to infertility, as these may help to narrow the differential diagnosis and achieve a more targeted subsequent treatment plan. For example, a history of sexually transmitted infections (STIs), especially chlamydia, and episodes of pelvic inflammatory disease have been associated with tubal factor infertility in women. Metabolic disorders such as obesity and polycystic ovarian syndrome, which may lead to anovulation, are an increasingly more prevalent concern and a major risk factor for infertility. Endocrinopathies such as thyroid disease and diabetes are common modifiable risk factors for infertility. Finally, certain genetic diseases such as fragile X, Turner syndrome, cystic fibrosis, and Klinefelter disease may also lead to inability to conceive or difficulty in conceiving.

### Pathophysiology

The pathophysiology of infertility should be grouped first by male and female factors and then by the component of their respective reproductive tracts. One must not discount the fact that multiple factors may coexist, including etiologies of infertility in both partners of a heterosexual couple. Unexplained infertility has been reported to be accountable for 8% to 28% of infertility in couples; however, in intensively evaluated couples, the rate is likely to be 25%.

### Prevention

Some etiologies of infertility may be preventable. Many cases of tubal factor infertility may be prevented by protecting against the transmission of STIs. Barrier contraception is essential to prevent STIs, particularly in high-risk individuals with an early age of coitarche and/or those with multiple sexual partners. Even with highly efficacious forms of contraception such as intrauterine devices, long-acting injectable progestins, and progestin-containing subdermal implants, providers must counsel their patients that barrier contraception is still of the utmost importance in preventing STI transmission.

There are also various medical therapies, particularly those related to cancer treatment, that may be detrimental to fertility. In these cases, oncofertility consultation prior to treatment will optimize fertility preservation. For men, sperm cryopreservation is a relatively easy, noninvasive method. For women, oocyte or embryo preservation, experimental approaches to medically induce ovarian suppression, ovarian transposition, and experimental ovarian tissue cryopreservation are all helpful tools for women undergoing gonadotoxic chemotherapy or radiation therapy.

Finally, fertility should also be considered when managing tubal ectopic pregnancy in women. Medical therapy, when not contraindicated, is an excellent option in the compliant patient with an ectopic pregnancy. When surgery is necessary, salpingostomy may be considered, when possible, in lieu of salpingectomy, in an attempt to preserve tubal function—particularly in the setting of a damaged or absent contralateral fallopian tube.

### Clinical Manifestations

Infertile patients generally present with failure to conceive after a variable time of home intercourse. The definition of infertility is subdivided into primary and secondary infertility. Primary infertility means the patient has not borne children in the past. Secondary infertility means the patient has successfully procreated in the past.

### Diagnosis

The diagnosis of infertility begins with a thorough history and physical examination. It is important to remember that a history must be obtained from both partners during this evaluation. The male partner assessment begins with a semen analysis. Semen analysis should be performed after 2 to 5 days of abstinence for optimal results. If abnormal parameters are noted, a second semen analysis may be warranted, preferably separated in time by at least 1 month.

Female partner assessment should focus on ovulatory function, ovarian reserve, and structural abnormalities. Initial evaluation should include determination of ovarian reserve by hormonal evaluation of antimüllerian hormone (AMH) or cycle day 2 to 5 follicle-stimulating hormone (FSH). A thyroid-stimulating hormone (TSH) may also be considered, especially if ovulatory dysfunction is suspected, as thyroid dysfunction is common in women. Ovulation may be confirmed with a midluteal progesterone level. Other labs may be ordered if clinically indicated, such as androgens in women with hirsutism or prolactin in the setting of oligomenorrhea with or without galactorrhea. Tubal patency is assessed by sono-hysterosalpingogram or hysterosalpingogram. These imaging tests also allow assessment of the uterine cavity for uterine contour and any abnormalities, including fibroids or polyps. Sonography may also be useful in identifying müllerian anomalies or anomalies of the basic structure of the uterus. Magnetic resonance imaging remains the gold standard for identifying müllerian anomalies; however, 3D ultrasonography has demonstrated promising and more cost-effective results in recent literature. In cases where other pelvic pathologies such as endometriosis and adhesions are suspected, diagnostic laparoscopy

may be considered. Chromotubation during laparoscopy may be performed to assess fallopian tube patency. Finally, in the setting of recurrent pregnancy loss, karyotype analysis may be considered for both partners.

### Differential Diagnosis

When determining a differential diagnosis, both male and female factors must be considered.

#### Male Factors

Male factor infertility is a component of infertility in approximately 40% to 50% of couples. The most common etiologies of male factor infertility are oligospermia and azospermia. The etiologies leading to these diagnoses are broad and varied, and include genetic conditions such as cystic fibrosis (leading to congenital absence of the vas deferens).

#### Female Factors

Female factors for infertility are numerous and most easily subdivided by system.

#### Ovulatory Dysfunction

Inability to produce a viable oocyte each month can be related to several factors. First, anovulation may occur, meaning oocytes are present in the ovaries but none are released on a regular basis. This can be related to hormonal ovarian suppression or metabolic disturbances. Alternatively, an oocyte may not be produced secondary to a paucity of oocytes owing to age, genetic factors, or prior insults to the ovaries, such as radiation therapy. In addition to the aforementioned AMH and day 2 to 5 FSH and serum estradiol to assess ovarian function, ultrasound may be employed to evaluate antral follicle count—another marker of ovarian reserve.

#### Tubal Factor

The fallopian tubes are responsible for transporting the oocyte from the ovaries to the uterine cavity. For this to occur, at least one fallopian tube must be patent. Perhaps the most common etiology of tubal factor infertility is a history of pelvic inflammatory disease, most frequently secondary to *Chlamydia trachomatis*. *C. trachomatis* is particularly problematic in women, as the initial infection may be asymptomatic. Other tubal infertility may arise from prior tubal ligation, other tubal surgery, history of ectopic pregnancy, or scarring of the tubal lumen.

#### Uterine Factor

Irregularities within the uterine cavity may also lead to infertility, generally secondary to poor implantation of the fertilized embryo. Some such etiologies may be present from birth—namely müllerian anomalies. The abnormally shaped uterine cavity in these anomalies reduces the opportunity for normal implantation and embryo growth.

During the course of a woman's life, she may develop benign intrauterine growths, including polyps and leiomyomas that can reduce the opportunity for normal embryo implantation. Finally, prior uterine surgery may damage the endometrium and myometrium, as in Asherman syndrome, or cause uterine cavity scarring, known as *synechiae*.

#### Combined

One must not forget that multiple etiologies in a wide variety of combinations may be at play in female factor infertility.

#### Unexplained

Perhaps the most frustrating of all diagnoses is unexplained infertility. In couples who have had a negative fertility workup, a specific etiology of infertility may never be revealed. There is new, burgeoning research in the area of sperm microRNA that

may identify male factor infertility in men with otherwise normal semen analyses. Although not currently in wide use, such studies may be of great utility in the future.

### Prior Diagnosis

As the field of infertility is becoming understood to an increasingly greater degree, there are prior diagnoses that have fallen out of favor. One such diagnosis is cervical factor insufficiency. It was previously evaluated by the postcoital test, in which a sample of cervical mucus would be taken after intercourse and was evaluated for the presence of motile sperm. This test has fallen out of favor owing to subjectivity, lack of reproducibility, and poor correlation with future fertility.

Also out of favor is the prior diagnosis of luteal phase deficiency (LPD), previously defined as inadequate endogenous progesterone production during the luteal phase of the menstrual cycle. No clinical tests have proven reliable for LPD; nor have any treatments demonstrated any significant improvement in treating infertility.

### Treatment

The mainstay of therapy is first treating underlying disorders such as obesity, thyroid disease, and so forth. Other known causes of infertility that require surgical management may include intrauterine pathology (e.g., polyps, fibroid tumors) or removal of a hydrosalpinx—a distally blocked fallopian tube filled with serous fluid.

With a normal male partner semen analysis, the first step in intervention is generally an oral agent to induce ovulation combined with intrauterine insemination. Options for induction include clomiphene citrate (Clomid) and off-label use of letrozole (Femara), an aromatase inhibitor. If this fails, therapy can proceed to treatment with injectable gonadotropins (i.e., FSH and luteinizing hormone) to stimulate the development of ovarian follicles and ovulation with intrauterine insemination or in vitro fertilization. Various additional procedures may be considered if in vitro fertilization is pursued, including assisted hatching of the embryo with the hope to increase implantation rates; intracytoplasmic sperm injection to increase fertilization rates of the oocytes, particularly in the setting of male factor infertility; and preimplantation genetic testing for aneuploidy to evaluate for embryonic genetic anomalies, particularly in women of advanced maternal age.

### Monitoring

To reduce the risks associated with ovulation induction and ovarian stimulation, monitoring of serum estradiol and follicular development is performed. Monitoring provides the ability to minimize the occurrence of multiple gestation and complications associated with ovarian hyperstimulation syndrome.

<sup>1</sup>Not FDA approved for this indication.

## MENOPAUSE

Method of

Andrew M. Kaunitz, MD; and JoAnn E. Manson, MD, DrPH

### CURRENT DIAGNOSIS

- In women who meet clinical criteria for menopause and present for management of vasomotor symptoms (VMS), checking follicle-stimulating hormone (FSH) and estradiol levels is not necessary. However, if no recent level is available, checking the thyroid-stimulating hormone (TSH) level to rule out thyroid disease is appropriate.
- Occasionally, nonmenopausal conditions can masquerade as menopausal VMS.
- Although genitourinary syndrome of menopause (GSM) can be presumptively diagnosed based on a characteristic history, a pelvic examination can help exclude other vulvovaginal conditions that can present with similar symptoms.
- Although laboratory assessment is not necessary to establish that GSM is present, vaginal pH is typically higher than 5.0.

### CURRENT THERAPY

- Estrogen represents the most effective therapy for VMS and related symptoms.
- Oral and transdermal estrogen have similar efficacy in treating menopausal VMS.
- Estrogen-progestin therapy (EPT) is appropriate when treating menopausal symptoms in women with an intact uterus.
- For healthy women with bothersome symptoms who are younger than 60 years of age and/or within 10 years of menopause onset, the benefits of systemic hormone therapy (HT) are likely to outweigh the risks.
- Randomized trial data clarifies that estrogen-only therapy, including conjugated equine estrogens and estradiol, does not elevate risk of breast cancer.
- Observational studies suggest that in contrast with oral estrogen, transdermal estradiol does not increase risk of venous thromboembolism, although randomized clinical data addressing this issue are not available.
- Observational studies suggest that, in contrast with synthetic progestins (including medroxyprogesterone acetate), use of micronized progesterone does not increase risk of breast cancer, although randomized clinical trial data are not available.
- Conjugated estrogen (CE) 0.45 mg combined with the selective estrogen receptor modulator bazedoxifene 20 mg (Dua-vee) (without concomitant use of a progestational agent) is approved to treat VMS and prevent osteoporosis in women with an intact uterus.
- Low-dose paroxetine mesylate (Brisdelle) 7.5 mg is the only nonhormonal formulation approved to treat VMS. Off-label use of venlafaxine (Effexor) is also effective in treating VMS. However, these agents are less effective than standard-dose HT.
- Arbitrary discontinuation of systemic HT when women turn 65 is not evidence based. Extended use of systemic HT may be appropriate in well-counseled women for treatment of persistent VMS, prevention of bone loss, and prevention/treatment of atrophic genital changes. Women considering extended use of systemic HT should be aware that with a longer duration of EPT, the risk of breast cancer increases. If GSM/atrophic changes represent the only indication for HT, local low-dose vaginal estrogen is appropriate and highly effective.

### Epidemiology

Menopause, the permanent cessation of menstruation caused by loss of ovarian function, occurs at a mean age of 51 to 52 years. With increases in life expectancy, currently more than 50 million women in the United States are 50 years of age or older.

### Risk Factors

Spontaneous menopause represents a natural event. Spontaneous menopause occurs at a younger age in women who smoke or undergo hysterectomy with ovarian conservation. Chemotherapy, radiotherapy, or bilateral oophorectomy can induce menopause.

### Clinical Manifestations and Pathophysiology

Often described by women as hot flashes or night sweats, VMS represent the most bothersome symptoms of menopause and the most common reason women present for care at the time of the menopausal transition. VMS often include a sudden sensation of heat in the face, neck, and chest and persist for several minutes or less. VMS may cause flushing, chills, anxiety, and sleep disruption. VMS are caused by estrogen withdrawal and are associated with pulsatile luteinizing hormone secretion, decreased endorphin concentration in the hypothalamus, and increased release of norepinephrine and serotonin. VMS occur in almost three-fourths of women during the late perimenopausal transition and are more prevalent among the groups listed in [Box 1](#). The median duration of moderate to severe VMS is approximately 10 years.

GSM, also known as *vulvovaginal* or *genital atrophy*, signifies the progressive changes in the vulva, vagina, and urethra resulting from estrogen deficiency. GSM, which characteristically causes vaginal dryness and pain with sex, represents a common condition that adversely affects health, sexuality, and quality of life in menopausal women.

### Diagnosis

Although FSH levels increase and estradiol levels decrease in menopausal women, such testing is not necessary when late perimenopausal or postmenopausal women report characteristic VMS as described previously. Because thyroid disease is common in women and can cause symptoms that mimic VMS, checking the TSH level is appropriate in women seeking treatment for VMS.

Although GSM can be presumptively diagnosed based on a characteristic history, a pelvic examination can help exclude other vulvovaginal conditions that can present with similar symptoms (see the next section). Physical examination findings characteristic of GSM are listed in [Box 2](#). Although laboratory assessment is not necessary to establish that GSM is present, vaginal pH is typically higher than 5.0.

### Differential Diagnosis

Nonmenopausal conditions that can masquerade as menopausal VMS include anxiety disorders, thyroid disease, autoimmune conditions, carcinoid syndromes, diabetic autonomic dysfunction/hypoglycemia, insulinoma/pancreatic tumors, epilepsy, infections, tuberculosis, mast cell disorders, new-onset hypertension, as well as the use of certain selective serotonergic reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors.

Lichen sclerosus, chronic candidiasis, contact dermatitis, and lichen planus represent vulvar/vaginal conditions that might be confused with GSM.

### Therapy

Estrogen represents the most effective therapy for VMS and related symptoms. Higher doses are more effective; oral and transdermal formulations have comparable efficacy. Many estrogen formulations/doses are also approved for the prevention of osteoporosis. Because estrogen-only therapy (ET) in women with an intact uterus increases the risk of endometrial neoplasia, EPT is appropriate when treating VMS in women with a uterus. In the United States, the most commonly used oral estrogens for systemic treatment of VMS are estradiol (E2, Estrace) and

**BOX 1** Risk Factors for Vasomotor Symptoms

African American ethnicity  
 Low income and/or low educational attainment  
 Cigarette smoking  
 Obesity  
 Mood disorders

**BOX 2** Physical Findings Characteristic of Genitourinary Syndrome of Menopause

Loss of mons and labia majora fat pads  
 Loss of labia minora tissue and pigmentation  
 Urethral meatus: erythematous and prominent in size in relation to introitus  
 Introital narrowing (consider use of ultrathin speculum)  
 Vaginal mucosa: smooth (decreased rugation), dry, and friable

conjugated equine estrogens (CEE, Premarin). Standard doses of these estrogens are 1.0 mg and 0.625 mg, respectively; lower and higher doses are available. Weekly and twice-weekly skin patches and other transdermal E2 formulations are available; estradiol patches releasing 0.05 mg and 0.0375 mg daily are considered standard dose; lower- and higher-dose patches are available. A 3-month vaginal systemic E2 ring (Femring) for treatment of VMS is also available; the ring that releases 0.05 mg E2 daily is considered the standard dose.

In the United States, the progestational agents most commonly prescribed to accompany systemic ET in women with an intact uterus are medroxyprogesterone acetate (MPA [Provera], available in 2.5-mg, 5-mg, and 10-mg doses) and micronized progesterone (Prometrium) in 100-mg and 200-mg capsules. Micronized progesterone is formulated with peanut oil. With standard-dose estrogen, an appropriate daily dose of MPA or micronized progesterone used continuously is 2.5 mg and 100 mg, respectively. Because micronized progesterone has a hypnotic effect, it should be taken at bedtime. A variety of oral estrogen-progestin formulations, all of which have demonstrated endometrial safety, are available in different doses and combine CEE with MPA (Prempro); E2 or ethinyl E2 with norethindrone acetate (Activella, Femhrt); or E2 with drospirenone (Angeliq), norgestimate (Prefast), or progesterone (Bijuva). Transdermal estrogen-progestin combination formulations combine E2 with norethindrone acetate (CombiPatch) or levonorgestrel (Climara Pro). The North American Menopause Society has posted tables listing all formulations approved in the United States or Canada for treating menopausal symptoms <http://www.menopause.org/docs/default-source/professional/nams-ht-tables.pdf?sfvrsn=18.pdf>. Although off-label use of testosterone can increase sexual desire in menopausal women, efficacy is achieved only with supraphysiologic doses, which may cause hyperandrogenic adverse effects.

CE 0.45 mg combined with the selective estrogen receptor modulator bazedoxifene 20 mg (Duavee; without the concomitant use of a progestational agent) is approved to treat VMS and prevent osteoporosis in women with an intact uterus and does not increase the incidence of uterine bleeding or endometrial hyperplasia. This novel combination formulation may be useful for women with an intact uterus who choose not to use progestin, including those intolerant of progestin side effects.

Among U.S. women using HT, approximately one-third are using compounded HT; most users are not aware that these formulations are not evaluated or approved by the U.S. Food and Drug Administration (FDA). FDA-approved HT is preferable to compounded HT, unless a specific FDA-approved formulation is not available.

Nonhormonal therapy with paroxetine (Paxil),<sup>1</sup> escitalopram (Lexapro),<sup>1</sup> citalopram (Celexa),<sup>1</sup> venlafaxine (Effexor),<sup>1</sup> desvenlafaxine (Pristiq),<sup>1</sup> gabapentin (Neurontin),<sup>1</sup> and pregabalin (Lyrica)<sup>1</sup> are more effective than placebo but less effective than HT in treating VMS. Low-dose paroxetine mesylate (Brisdelle) 7.5 mg is the only nonhormonal formulation approved to treat VMS. Lowering the ambient temperature, using fans, wearing layered clothing, and avoiding tobacco, alcohol, and caffeine represent commonsense measures for women bothered by VMS. In a clinical trial, clinical hypnosis was found more effective than placebo in addressing VMS. Although over-the-counter herbal formulations, including soy and black cohosh, have been widely used to treat VMS, these have not been found to be more effective than placebo.

When clinicians identify GSM, they should advise women that (unlike VMS) without proactive management, GSM progresses. If severe symptoms are not present, recommending use of over-the-counter lubricants (or substances such as coconut oil or olive oil) for sexual activity as well as regular use of vaginal moisturizers is helpful. Such women should also be advised that regular sexual activity that includes penetration may help improve symptoms and prevent progression. If other indications for systemic HT such as treatment of VMS or prevention of osteoporosis are present, systemic HT is effective in treating GSM. However, if GSM represents the only indication for HT, local low-dose vaginal estrogen is appropriate and highly effective. Vaginal estrogen also reduces the risk of recurrent urinary tract infections and overactive bladder symptoms in menopausal women. In the United States, two low-dose creams, estradiol (Estrace and generics) and CEE (Premarin), are available. Although package labeling provides instructions for patients regarding dose and schedule, in practice, most women apply a fraction of an applicator vaginally (and often also benefit from digital application to vestibular tissues) 1 to 3 nights weekly. Some women find the use of vaginal estrogen creams to be messy. Vaginal tablets (Vagifem and generics) equivalent to 10 mcg E2 are inserted vaginally with an applicator nightly for 2 weeks, and then twice weekly for maintenance. Vaginal 4 mcg or 10 mcg E2 inserts (Imvexxy) are placed digitally nightly for 2 weeks, and then twice weekly for maintenance. The 3-month low-dose E2 vaginal ring (Estring) releases 7.5 mcg E2 daily. An oral systemic selective estrogen receptor modulator, ospemifene (Osphena), improves symptoms of GSM; some users report VMS. In addition, vaginal dehydroepiandrosterone (DHEA, prasterone [Intrarosa]) is approved for the treatment of GSM.

**Monitoring**

For most women using systemic HT, monitoring of serum estrogen levels is not indicated. However, when women continue to report bothersome symptoms despite escalating HT doses, monitoring can be useful. In contrast with fluctuating serum estrogen levels in women using oral estrogen, transdermal ET results in relatively steady-state levels; serum E2 levels of 40 to 100 pg/mL represent a reasonable target range for menopausal women 50 years of age or older. Serum E2 levels as high as 120 pg/mL may be appropriate for younger menopausal women.

**Side Effects of Systemic Hormone Therapy**

Breast tenderness, bloating, and uterine bleeding represent common side effects of ET. Although lowering the ET dose may reduce side effects, this may cause VMS to increase. Progestins cause dysphoria in some women. Prescribing a different progestin, prescribing progestins sequentially, off-label use of a progestin intrauterine device (Skyla, Kyleena, Mirena, Liletta), or use of the CEE/bazedoxifene combination formulation (Duavee) or antidepressant therapy may be helpful in this setting.

<sup>1</sup>Not FDA approved for this indication.

## Safety of Hormone Therapy

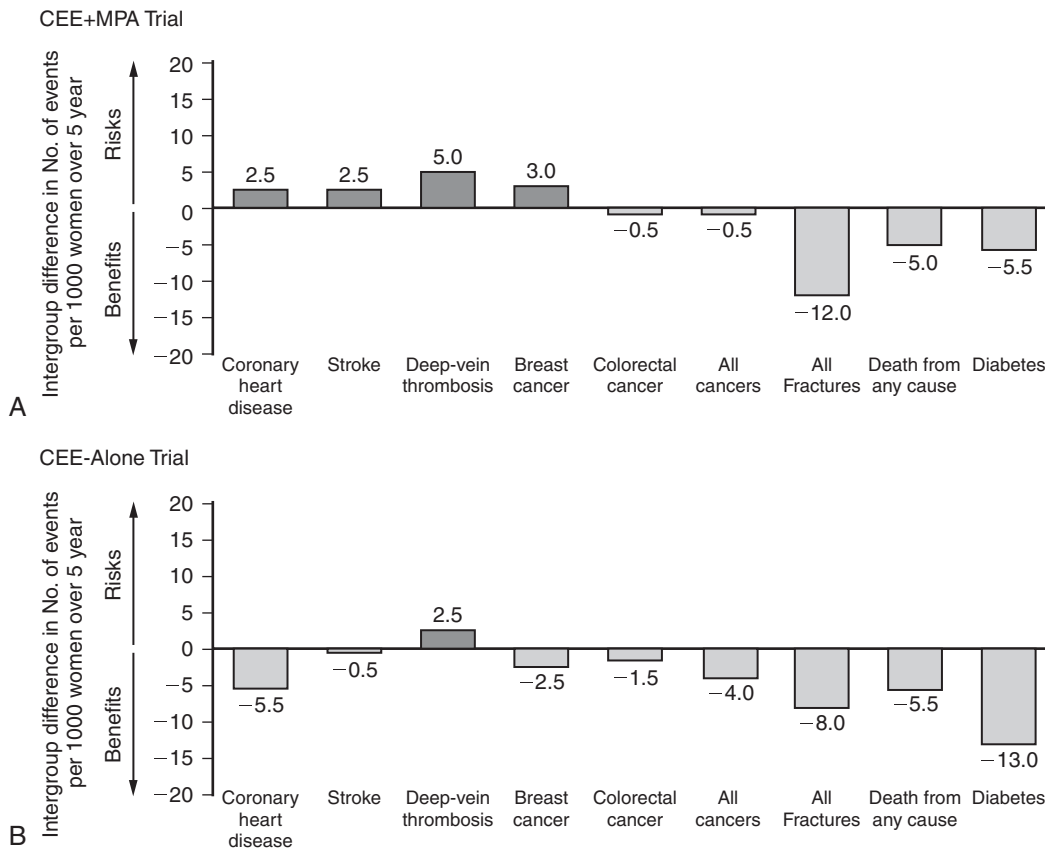

Findings from the Women's Health Initiative (WHI) study of oral CEE and MPA as well as CEE alone, and other recent randomized clinical trials have helped clarify the benefits and risks of combination EPT and estrogen-alone therapy. A 2013 WHI report detailed findings from the two HT trials with a median 13 years of cumulative follow-up. Since initial findings of the WHI were first published in 2002, use of systemic HT has dramatically decreased as a result of misinterpretation of WHI findings, which has generated anxiety and confusion among clinicians and women. Importantly, absolute risks of adverse events related to hormone therapy (HT) were much lower for younger women (50 to 59 years of age) than for older women (Figure 1). Overall, for healthy women with bothersome VMS younger than 60 years of age and/or within 10 years of menopause onset, the benefits of HT for women outweigh the risks.

With respect to coronary heart disease (CHD), the impact of HT varies by age of users. Among women who initiate HT before 60 years of age and/or within 10 years of menopause, HT does not increase (and may reduce) risk. In contrast, among women older than 60 years of age and/or more than 10 years following menopause onset, initiating HT appears to increase CHD risk.

With respect to stroke, the WHI found that CEE alone or with MPA increased risk; however, for women younger than 60 years of age, the absolute increase in risk was small (see Figure 1).

With respect to venous thromboembolism (VTE), including pulmonary embolism, oral estrogen with or without progesterin increases risk, particularly within 2 years of HT initiation. Absolute risks of VTE are higher for women initiating HT more

than 10 years following menopause onset. The majority of observational studies have found that in contrast with oral HT, HT with transdermal (e.g., skin patch) estrogen elevates VTE risk less (if at all). Because oral estrogen and body mass index represent independent risk factors for VTE, transdermal estrogen is preferable for most women at elevated baseline VTE risk, including obese women. Personal and familial risk of cardiovascular disease, stroke, and VTE should be considered when initiating HT. Low-dose vaginal estrogen has not been found to elevate the risk of CHD, stroke, VTE, breast cancer, or endometrial cancer. With respect to breast cancer risk, WHI results diverged, with increased risk in the CEE-plus-MPA group and borderline reduced risk in the CEE-alone group. Data from other randomized controlled trials also indicate that neither CEE-alone nor estradiol-alone elevates breast cancer risk. With 13 years of follow-up, a modest elevation of risk (hazard ratio [HR] 1.28) persisted in the CEE-plus-MPA group in all participant age strata. To put the elevated risk of breast cancer observed among women randomized to CEE plus MPA into perspective, the attributable risk with combination HT is less than one additional case of breast cancer diagnosed per 1000 users of combination HT annually. Another way to put this elevated HR into perspective is to recognize that the HR of 1.28 is slightly higher than that seen with one daily glass of wine, and less than that noted with two daily glasses. With long-term follow-up of WHI participants randomized to CEE alone, a significantly reduced risk of breast cancer (HR = 0.79) emerged over this period. During a cumulative 18-year follow-up of participants in the WHI hormone therapy trials, all-cause mortality rates did not differ appreciably between the intervention and control groups in the overall cohort. The HR for all-cause mortality

**Figure 1** Benefits and risks of the two hormone therapy formulations evaluated in the Women's Health Initiative. Results are shown for the two formulations, conjugated equine estrogens (CEEs) alone (B) or in combination with medroxyprogesterone acetate (A; MPA), for women 50 to 59 years of age. Risks and benefits are expressed as the difference in the number of events (number in the hormone therapy group minus the number in the placebo group) per 1000 women over 5 years. Data from Manson JE, Chlebowski RT, Stefanick ML, et al.: Menopausal hormone therapy and health outcomes during the intervention and extended poststopping phases of the Women's Health Initiative randomized trials. *JAMA* 310[13]:1353-1368, 2013.

among women assigned HT compared with those assigned placebo was 0.99 (95% confidence interval [CI], 0.94 to 1.03) in the overall pooled cohort; HRs were 1.02 (95% CI, 0.96 to 1.08) with CEE plus MPA and 0.94 (95% CI, 0.88 to 1.01) with CEE alone. In a 2019 report, women with prior bilateral oophorectomy and randomized to estrogen-alone in their 50s, compared with those randomized to placebo, were found to have a statistically significant 32% reduction in all-cause mortality during long-term follow up. With more than 20 years of follow-up of WHI participants in the two randomized trials, prior randomized use of CEE alone, compared with placebo, among women who had a previous hysterectomy, was associated with a significantly lower breast cancer incidence and lower breast cancer mortality. In contrast, prior randomized use of CEE plus MPA, compared with placebo, among women who had an intact uterus was associated with a significantly higher breast cancer incidence but no significant difference in breast cancer mortality. Although randomized clinical trial data are not available, observational studies suggest that in contrast with synthetic progestins (including medroxyprogesterone acetate), use of micronized progesterone does not increase risk of breast cancer.

Although trials up to 2 years in duration found that CEE plus bazedoxifene did not increase the risk of breast cancer, long-term trials are needed. In women with *BRCA1* or *BRCA2* mutations, limited observational data suggest that use of HT does not increase breast cancer risk and that safety concerns regarding HT treatment for VMS should not cause mutation carriers to defer risk-reducing salpingo-oophorectomy.

Low-dose vaginal ET may be used as long as needed, including indefinitely; routine use of concomitant progestin therapy for endometrial protection is not recommended. In the absence of reported spotting or bleeding, routine endometrial surveillance during the use of vaginal ET is not recommended. However, clinicians should recognize that endometrial safety data for currently marketed formulations are based on 1-year trials, with no trials assessing the safety of longer-term administration available.

Current package labeling for low-dose vaginal estrogen, as for all systemic HT formulations, includes a boxed warning that refers to endometrial cancer, myocardial infarction, stroke, invasive breast cancer, pulmonary emboli, and dementia. This warning reflects safety concerns associated with findings from clinical trials of systemic HT and does not reflect current evidence regarding local low-dose vaginal estrogen.

A personal history of breast cancer is listed as a contraindication to use of all systemic and local low-dose vaginal HT (other contraindications to the use of HT are listed on the package labeling). However, one study found that use of the low-dose estrogen vaginal ring does not cause persistently elevated serum estradiol levels in breast cancer survivors using aromatase inhibitors; some oncologists prescribe this ring, as well as other low-dose vaginal estrogen formulations, off-label to treat symptomatic atrophy in breast cancer survivors (including those using aromatase inhibitors), periodically checking serum estradiol levels. Nonetheless, many oncologists caution against the use of vaginal HT in breast cancer survivors. In package labeling for vaginal DHEA (Intrarosa), a personal history of breast cancer is not listed as a contraindication, although current or past history of breast cancer is listed in the Warning and Precautions section.

### Early/Induced Menopause

Whether spontaneous or induced by surgery, radiation, or chemotherapy, early menopause is associated not only with an adverse effect on quality of life, but also with cardiovascular, neurologic, and skeletal morbidity and mortality. Clinicians caring for women with early surgical menopause should recognize that in addition to effectively treating menopausal symptoms, HT may

mitigate the potential long-term adverse effects of early estrogen deprivation on bone mineral density, cognitive health, and cardiovascular health. Accordingly, unless a contraindication is present, use of HT is appropriate for women with early menopause at least up to the normal age of spontaneous menopause (51 to 52 years of age).

### Extended Use/Discontinuation of Systemic Hormone Therapy

Arbitrary discontinuation of systemic HT when women turn 65 is not evidence based. Although controversial, extended use of systemic HT may be appropriate for the treatment of persistent VMS, prevention of bone loss, and prevention/treatment of GSM in selected, well-counseled women. Extended use of systemic HT should not be confused with the initiation of systemic HT by women older than 60 years of age or more than 10 years following menopause onset—a practice that is known to be associated with an elevated risk of CHD (see the “Safety of Hormone Therapy” section earlier in this chapter). Women considering extended use of systemic HT should be aware that with longer duration of EPT using synthetic progestins, the risk of breast cancer increases. Because older age is an independent risk factor for VTE, the use of transdermal estrogen formulations should be considered in this setting.

When women discontinue systemic HT, a loss of bone mass and progression of GSM/atrophic genital changes occur. The likelihood of recurrent VMS in this setting appears similar with abrupt and gradual (dose-tapering) discontinuation of HT.

### Financial Disclosure

Dr. Kaunitz's department receives research funding from Bayer and Mithra. Dr. Manson does not report any potential conflicts of interest.

### CURRENT DIAGNOSIS

- The US Preventive Services Task Force (USPSTF), the American College of Obstetricians and Gynecologists (ACOG), and the Society of Gynecologic Oncologists (SGO) recommend against the routine screening of low-risk asymptomatic women with transvaginal ultrasonography or serum tumor marker testing.
- Women at high risk (presenting with an identified *BRCA* gene mutation or a family history of cancer suggestive of a hereditary cancer syndrome) should be referred for formal genetic counseling and testing. Current National Comprehensive Cancer Network guidelines recommend screening this population with transvaginal ultrasonography every 6 months with serum CA 125 levels.
- Patients with persistent and progressive abdominal symptoms should be evaluated for ovarian cancer. A pelvic exam and imaging studies (transvaginal ultrasonography) may be helpful in identifying a pelvic mass. Findings such as an elevated CA 125 (in a postmenopausal woman), a nodular or fixed pelvic mass, ascites, or evidence of abdominal or distant metastasis warrant referral or consultation with a gynecologic oncologist.

### CURRENT THERAPY

- Asymptomatic women at high risk for ovarian cancer due to a hereditary cancer syndrome should be referred for consideration of a prophylactic bilateral salpingo-oophorectomy (BSO). The timing of this procedure may depend on the cancer syndrome and the patient's reproductive wishes. Referral to a gynecologic oncologist for this discussion may be appropriate.
- Ovarian cancer is treated with a combination of surgical debulking and chemotherapy. The sequence of treatment depends on the clinical status of the patient and whether or not the disease can be resected. Conventional chemotherapy remains the backbone of adjuvant treatment; myelosuppression, fatigue, and neuropathy are some of the most common side effects during treatment.

### Epidemiology

Ovarian cancer is the second most common type of female reproductive cancer, but the leading cause of death from gynecologic cancer. There are approximately 22,000 new cases of ovarian cancer per year in the United States, with almost 14,000 deaths yearly. There are several histologic subtypes of ovarian cancer, including epithelial (arising from the surface epithelium of the ovary), sex cord-stromal (arising from the cells that support and surround the oocytes), and germ cell tumors (derived from primordial oocytes). In women under 20 years of age, germ cell tumors are the most common, while epithelial ovarian cancer occurs most commonly in women over 50 years of age. The stage at diagnosis and prognosis vary significantly based on histology. Epithelial tumors account for the vast majority of cases and deaths from ovarian cancer.

Epithelial ovarian cancer has a low prevalence of approximately 1 case per 2500 women per year, with an approximate 1.3% lifetime risk for developing ovarian cancer. Average age at the time of diagnosis is approximately 63 years. Because of a lack of accurate screening tests and vague presenting symptoms,

approximately 75% of patients are diagnosed with advanced-stage disease, with an average 5-year survival of 20% to 30%. Caucasian women have the highest incidence rate of ovarian cancer.

The remaining subtypes of ovarian cancer are rare but more likely to be benign. In contrast to epithelial ovarian cancer, most patients with malignant sex cord-stromal neoplasms are diagnosed at an earlier stage and age. Incidence is as low as 0.2 per 100,000 women. Germ cell tumors occur predominantly in young women between 10 and 30 years of age. These neoplasms are primarily limited to one ovary but tend to grow rapidly compared to epithelial or sex cord-stromal tumors. Young women of Asian/Pacific Islander and Hispanic descent are more likely to develop germ cell tumors than Caucasians.

### Risk Factors

Significant risk factors for epithelial ovarian cancer are age, early menarche, late menopause, hereditary cancer syndromes, nulliparity, endometriosis, and asbestos. Age and each additional year of ovulation (early menarche/late menopause, nulliparity) are hypothesized to increase risk due to trauma to the ovarian epithelium, which can lead to malignant transformation. Other factors are controversial and include menopausal hormone therapy, obesity, polycystic ovary syndrome, intrauterine devices, talc, cigarette smoking, diet, or infertility and infertility treatments. Systemic reviews of these factors do not currently show clear associations with an increased risk of ovarian cancer.

Approximately 15% to 20% of ovarian cancer cases may be due to hereditary cancer syndromes. More than half of women with an inherited ovarian cancer will have a deleterious mutation in *BRCA1/2* or have Lynch syndrome (mutations in *MLH1*, *MSH2*, *MSH6*, *PMS2*). Other rare hereditary syndromes such as Li-Fraumeni (*TP53*), Cowden (*PTEN*), or Peutz-Jeghers (*STK11*) syndromes can also increase the risk for ovarian cancer. The lifetime risk of ovarian cancer can vary significantly by mutation, with an estimated 40% risk for *BRCA1*, 15% risk with *BRCA2*, and 11% to 24% risk with Lynch syndrome (depending on genotype). As medical genetic counseling and testing rates increase, additional genes (*BRIP1*, *RAD51C*, *RAD51D*, *PALPB2*) continue to be identified that may increase the risk for ovarian cancer.

*BRCA1/2* mutations are inherited in an autosomal dominant pattern and markedly increase susceptibility to breast and ovarian cancer, with some increased risk for tumors in prostate, male breast, and pancreas. Certain ethnic groups such as Ashkenazi Jewish (2.5%), Icelandic (0.6%), and French Canadian have increased rates of *BRCA* mutations, although *BRCA* mutations have also been identified in Hispanic and African American populations as well. The risk for ovarian cancer under 40 years is low; however, women with *BRCA* mutations tend to have a younger average age at the time of diagnosis (age 50 for *BRCA1*; age 60 for *BRCA2*). Therefore, discussion of risk-reducing BSO in these women is recommended (see Prevention, later) to reduce ovarian as well as breast cancer risk.

Lynch syndrome is also inherited in an autosomal dominant fashion and is similarly associated with the development of multiple cancer types—primarily colon and endometrial cancer. Ovarian cancer is less common than endometrial cancer in these women, but surveillance for gynecologic malignancies is recommended, with risk-reducing surgery indicated at the completion of childbearing and/or by a certain age (see Prevention, later).

### Pathophysiology

Approximately 95% of malignant ovarian cancers are epithelial ovarian cancers. The most common subtype of epithelial ovarian cancers is high-grade serous carcinoma, which comprises approximately 70% of cases. The remaining 30% are considered rare and include histologies, including low-grade carcinoma, mucinous carcinoma, clear cell carcinoma, and endometrioid carcinoma. High-grade serous carcinomas are

more likely to present at an advanced stage (III or IV, with intraabdominal spread), whereas the rare subtypes are more likely to present in early stages (stage I or II, limited to the pelvis).

High-grade serous ovarian cancer, fallopian tubal carcinoma, and primary peritoneal carcinoma are considered a single clinical entity due to shared clinical behavior and treatment. Embryologically, the coelomic epithelium differentiates into a variety of cell types, including those found in the fallopian tube, uterus, cervix, and ovarian stroma. Historically, the ovary was the presumed source, as most patients would present with large ovarian masses at the time of diagnosis. Current evidence suggests that there may be more than one mechanism for carcinogenesis, including malignant transformation of the ovarian surface epithelium, tubal neoplasia that leads to metastasis to the ovary, or malignant transformation from endometriosis or endosalpingiosis. These carcinomas generally demonstrate genetic instability, grow and metastasize rapidly, but are more chemosensitive. Even though most high-grade serous ovarian cancer patients are diagnosed at an advanced stage, the majority will respond to chemotherapy and enter remission. Unfortunately, many of these patients will then recur and eventually succumb to their disease.

Low-grade serous tumors account for less than 5% of all cases of ovarian carcinoma and are typically diagnosed at advanced stages as well. However, they share characteristics with borderline ovarian neoplasms (tumors of low malignant potential). Borderline tumors are intermediate lesions between benign cysts and malignant tumors, with characteristics of atypical proliferation and can recur, but are noninvasive. Low-grade tumors may arise from a prior borderline tumor, are invasive, but are relatively indolent. Once diagnosed, primary surgery is the recommended approach, as low-grade serous ovarian cancers are rather chemoresistant.

Clear cell and endometrioid carcinoma differ from serous tumors in that they may arise from foci of preexisting endometriosis. Mucinous carcinomas of the ovary may arise from a mucinous borderline tumor. These subtypes are generally diagnosed at earlier stages but generally behave more aggressively if metastatic. At advanced stages, there is worse overall survival when compared with high-grade serous carcinoma; this is generally thought to be due to resistance to chemotherapy.

Sex cord-stromal neoplasms include granulosa cell and Sertoli-Leydig cell neoplasms. Compared to epithelial neoplasms, they are more likely to produce sex steroid hormones, present with early-stage disease, and rarely metastasize to the lymph nodes. Prognosis due to early-stage disease is generally favorable.

Germ cell tumors include a variety of benign and malignant neoplasms. The most common germ cell tumor is a mature cystic teratoma (dermoid), which is benign. Dysgerminomas are the most common malignant ovarian germ cell tumor, but other malignant subtypes include yolk sac tumors, immature teratomas, and embryonal carcinomas. These subtypes are often chemosensitive, with an excellent prognosis if diagnosed early.

### Prevention

No routine screening for ovarian cancer in the general population is recommended. Due to the low prevalence of ovarian cancer, the sensitivity, specificity, positive predictive value, and negative predictive value of transvaginal ultrasonography and serum tumor markers (CA125) have been unreliable and does not reduce ovarian cancer mortality. Due to the high false-positive rate, this can lead to moderate to substantial harm from unnecessary surgical interventions in women who do not have cancer (US Preventive Services Task Force [USPSTF] recommendations). This was recently evaluated by the large, randomized Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, which found that annual screening of postmenopausal women with both CA 125 and TVUS compared with usual care did not reduce mortality in the general population. The

incidence of ovarian cancer was not different for women who were screened, and the majority of women were still diagnosed with advanced-stage disease.

Factors that may decrease the risk of epithelial ovarian cancer include BSO, tubal ligation/salpingectomy, hysterectomy, oral contraceptive use, breastfeeding, and parity. BSO is the most effective risk-reducing strategy; however, women may still develop peritoneal carcinoma at a rate of approximately 1%. Due to the role of tubal neoplasia in epithelial ovarian cancer, tubal ligation (regardless of the technique used) has been associated in large epidemiologic studies with an approximate 20% decrease in risk of ovarian cancer. Studies on the effect of opportunistic salpingectomy (removal of fallopian tubes in average-risk women undergoing pelvic surgery for another indication) without oophorectomy are currently ongoing. A meta-analysis of hysterectomy without BSO similarly showed a 20% reduction in the risk of ovarian cancer. Prolonged oral contraceptive use has also been shown to reduce the risk of ovarian cancer, with a meta-analysis showing more than 50% reduction in risk among average-risk women with greater than 10 years of use. Due to the rarity of sex cord-stromal and germ cell tumors, protective factors are less clear.

Women with a significant family history for breast (notably male breast cancer), uterine, ovarian, or colon cancer should be referred for genetic counseling and possible genetic testing. Expert opinion suggests screening for women at high risk for a hereditary ovarian cancer with transvaginal ultrasound and CA125 every 6 months—starting at age 30 for BRCA patients, or 5 to 10 years before the earliest age of first diagnosis of ovarian cancer in the family. Screening for Lynch patients may begin at age 30 to 35 or 5 to 10 years before the earliest age of first diagnosis of any Lynch-related cancer in the family.

In women with a known BRCA mutation, risk-reducing BSO is recommended at completion of childbearing, between 35 and 40 years in women with BRCA1, or 40 to 45 years in women with BRCA2. BSO has been shown to decrease ovarian cancer risk as well as mortality in these patients; however, there remains a baseline 1% risk for developing primary peritoneal cancer. Hysterectomy is not routinely recommended as part of the risk-reducing procedure. While general gynecologists may be able to perform this procedure, referral to a gynecologic oncologist, if available, is recommended, as there are specific protocols for pathologic review, as well as for the management of abnormal findings. In women who have not completed childbearing, oral contraceptive use has been shown to have potentially up to a 5% decrease in ovarian cancer risk per year of use. There is some theoretical concern that hormonal contraception may increase the risk of breast cancer in these patients; however, in the large meta-analysis available, there is no evidence supporting increased risk in current users or in the first 10 years after cessation of use. Use of other contraceptives, such as the patch or vaginal ring, have not yet been studied in this context.

ACOG, SGO, and the American College of Gastroenterology recommend risk-reducing total hysterectomy with BSO for women with Lynch syndrome after completion of childbearing or by age 40 to 45. The remaining risk for peritoneal cancer of 1% following BSO is extrapolated from studies in women with BRCA mutations.

### Clinical Manifestations

Patients with ovarian cancer may present with a wide variety of symptoms (Box 1). Most commonly, women will present in the outpatient setting with vague symptoms such as pelvic or abdominal pain, or gastrointestinal symptoms such as abdominal enlargement (from ascites or from mass effect), bloating, early satiety, or changes in bowel habits. Occasionally, incidental findings of a pelvic mass or signs of more advanced disease (peritoneal spread, lymphadenopathy) may be identified at the time of imaging performed for other indications. Acute presentations are typically due to widely metastatic disease,

**BOX 1** Presenting Symptoms

Nausea  
 Abdominal fullness or early satiety  
 Pelvic/back pain  
 Abdominal mass or umbilical mass (Sister Mary Joseph nodule)  
 Bowel dysfunction (diarrhea, constipation)  
 Urinary dysfunction (urinary frequency, new incontinence, or obstruction due to mass effect)  
 Bowel obstruction  
 Shortness of breath (pleural effusions)

**BOX 2** Indications for Referral

CA125 >200 in a premenopausal woman  
 CA125 >35 in a postmenopausal woman  
 Nodular or fixed pelvic mass on exam  
 Ascites seen on imaging  
 Evidence of abdominal or distant metastasis on imaging

**BOX 3** Differential Diagnosis of an Adnexal Mass

Functional cyst  
 Endometrioma  
 Tuboovarian abscess  
 Benign neoplasms (mature teratomas, cystadenomas)  
 Hydrosalpinx  
 Pedunculated leiomyoma  
 Malignant neoplasms (epithelial, germ cell, sex cord-stromal tumors)  
 Diverticular abscess  
 Appendiceal abscess  
 Metastatic cancer (breast, gastrointestinal)  
 Colorectal malignancy  
 Retroperitoneal sarcoma

causing conditions such as bowel obstruction or pleural effusions that may require prompt intervention. Postmenopausal bleeding may be a presenting symptom but is more likely to be associated with uterine pathology. Of note, young patients with signs of precocious puberty, abnormal vaginal bleeding, or hirsutism (likely due to abnormal hormone production) should be evaluated for possible sex cord-stromal neoplasms. Rarely, patients may present with paraneoplastic syndromes with neurologic findings, hemolytic anemia, or nephrotic syndromes.

**Diagnosis**

Patients with persistent and progressive abdominal symptoms should be evaluated for ovarian cancer. A pelvic exam and imaging studies (transvaginal ultrasonography) may be helpful in identifying a pelvic mass. Composition of the mass (mixed cystic and solid), as well as the presence of thick septations, mural nodules, or papillary excrescences on imaging, would increase suspicion for malignancy. Other diagnostic findings (Box 2), such as an elevated CA125 (in a postmenopausal woman), a nodular or fixed pelvic mass on exam, or evidence of ascites, abdominal, or distant metastasis on imaging warrants referral or consultation with a physician trained to stage and debulk ovarian cancer, such as a gynecologic oncologist. Aspiration or biopsy of a cystic pelvic mass is not generally recommended. Needle biopsy of a solid metastatic lesion or paracentesis for cytology may be considered for diagnosis.

**Differential Diagnosis**

Due to the varied and nonspecific symptoms on presentation, the differential diagnosis is broad. If an adnexal mass is identified, different gynecologic as well as gastrointestinal or urologic causes should be considered. These may include benign or malignant conditions (Box 3).

**Therapy**

Historically, ovarian cancers have been treated, regardless of histology, with a combination of chemotherapy and surgery. Referral to a gynecologic oncologist for management is recommended. The backbone of chemotherapy is a platinum agent in combination with a taxane. Newer data suggest benefit for potential combinations with other agents, such as the anti-angiogenic agent bevacizumab or poly(ADP-ribose) polymerase

(PARP) inhibitors. Immunotherapy has had limited efficacy in ovarian cancer at this time. All patients with a diagnosed ovarian cancer should also be referred for genetic counseling and for genetic testing.

**Monitoring**

During chemotherapy, myelosuppression, fatigue, and neuropathy (from a combination of a taxane and platinum agent) are some of the most common side effects. Management of these symptoms will be in coordination with the treating oncologist or potentially with palliative care. Neuropathy, difficulties with memory and concentration (“chemo brain”), and fatigue may improve in the first year after completion of therapy, but some symptoms may persist long term, with effects on quality of life. The etiology of cognitive dysfunction and fatigue is not well understood, but these patients may respond to cognitive behavioral therapy and exercise.

Current SGO recommendations for post-treatment surveillance include a thorough evaluation of symptoms and physical examination. For years 0 to 2 after completion of treatment, surveillance visits are scheduled every 3 to 4 months. For years 2 to 3, visits are every 4 to 6 months; and for years 3 to 5, they are every 6 months. After 5 years, yearly visits with a gynecologic oncologist or general gynecologist are appropriate. No Pap tests or cytology studies are indicated during this time, and routine CA125 levels upon each visit are optional. No routine radiographic imaging (chest XR, PET or CT scans, MRI, or ultrasounds) is recommended during surveillance, due to insufficient data to support this use. If recurrence is suspected due to symptoms, CT scans or CA125 may be useful prior to repeat consultation with a gynecologic oncologist.

## PELVIC INFLAMMATORY DISEASE

Method of  
Amy Curry, MD

### CURRENT DIAGNOSIS

- Pelvic inflammatory disease is a clinical diagnosis based on suspicious clinical findings in a woman who is at risk.
- Patients may be asymptomatic. Symptoms may range from nonspecific complaints including lower abdominal pain, vaginal discharge, dyspareunia, and irregular uterine bleeding to high fever, vomiting, and lower abdominal tenderness with rebound tenderness.
- Physical examination findings may include vaginal and endocervical discharge as well as cervical motion, uterine and adnexal tenderness, and adnexal fullness.
- Cultures should be performed for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, the two most commonly implicated organisms, though a variety of infectious agents may be causative.

### CURRENT THERAPY

Empiric treatment for pelvic inflammatory disease (PID) should be initiated in any woman at risk for sexually transmitted infections if:

- Pelvic or lower abdominal pain is present
- Cervical motion tenderness *OR* uterine tenderness *OR* adnexal tenderness is found on pelvic examination
- No other cause for the pain can be identified

Recommended inpatient treatment for PID:

- Ceftriaxone (Rocephin) 1 g IV every 24 hours *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO/IV every 12 hours *PLUS* metronidazole (Flagyl) 500 mg PO/IV every 12 hours.  
*OR*
- Cefotetan (Cefotan) 2 g IV every 12 hours *OR* ceftiofexin (Mefoxin) 2 g IV every 6 hours *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO/IV every 12 hours.

Alternative inpatient treatment for PID:

- Ampicillin/sulbactam (Unasyn) 3 g IV every 6 hours *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO/IV every 12 hours.  
*OR*
- Clindamycin (Cleocin) 900 mg IV every 8 hours *PLUS* gentamicin (Garamycin)<sup>1</sup> 2 mg/kg of body weight loading dose followed by 1.5 mg/kg of body weight IV/IM every 8 hours. A single daily dose of 3 to 5 mg/kg of body weight IV/IM can also be used.

Outpatient treatment for PID:

- Ceftriaxone (Rocephin) 500 mg (1 g if weight  $\geq 150$  kg) IM single dose *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO every 12 hours for 14 days *WITH* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.  
*OR*
- Cefoxitin (Mefoxin) 2 g IM and probenecid (Benemid)<sup>1</sup> 1 g PO both given concurrently as a single dose *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO every 12 hours for 14 days *WITH* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.  
*OR*
- Other parenteral third-generation cephalosporins: either ceftizoxime (Cefizox)<sup>2</sup> 1 g IM single dose *OR* cefotaxime (Claforan) 1 g IM single dose *PLUS* doxycycline (Vibramycin)<sup>1</sup> 100 mg PO every 12 hours for 14 days *WITH* metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days.
- Alternative treatment options are available for those who have penicillin or cephalosporin allergies.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

Pelvic inflammatory disease (PID) is a polymicrobial infection of any or all of the upper genital tract organs in women. It is initiated by a community-acquired sexually transmitted agent and can involve the uterus, fallopian tubes, ovaries, and adjacent pelvic structures.

### Epidemiology

In the United States, the diagnosis of PID accounted for 90,000 initial visits to physician offices between 2007 and 2016, and 4.4% of women (2.5 million) 18 to 44 years of age reported a history of PID based on 2013 to 2014 survey data.

### Risk Factors

The single greatest risk factor for PID is a history of multiple sex partners. Other risk factors include 15 to 25 years of age, a male partner with symptoms of a sexually transmitted infection (STI) such as dysuria or urethral discharge, history of previous STI or PID, inconsistent use of condoms, African American ethnicity, and use of vaginal douching. Any phenomenon that disrupts the mucus barrier of the endocervical canal can also potentially facilitate PID, such as menses, bacterial vaginosis, or intrauterine instrumentation. Accordingly, the risk of an intrauterine device (IUD) causing PID usually occurs during the first 3 weeks following insertion and rarely thereafter.

### Pathophysiology

PID occurs when bacteria from the vagina ascend into the normally sterile environment of the upper genital tract. This often occurs in the setting of a *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection, although this is occurring less frequently. Ascending bacteria can include anaerobes, especially those implicated in bacterial vaginosis, group A and B *Streptococcus*, *Escherichia coli*, *Klebsiella*, *Proteus mirabilis*, *Haemophilus influenzae*, *Peptococcus*, genital *Mycoplasma*, *Actinomycosis*, and cytomegalovirus. Methicillin-resistant *Staphylococcus aureus* has been reported to cause PID, but rarely. Once present, this polymicrobial infection can remain asymptomatic or cause endometritis, salpingitis, oophoritis, peritonitis, perihepatitis, or tubo-ovarian abscesses.

### Clinical Presentation

PID may be asymptomatic. It may have an indolent presentation of low-grade fever, weight loss, and nonspecific abdominal pain. A more symptomatic presentation of PID includes bilateral lower-quadrant abdominal pain, recent onset of dyspareunia, abnormal vaginal bleeding, and vaginal discharge. On physical examination, the patient may have fever, decreased bowel sounds, diffuse lower abdominal tenderness with rebound tenderness, and/or right upper quadrant tenderness. During the pelvic examination, purulent vaginal or endocervical discharge, vaginal mucosa redness, and cervical irritation or friability may be noted. Cervical motion pain or tenderness of the adnexa or uterus during the bimanual examination is strongly suggestive of PID.

There are several diagnostic findings that support the diagnosis of PID: the presence of abundant white blood cells or clue cells in vaginal or cervical mucus; the presence of an STI, especially gonorrhea or chlamydia; an elevated erythrocyte sedimentation rate or C-reactive protein; an elevated serum white blood cell count; evidence of endometritis on endometrial biopsy; findings of thickened, fluid-filled fallopian tubes, free fluid in the pelvis, or a tubo-ovarian abscess on transvaginal ultrasonography or magnetic resonance imaging; or evidence of pelvic organ inflammation on laparoscopic exploration.

### Diagnosis

Unfortunately, no single element of the history, finding on physical examination, laboratory test result, or diagnostic procedure has both the sensitivity and the specificity to help the clinician accurately diagnose PID. Consequently, PID remains a diagnosis based primarily on clinical suspicion in at-risk women.

## Differential Diagnosis

The differential diagnosis of PID includes ectopic pregnancy, inflammatory bowel disorders, ovarian cysts and cyst rupture, ovarian torsion, appendicitis, endometriosis, proctitis, urinary tract infections, diverticulitis, constipation, or functional pain related to current or past abuse.

## Treatment

The 2021 Centers for Disease Control and Prevention (CDC) treatment guidelines for PID are outlined in the Current Diagnosis and Current Therapy boxes. These guidelines recommend empiric treatment for PID in all at-risk women who meet the criteria listed, as “prevention of long-term sequelae is dependent on early administration of recommended antimicrobials.”

Treatment guidelines are based on the patient’s need for inpatient versus outpatient care. The Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) trial demonstrated no difference in the reproductive outcomes of women with mild-to-moderate PID who were randomized to inpatient treatment versus those randomized to outpatient treatment.

Indications for inpatient treatment of PID include the following: pregnancy; failed trial or intolerance to oral medications; signs of severe PID such as high fever, nausea, vomiting, or intractable abdominal pain; complicated PID (e.g., peritonitis, perihepatitis); and pelvic abscess. The need for surgical intervention or diagnostic exploration to rule out other abdominal pathology would also mandate inpatient treatment. In patients who require inpatient treatment, any one of the parenteral antibiotic regimens as outlined earlier may be administered, depending on the patient’s history of allergies and the cost and availability of treatment options. When possible, the use of oral doxycycline (Vibramycin)<sup>1</sup> and metronidazole (Flagyl) is preferred over intravenous (IV) infusion as they both have similar oral bioavailability compared with IV infusion, and infusion of IV doxycycline (Vibramycin) can be painful. Treatment should also include appropriate analgesia, antiemetics, antipyretics, IV fluids, and rest. Patients may be transitioned from parenteral to oral therapy after 24 to 48 hours of sustained clinical improvement including lack of fever. Further completion of a total of 14 days of treatment with oral medications is recommended. Patients who are treated with any of the recommended inpatient regimens should be transitioned to oral doxycycline (Vibramycin)<sup>1</sup> 100 mg every 12 hours and metronidazole (Flagyl) 500 mg PO every 12 hours to complete 14 days of total treatment.

Those treated with clindamycin (Cleocin) and gentamicin (Garamycin)<sup>1</sup> should be transitioned to oral doxycycline (Vibramycin)<sup>1</sup> 100 mg every 12 hours or oral clindamycin (Cleocin) 450 mg every 6 hours to complete 14 days of total treatment. If a tubo-ovarian abscess is present, in addition to surgical consultation and at least 24 hours of inpatient monitoring, the patient should be transitioned to oral clindamycin (Cleocin) 450 mg every 6 hours or oral metronidazole (Flagyl) 500 mg every 12 hours plus doxycycline (Vibramycin)<sup>1</sup> 100 mg every 12 hours for a total of 14 days of treatment.

In patients who do not meet the criteria for inpatient treatment, any of the outpatient treatment regimens as outlined earlier may be used, the choice being again dependent on the cost and availability of treatment options. The addition of metronidazole (Flagyl) is recommended because of cephalosporin limitations in anaerobic coverage and in the case of *Trichomonas* or bacterial vaginosis infections. The addition of metronidazole (Flagyl) is also recommended if there is a history of recent uterine instrumentation.

Routine use of quinolones is no longer recommended in empiric treatment of PID because of increasingly resistant *N. gonorrhoeae*. If a cephalosporin allergy exists and inpatient treatment with clindamycin (Cleocin) and gentamicin (Garamycin)<sup>1</sup> is not available, risk for gonorrhea is low, cultures are obtained, and follow-up is available, levofloxacin (Levaquin)<sup>1</sup> 500 mg PO every 24 hours or moxifloxacin (Avelox)<sup>1</sup> 400 mg PO every 24 hours with metronidazole (Flagyl) 500 mg PO every 12 hours for 14 days may be used. Azithromycin (Zithromax) 500 mg IV every 24 hours for one to two doses followed by 250 mg PO every 24 hours with metronidazole 500 mg PO every 12 hours for 12 to 14 days total can also be used.

In patients with a history of penicillin allergy, a careful reaction history should be taken to assess the risk of using a cephalosporin in the empiric treatment of PID. There is negligible cross-reactivity between penicillins and third-generation cephalosporins. If a cephalosporin cannot be safely used, the patient can be admitted for treatment with parenteral clindamycin (Cleocin) and gentamicin (Garamycin).<sup>1</sup>

Regardless of the treatment regimen used, patients should be advised to abstain from intercourse until treatment is completed and they are free from symptoms. In patients with an IUD, there is inconclusive data to recommend its removal, unless clinical improvement does not occur, but close clinical follow-up is warranted. There is no difference in the treatment regimens for PID in women with a history of HIV.

## Patient Monitoring and Counseling

Patients treated with an outpatient regimen should be evaluated for clinical improvement within 48 to 72 hours. If no improvement is noted, the patient should be hospitalized for parenteral antibiotics and further diagnostic evaluation. All patients should be counseled on the need to complete the full course of antibiotic treatment to decrease the potential complications of PID. Patients should be informed of the cause of their infection, if known, and the need for any sexual partners to be tested and treated. Patients with PID caused by *N. gonorrhoeae* or *C. trachomatis* infections should be retested 3 months after completing treatment. Testing for HIV, syphilis, and hepatitis B and C should also be offered. If the patient is an appropriate candidate, immunization against hepatitis B (Engerix-B, Recombivax HB) and human papillomavirus (Gardasil 9) should also be offered. To decrease future PID episodes, patients should be advised on the need for safe sex practices and the recommendation for future routine screening for chlamydia and gonorrhea.

## Complications

Complications of PID include recurrence of the infection, infertility secondary to fallopian tube scarring, chronic pelvic pain, and ectopic pregnancy. Extension of the infection can also occur, potentially causing pelvic abscess, peritonitis, and perihepatitis (Fitz-Hugh–Curtis syndrome).

## PREMENSTRUAL SYNDROME

Method of

Ellen W. Freeman, PhD

### CURRENT DIAGNOSIS

- Confirm that symptoms occur premenstrually and abate following menses.
- Confirm that symptoms are clinically significant and impair daily activities and/or cause problems for the woman.
- Obtain a medical history and conduct a physical examination to determine that other disorders are not causing the symptoms.
- Assess depression, stress, substance abuse, and other diagnoses that could cause the symptoms.
- Ask the woman to maintain a daily symptom report for two or more menstrual cycles to confirm the reported symptoms and their relation to the menstrual cycle.
- Perform laboratory tests only as needed to confirm general good health or rule out other suspected conditions.

### CURRENT THERAPY

SSRI	Range Studied (mg)	Mean Dose (mg/d)
Citalopram (Celexa <sup>1</sup> )	10–30	20
Escitalopram (Lexapro <sup>1</sup> )	10–20	15
Fluoxetine (Prozac, <sup>1</sup> Sarafem <sup>*</sup> )	10–60	20
Paroxetine (Paxil <sup>1</sup> )	10–30	20
Paroxetine-CR <sup>*</sup> (Paxil-CR)	12.5, 25	NA <sup>†</sup>
Sertraline (Zoloft <sup>*</sup> )	50–150	75
SNRI		
Venlafaxine (Effexor <sup>1</sup> )	37.5–200	112.5

<sup>1</sup>Not FDA approved for this indication.

<sup>\*</sup>FDA approved for the indication of premenstrual dysphoric disorder (PMDD).

<sup>†</sup>Not applicable because of fixed-dose study.

The premenstrual syndromes (PMS) are characterized by mood, behavioral, and physical symptoms that occur from several days to 2 weeks before menses and remit with the menstrual flow. The term PMS as used by clinicians and the general public is generic, imprecise, and commonly applied to numerous symptoms. Included symptoms range from the mild and normal physiologic changes of the menstrual cycle to clinically significant symptoms that limit or impair normal functioning. In recent years, randomized controlled trials and other well-designed studies have defined diagnostic criteria for PMS and identified effective treatments for this disorder.

Based on scientific evidence at this time, serotonergic antidepressants are considered the primary treatment for clinically significant PMS, and particularly its severe form termed *premenstrual dysphoric disorder* (PMDD). This review focuses on PMS and its treatment with serotonergic antidepressants. It is not a comprehensive review of all treatments or associated literature. Other recent reviews may guide the reader to further information and other treatments for PMS and PMDD.

### Symptoms

Numerous symptoms were traditionally attributed to PMS. This plethora is related in part to the absence of a clear diagnosis that distinguishes PMS from other comorbid conditions. Many

### BOX 1 Symptoms of Premenstrual Syndrome

#### Affective

- Irritability
- Anxiety
- Angry outbursts
- Confusion
- Social withdrawal
- Depression

#### Somatic

- Abdominal bloating
- Breast tenderness or swelling
- Swelling of extremities
- Headache
- Joint or muscle pain

From the American College of Obstetricians and Gynecologists (ACOG), FAQ057, May 2015.

disorders, both physical and psychiatric, are exacerbated premenstrually or occur as a comorbid disorder with PMS. When a careful diagnosis is made to distinguish PMS from other conditions, a much smaller group of symptoms appear to be typical of the disorder (Box 1).

Mood symptoms are usually the main complaint (irritability, anxiety, tension, mood swings, feeling out of control, depression), but behavioral symptoms (e.g., decreased interest, fatigue, poor concentration, poor sleep) and physical symptoms, most commonly breast tenderness and abdominal swelling, are also present. Multiple studies suggest that irritability is the cardinal symptom of PMS. Although depressive symptoms such as low mood, fatigue, sleep difficulties, and poor concentration are frequent complaints of women with PMS, the growing evidence indicates that PMS is not a simple variant of depression but has distinct mechanisms that differ from those of depressive disorders.

### Prevalence

Surveys indicate that PMS is among the most common health problems reported by reproductive-age women. Current estimates from epidemiologic data indicate that up to 30% of women experience severe and clinically significant premenstrual symptoms, although only 6% to 8% of menstruating women meet the stringent and predominantly dysphoric criteria for PMDD.

### Morbidity

The morbidity of PMS is related to its severity, chronicity, and resulting distress that affect work, personal relationships, or daily activities. The level of impairment is significantly above community norms and similar to that of other health problems such as major depressive disorder. Studies consistently demonstrate that the greatest impairment or distress resulting from PMS is in relationships with the partner or children and in the effectiveness of work.

### Etiology

The etiology of PMS remains undefined, although the monthly cycling of the reproductive hormones appears to have an essential role in the disorder. While circulating levels of the hormones are in normal range, the dominant theory is that some women have an underlying vulnerability to the normal fluctuations of one or more of these hormones. It is further believed that PMS involves central nervous system-mediated interactions of the reproductive steroids with neurotransmitters. A current review of the genetic etiology found only limited evidence for the genetic basis of PMDD, with both familial and candidate gene studies having negative or conflicting results. The principal research evidence at this time supports the involvement of reproductive hormones, serotonergic dysregulation, and possibly dysregulation of GABAergic receptor functioning. Recent evidence suggested

## Presenting symptoms:

- Consistent with premenstrual syndrome
- Restricted to the luteal phase
- Cause impairment or distress
- Not an exacerbation of another disorder
- Confirmed by 2-3 consecutive cycles of daily symptom rating

From the American College of Obstetricians and Gynecologists (ACOG), FAQ057, May 2015.

a pathophysiological role of beta-adrenergic mechanisms in the clinical pain of PMS.

### Diagnosis

A diagnosis of PMS is determined primarily by the *timing* and the *severity* of the symptoms. These factors, together with an assessment of whether other physical or psychiatric disorders may account for the symptoms, are more important for the diagnosis than the particular symptoms, which are typically nonspecific and must be assessed for their relationship to the menstrual cycle.

Box 2 lists the diagnostic criteria for PMS presented by the American College of Obstetricians and Gynecologists. These criteria indicate that PMS symptoms must be experienced during the 5 days before menses and abate during the menstrual flow. The symptoms should cause identifiable impairment or distress, be confirmed by prospective reports recorded daily by the woman for at least two to three consecutive menstrual cycles, and not be accounted for by other disorders.

To diagnose PMS, a medical history should be obtained and a complete physical with gynecologic examination performed. PMS is understood to occur in ovulatory menstrual cycles; cycles that are irregular or outside the normal range are an indication for further gynecologic investigation. Comorbid conditions such as dysmenorrhea, endometriosis, uterine fibroids, pelvic inflammatory disease, thyroid disorders, migraine, diabetes, mood disorders, substance abuse, and numerous other possibilities should be identified. It may be difficult to determine whether the symptoms under investigation are an exacerbation of a comorbid condition or superimposed on another condition. In either case, the usual recommendation is to treat the ongoing condition first, then reassess and possibly add treatment for the symptoms that arise premenstrually.

The diagnostic criteria for PMDD are listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) and are intended to diagnose a severe, dysphoric form of PMS. Importantly, the Food and Drug Administration (FDA) has approved medications only for the indication of PMDD and not for the indication of PMS at the present time. Briefly, the PMDD criteria require 5 of 11 *listed* symptoms including at least one mood symptom. Physical symptoms, regardless of the number, are considered a single symptom in meeting the diagnostic criteria. The 11 PMDD symptoms are depressed mood, anxiety or tension, mood swings, anger or irritability, decreased interest, concentration difficulties, fatigue, appetite change or food cravings, sleep disturbance, feeling overwhelmed, and physical symptoms. At least five of these symptoms must *each* be severe premenstrually and abate with the menstrual flow. The symptoms must markedly interfere with functioning, be confirmed by daily symptom reports for at least two menstrual cycles, and not be an exacerbation of another physical or mental disorder.

No laboratory test identifies PMS or PMDD and none should be routinely performed for diagnosis. Laboratory tests that indicate or confirm other possible disorders are useful if suggested by the individual woman's symptom presentation or medical findings.

The key diagnostic tool for evaluating premenstrual symptoms is the daily symptom report. The diagnostic criteria for both PMS

and PMDD include a daily symptom report that is maintained by the woman for at least two menstrual cycles to confirm that the woman's reported symptoms are linked to the menstrual cycle in the requisite pattern. Numerous symptom reports appropriate for this diagnosis are identified in the medical literature. It is important that the ratings indicate the severity of each symptom (and not simply check the presence or absence of symptoms).

It is informative to use two visits for the diagnostic evaluation. Although counterintuitive, seeing the patient following menses when PMS symptoms have abated is instructive. If symptoms are absent, it provides strong evidence for the diagnosis. If symptoms are present in the follicular phase, the type and severity of the symptoms are important diagnostic information for identifying other physical or mental disorders that may be the primary focus of treatment.

### Treatment

#### Selective Serotonin Reuptake Inhibitors

Serotonergic antidepressants are the primary treatment for severe PMS and PMDD at this time. Modulating serotonergic function is consistent with a leading theoretical view that the normal gonadal steroid fluctuations of the menstrual cycle are associated with an abnormal serotonergic response in vulnerable women. A meta-analysis of randomized controlled trials of selective serotonin reuptake inhibitors (SSRIs) in treatment of PMS and PMDD determined that these drugs were an effective first-line therapy, with both a statistically significant and clinically meaningful difference from placebo. The FDA has approved fluoxetine (Sarafem), sertraline (Zoloft), and controlled-release paroxetine (Paxil CR) for the indication of PMDD. Other randomized, placebo-controlled, double-blind trials show efficacy of citalopram (Celexa<sup>1</sup>), escitalopram (Lexapro<sup>1</sup>), venlafaxine (Effexor<sup>1</sup>) (a selective serotonin-norepinephrine reuptake inhibitor [SNRI]), and clomipramine (Anafranil<sup>1</sup>) (a tricyclic antidepressant) for treatment of PMS and PMDD, but they are not FDA approved for this indication.

Effective doses of SSRIs are consistently at the low end of the dose range for depressive disorders in all reports of PMS and PMDD treatments. Significant response is often seen in the first menstrual cycle of treatment, with smaller increments with or without dose adjustments in the second and third treatment cycles. If there is not sufficient response in the first treated menstrual cycle, the dose should be increased in the next cycle unless precluded by side effects.

Side effects are common with the initiation of an SSRI but are usually transient and abate within 1 to 2 weeks of continued treatment. The most common side effects include headache, nausea, insomnia, fatigue or lethargy, diarrhea, decreased concentration, dizziness, and decreased libido or delayed orgasm. The sexual side effects of SSRIs have received considerable attention, although it is often difficult to determine the extent to which sexual effects are related to the medication or to preexisting conditions. The incidence of decreased sexual interest or delayed orgasm in the few published reports of PMS patients is approximately 9% to 16%, which is notably lower than the rates reported with the use of SSRIs by depressed patients. Another important issue is the lack of any well-controlled clinical trials of SSRI treatment for PMS and PMDD in adolescents. Whether SSRIs are safe and effective for this indication in women younger than 18 years is not demonstrated.

#### Luteal Phase Dosing

The use of medication only in the symptomatic luteal phase of the menstrual cycle is particularly important in PMS because of the cyclic pattern of the symptoms, which occur only in the premenstrual phase and abate following menses. Efficacy of luteal phase administration of the SSRIs is demonstrated in multiple trials: three large multicenter, randomized, placebo-controlled

<sup>1</sup>Not FDA approved for this indication.

trials that examined fluoxetine (Sarafem), paroxetine (Paxil), and sertraline (Zoloft); a trial that directly compared continuous and luteal phase administration of sertraline; and multiple preliminary studies.

Luteal phase administration of an SSRI is typically initiated 14 days prior to the expected onset of menstrual bleeding and concluded within several days of bleeding, using a taper for increased doses. As with continuous dosing, the SSRI doses are usually at the low end of the dose range.

A preliminary study compared symptom-onset dosing (mean of 6 days before menses) to luteal-phase dosing and found no difference between the two dosing regimens in improvement overall, although there was suggestion that women with more severe symptoms may respond better to full luteal-phase dosing. A recent RCT of sertraline in symptom-onset dosing suggested greater improvement with sertraline compared to placebo, but results were inconsistent and varied with the symptom scale. Importantly, however, this study showed that cessation of symptom-onset treatment was not associated with discontinuation symptoms.

Side effects may be less frequent with an intermittent dosing regimen because they may not occur when not taking the medication. However, some women experience recurring side effects when dosing is resumed.

### *Insufficient Response to Selective Serotonin Reuptake Inhibitors*

Approximately 60% of PMS and PMDD patients in controlled studies respond well to an SSRI. There are no clear predictors of response. An adequate trial of an SSRI for PMS and PMDD is at least two menstrual cycles at a dose level of demonstrated efficacy, with a third cycle when there is partial response. If a woman has an insufficient response or unacceptable side effects, it is reasonable to try another SSRI. Although the SSRIs are similar in their structure and have similar response rates and side-effect profiles, an individual patient may respond better to one SSRI versus another.

Other approaches to a poor treatment response include augmenting the SSRI with another medication to address the nonresponding symptoms, but there is no systematic information on this in PMS or PMDD treatment. Switching to another class of medication, such as anxiolytics, is suggested, but no data indicate whether nonresponders to SSRIs will respond to another class of medication. Nonresponse may also be related to other comorbid disorders. A thorough review of the diagnosis and adjustments of the premenstrual doses of medication for both the primary disorder and PMS should be considered before pursuing other treatments.

### **Other Treatments**

#### *Hormonal*

In spite of the evidence for hormonal involvement in PMS and PMDD, traditional oral contraceptives (OCs) do not show efficacy for the disorder. However, some data indicate that shortening or omitting the placebo week in the traditional OC pill pack may effectively treat PMS and PMDD. The FDA has approved the oral contraceptive YAZ (ethinyl estradiol 20 mcg/drospirenone 3 mg), a 24/4-day combination pill, to treat PMDD. The continuous daily use of an OC (without a hormone-free interval) suppresses ovulation-related hormone cyclicality. Continuous daily levonorgestrel 90 mcg/ethinyl estradiol 20 mcg (Amethyst<sup>1</sup>) has been evaluated for continuous use up to one year and may be useful for managing the symptoms of PMDD. A Cochrane review of estrogen preparations for management of PMS found only five randomized controlled trials out of more than 500 reports. The evidence was considered low-quality, inconclusive with regard to effectiveness, and too limited to provide answers regarding the safety of these preparations for the indication of PMS.

Gonadotropin-releasing hormone (GnRH) agonists such as depot leuprolide (Lupron<sup>1</sup>) and buserelin<sup>2</sup> (Suprefact) are effective for PMS and PMDD but are of limited usefulness because of the risks associated with low estrogen levels that result from these treatments. Although add-back therapy using low-dose estrogen and progesterone together with the GnRH agonist did not appear to reduce efficacy in a meta-analysis, there are no definitive data on the safety and efficacy of this approach in long-term treatment. The historic use of progesterone has failed to show efficacy for the mood and behavioral symptoms of PMS in numerous controlled trials.

#### *Anxiolytics*

Alprazolam (Xanax<sup>1</sup>) and buspirone (Buspar<sup>1</sup>) showed modest efficacy for PMS in some studies but not others. Although these medications offer an alternative to antidepressants, the response rates appear much lower, and it is not known whether a PMS patient who does not respond to antidepressants will respond to an anxiolytic. The risk of dependency with alprazolam should be considered. Dosing should be strictly limited to the luteal phase, and the patient should have no history of substance abuse.

#### *Nonpharmacologic*

Calcium supplementation<sup>1</sup> (500 mg daily; 600 mg twice daily) reduced PMS symptoms significantly more than placebo in several clinical trials. Improved symptoms included anxiety, depression, water retention, and somatic changes. Calcium offers a dietary supplement approach that may be beneficial for some women with PMS, although there are no predictors of which women will respond well to this therapy. Vitex agnus castus (chasteberry<sup>7</sup>) appears to be a safe and effective treatment for PMS or PMDD in randomized controlled trials. Other complementary and alternative therapies may be helpful for some women, but there is no consistent evidence of their efficacy for PMS.

Behavioral treatments that facilitate coping or reduce stress may reduce PMS symptoms. Cognitive-behavioral therapy is effective for PMS, and in one study it was as effective as the SSRI fluoxetine after 6 months of treatment.

#### **Treatment Duration**

The published studies of treatment efficacy for PMS and PMDD are based on acute treatment of 2 to 3 months' duration. Several investigations suggest that PMS symptoms are likely to return within several months after medication is stopped. It also appears that PMS symptoms do not resolve spontaneously but continue for many years. These observations of PMS as a chronic condition and the swift return of symptoms following the cessation of medication suggest that treatment can be expected to be long term. In a controlled study that compared 4 months to 1 year of SSRI treatment, approximately half of the patients who improved with SSRI treatment relapsed within 6 to 8 months after discontinuing medication. Longer treatment was marginally better at preventing relapse. Patients with more severe symptoms before treatment were the most likely to relapse, while patients who experienced symptom remission with treatment were least likely to relapse.

#### **Conclusions**

The SSRIs are currently the first-line treatment for severe PMS and PMDD. Continuous dosing and luteal phase dosing regimens are similarly effective for these disorders when the symptoms are clearly limited to the luteal phase of the menstrual cycle. Hormonal treatments have lacked consistent scientific evidence of their efficacy or safety or both for PMS treatment. Several new oral contraceptives that decrease or omit the placebo interval, calcium supplementation, and cognitive behavioral therapy may provide an effective alternative to antidepressant medications. Evidence indicates that long-term maintenance of the medication may be required for PMS and PMDD.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>7</sup>Available as dietary supplement

## UTERINE LEIOMYOMA

Method of

James W. Haynes, MD; and Theodore T. Tsaltas, MD

### CURRENT DIAGNOSIS

- Uterine leiomyomas are the most common pelvic tumors in women.
- Risk factors include African American ethnicity, family history, obesity, decreased physical activity, nulliparity, and early menarche.
- Exact pathophysiologic mechanism is unknown but tumors consist of swirls of smooth muscle cells and fibroblasts.
- The primary clinical manifestations of uterine fibroids include heavy menstrual bleeding and pelvic pain.
- Ultrasonography is the primary diagnostic test of choice when fibroids are suspected.
- Differential diagnoses includes adenomyosis, ectopic pregnancy, endometrial polyp, endometriosis, pregnancy, endometrial carcinoma, uterine sarcoma, and metastatic disease.

### CURRENT THERAPY

- Therapy for uterine leiomyomas is based on symptoms, uterine size, and future fertility desires.
- Nonsurgical treatment options include nonsteroidal antiinflammatory drugs, oral contraceptives, progestational, and gonadotropin-releasing hormonal pharmaceutical agents.
- Indications for surgical treatment include uterine size >12 weeks, anemia from menometrorrhagia, soiling of clothing or bedding from menometrorrhagia, intractable dysmenorrhea or dyspareunia, and urinary or bowel obstruction.
- The definitive treatment option is hysterectomy with laparoscopic/robotic vaginal route being preferred.
- Other viable surgical interventions include myomectomy, uterine artery embolization, radio frequency focused ablation, and endometrial ablation.

## Epidemiology

Uterine leiomyomas (fibroids) are the most common pelvic tumors in women. Approximately 30% to 50% of premenopausal women have ultrasound evidence of fibroids without symptoms. Leiomyomas rarely occur prior to puberty and incidence increases with age, peaks at age 50, and decreases after menopause. African American women have a two- to threefold incidence compared with Caucasian, Asian, and Hispanic women who have similar frequencies of fibroids. African American women have an earlier onset of disease with an average age of onset 5 years earlier compared with Caucasian women. Additionally, African American women have larger and more numerous fibroids compared with Caucasian women.

## Risk Factors

**Box 1** includes risk factors for uterine fibroid development. Consumption of vegetables and fruits, dark-meat fish, vitamin D, and vitamin A, as well as physical activity, are associated with a decreased risk of fibroids. Data is conflicting with respect to oral contraceptives and smoking, while breastfeeding, vitamin C, vitamin E, and folates have no association with the development of fibroids.

## Pathophysiology

Uterine leiomyomas consist histologically of smooth muscle cells and fibroblasts that ultimately form round, hard tumors. The exact pathologic mechanism of disease is unknown but a smooth muscle cell mutation has been hypothesized.

## Prevention

There are currently no proven therapies that prevent uterine fibroid formation. Identification of the genes responsible for fibroid growth in patients genetically predisposed to fibroids could possibly lead to genomic-mediated prevention of fibroids.

## Clinical Manifestations

About 50% to 80% of uterine fibroids are asymptomatic. Heavy menstrual bleeding and pelvic pain are the most common symptoms associated with uterine fibroids. Additional symptoms include secondary dysmenorrhea, abdominal distention, pelvic pressure, urinary symptoms (urgency, frequency, incontinence, hydronephrosis), bowel dysfunction including constipation, back pain, dyspareunia, and infertility.

## Diagnosis

Physical examination of the abdomen and pelvis may elucidate an enlarged uterus secondary to uterine fibroids. Transvaginal ultrasonography is 90% to 99% sensitive in the detection of uterine fibroids but may miss small or subserosal fibroids. Hysteroscopy or sonohysterography increase diagnostic sensitivity for subserosal myomas.

### BOX 1 Uterine Fibroid Risk Factors

- African American descent
- First-degree relative with uterine fibroid
- Early menarche
- Less than three obstetric deliveries
- Five years since last birth
- Obesity
- Metabolic syndrome
- Decreased physical activity
- Childhood trauma
- Beef, red meat, ham
- Vitamin D deficiency
- Alcoholic beverages (especially beer)
- Caffeine intake (younger women)
- Hormone replacement therapy

## Differential Diagnosis

Diagnostic possibilities in patients presenting with symptoms of uterine fibroids include adenomyosis, ectopic pregnancy, endometrial polyp, endometriosis, pregnancy, endometrial carcinoma, uterine carcinosarcoma, uterine sarcoma, and metastatic disease.

## Treatment of Myomas

Myomas are benign lesions, hence, there is no a priori requirement for treatment. Management is based on symptoms and patient's wishes. Three parameters control recommendations: uterine size, severity of symptoms, and the patient's interest in childbearing.

There are a limited number of options for management:

- Definitive surgery
  - Hysterectomy (various methods)
- Palliative/uterine conserving surgery
  - Myomectomy (open or laparoscopic)
  - Hysteroscopic myomectomy
  - Uterine artery embolization
  - Radiofrequency focused ablation
- Symptomatic treatment
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - Oral contraceptives
  - Progestational agents
  - Gonadotropin-releasing hormone (GnRH) agonists
  - Endometrial ablation

The indicators for surgical intervention include the following:

- Uterine size >12 weeks (>14 weeks for some insurers to cover)
- Anemia from menometrorrhagia
- Soiling of clothing or bedding from menometrorrhagia
- Intractable dysmenorrhea or dyspareunia
- Urinary or bowel obstruction

The choice of procedure is strongly constrained by a patient's desire for future childbearing. This precludes hysterectomy and procedures that destroy the endometrial cavity to stop bleeding, such as endometrial ablations. Uterine conservation may prove impossible or have marked complications if the number of myomas is large. Of note, surgical intervention for subfertility is indicated in selected cases but the data related to optimal methods of management is limited and inconclusive.

## Hysterectomy

While multiple newer treatments have been introduced, hysterectomy remains the single most common management. It is definitive, ending mass impingement symptoms, bleeding, pain, urinary frequency, and constipation with a single intervention. Recurrence of myomas is extremely rare after hysterectomy.

The route of hysterectomy remains under debate. When possible, a vaginal hysterectomy is the preferred route, as it has the lowest morbidity of all types. More than two-thirds of hysterectomies for myomas are still done by open abdominal route, despite laparoscopy and robotic surgery having been repeatedly demonstrated as equivalent or superior for blood loss and complications.

Surgical complications of hysterectomy are common, but significant complications are rare. The most common problems are urinary tract infection (~25%) and superficial wound disruptions. More serious complications include deep venous thrombosis and pulmonary embolism, anaerobic pelvic cellulitis, and pneumonia. Organ injury to bowel, bladder, blood vessel, or ureter occurs in approximately 1/500 cases, 1/1000 for vaginal procedures. Bleeding sufficient to require transfusion occurs in about 1% of hysterectomies.

## Myomectomy

Myomectomy is the procedure of choice for symptomatic myomas in women desiring fertility preservation. Myomas may be removed abdominally, vaginally, laparoscopically, or via hysteroscopy, depending on their size and location. Myomectomy does not necessarily lead to future cesarean delivery, but if cavity

integrity is violated or there is an extensive dissection it then becomes mandatory.

Laparoscopic procedures are much less invasive but require significant skill. Closure of myomectomy defects is also difficult and time consuming. Hysteroscopic resection is an elegant technique applicable only to intracavitary myomas.

Between 40% and 75% of patients undergoing myomectomy will have a future hysterectomy. Complication rates from open myomectomy are significantly higher than for hysterectomy, accounted for by fever and blood loss.

## Uterine Artery Embolization

Uterine artery embolization (UAE) now accounts for approximately 3% of myomectomies. The method uses injectable microspheres placed under fluoroscopic guidance. It is effective for isolated myomas of moderate size (up to 5 cm), although lesions up to 9 cm have been treated by UAE. It is an outpatient procedure done in interventional radiology suites without entering the abdominal cavity.

There are several significant problems with UAE that have limited its broad application. Inflammatory mediators released by myoma necrosis can cause substantial cramping and bowel symptoms. Lesion defects cannot be closed, leading to uterine wall defects with secondary placental implantation abnormalities and uterine rupture in pregnancy. Vascular anatomy is quite variable, and microspheres can be injected into any of the branches of the internal iliac. This can lead to necrosis of bladder, buttock, or vulva. Limitations in available facilities as well as trained and experienced operators, combined with the significant complications, has limited usage of UAE.

## Radiofrequency Ablation

This technique uses focused, high frequency radio wave or ultrasound to cause mechanical destruction of myomas. It is an uncommon technique because of limited facilities and experienced practitioners. It does not have the potentially disfiguring complications of UAE but does have all its other problems, as well as risk of destruction of normal uterine tissue.

## Observation

Since myomas are benign, they may be observed if indications for hysterectomy noted above are not met. In this setting the goal is symptom control. Cramping can be managed with NSAIDs. Acetaminophen (Tylenol) has less than 30% of the peripheral antiinflammatory activity of ibuprofen (Advil, Motrin) so that ibuprofen, aspirin, and other NSAIDs are much preferred. The individual drug choice relies with the patient and practitioner.

Bleeding can be improved with oral contraceptives, progestational agents, or tranexamic acid (Lysteda). In pooled results, tranexamic acid was more effective than medroxyprogesterone injection (Depo-Provera)<sup>1</sup> used over an equivalent time, reducing menstrual blood loss by 30%. Depo-Provera also provides contraception and uterine mass shrinkage at the expense of breakthrough bleeding. Progestational intrauterine devices are a possible option for bleeding control without causing systemic side effects. While appealing, like other medical management options, these devices do not alter the course of the myoma.

GnRH agonists are extremely effective in effecting uterine mass shrinkage. Volume reduction up to 70% is possible with a 3-month course. Myoma reexpansion is, however, prompt and returns to original size. GnRH agonists are thus not suitable for treatment of myomas. Rather, they are best used to shrink myomas prior to surgery, making their removal easier and faster. Since Depo-Provera achieves almost as much shrinkage, few insurers cover GnRH agonists for this purpose.

<sup>1</sup>Not FDA approved for this indication.

## Managing Complications

Complications other than pain and bleeding are uncommon. Uterine mass and distortion can become so great as to obstruct venous return from the legs and pelvis, leading to deep venous thrombosis. Obstipation can occur, requiring manual disimpaction. More frequently, but still uncommon, urinary obstruction with retention or inability to void is possible.

The most frequent problem during observation of myomas is degeneration. Myomas are monoclonal tumors and thus have only a single, primary blood supply. If their growth outstrips available perfusion, the myocytes undergo necrosis. This can be quite painful. Management consists of NSAIDs, heavy hydration, rest, and occasional use of opioids. If initial interventions fail, inpatient management may be necessary for pain control. Intramuscular ketorolac (Toradol) materially reduces pain and can be used in an outpatient setting.

Leiomyomatosis peritonealis disseminata is a very rare condition where myomatous change occurs along the smooth muscle of the internal iliac arterioles. It can produce pelvic congestion, altered perfusion, and deep venous thrombosis. Management is by hysterectomy followed by GnRH agonists for 3 to 6 months. Complete resolution is the norm.

Myomas do not undergo malignant degeneration, but the frequency of uterine sarcoma is generally expressed as a proportion of all myoma cases. Uterine sarcomas are rare, with incidental discovery in a myomatous uterus in about 1/1000 myomatous uteri. Early epidemiologic studies on power morcellators indicated a rate of sarcoma in myomatous uteri of up to 1%. Larger studies have clearly shown this is a massive overstatement. Many hospitals are accordingly again allowing use of power morcellation for myomectomy and laparoscopic removal of large hysterectomy specimens.

Some situations with myomas require prompt attention. Sudden, rapid uterine growth in a woman over 40 years of age should prompt consideration for sarcoma. Similarly, such tumors should not be morcellated but removed intact, either by open surgery or a laparoscopy with minilap.

Myomas can be confused with thecoma-fibromas, a benign ovarian tumor. The thecoma-fibroma is usually stone hard and heavily calcified on ultrasound but can be so large and firm that it cannot be distinguished from a myoma. Laparoscopy can distinguish the lesions.

## VULVAR NEOPLASIA

Method of

Christine Conageski, MD

### CURRENT DIAGNOSIS

- Most cystic lesions are benign. Excision is reserved for symptomatic cysts and suspicious Bartholin's gland cysts, especially in women older than 40 years of age.
- All solid lesions should be biopsied for diagnostic purposes.
- Multifocal disease requires multiple biopsies to rule out invasive disease.
- Most premalignant and malignant lesions cause pruritus, discomfort, or a noticeable lesion.
- The vagina and cervix in women with dysplastic or malignant vulvar lesions should be evaluated.

### CURRENT THERAPY

- Benign solid lesions should be excised.
- After ablative treatment of vulvar intraepithelial neoplasia (VIN), excise any residual lesions to rule out occult invasive disease.
- Avoid podophyllin and 5-fluorouracil in women of reproductive potential.
- Rule out synchronous neoplasms in women with Paget's disease.
- Invasion more than 1 mm requires radical excision and lymph node evaluation.

The female external genitalia includes the mons pubis, labia majora, labia minora, clitoris, perineal body, and the structures of the vaginal introitus or vestibule. Whether benign or malignant, vulvar neoplasms are uncommon, occur at all ages, and have varying characteristics. Therefore liberal use of biopsies is usually required for diagnosis and treatment decisions.

## Benign Cystic Neoplasms

Benign cystic lesions of the vulva include Bartholin's duct cyst, sebaceous and epidermal inclusion cysts, mucinous cysts, Skene duct cysts, and cysts of the canal of Nuck. Bartholin's duct cyst, located in the posterior labia near the vaginal introitus, is most common. Treatment is usually not required in asymptomatic young women (<40 years). If the cyst is symptomatic or infected, however, drainage, marsupialization or use of a Word catheter, is indicated. Bartholin's gland carcinomas are rare, especially in women younger than 40 years of age. But if the mass feels firm or nodular, it should be biopsied.

Sebaceous and epidermal inclusion cysts are also common. They are prone to infection but rarely malignant. If an infection develops, they should be incised and drained. Mucinous cysts are rare and possibly arise from the minor vestibular glands. They are located anteriorly on the vulva, typically on the inner labia minora. Skene duct cysts are located next to the urethra. Excision of these cysts is necessary only if symptomatic.

Cysts of the canal of Nuck are located in the anterior portion of the labia majora at the termination of the insertion of the round ligament. These cysts represent herniation of the peritoneum through the inguinal canal and contain peritoneal fluid. If symptomatic, excision must be accompanied by closure of the fascial defect to prevent recurrence.

## Benign Solid Neoplasms

The benign solid tumors of the vulva include fibromas, myomas, lipomas, hidradenomas, syringomas, myoblastomas, vestibular

adenomas, and angiomas, among others. Benign pigmented lesions, such as nevi and seborrheic keratoses, may occasionally be found. Malignancy is rare, but most should be excised for diagnostic and therapeutic purposes.

### Condyloma Acuminatum

Vulvar condyloma acuminatum is a sexually transmitted verrucous lesion of the vulva caused by human papilloma virus (HPV), most frequently types 6 and 11. These lesions are warty growths that frequently cover large areas of the vulva. Smoking and immunosuppression are risk factors. Representative biopsies should be obtained to document disease and rule out malignancy. Wide local excision can be used for small lesions, although these growths are usually best treated by ablation to avoid morbidity associated with excision.

Chemical ablative techniques include self or provider-administered medications. Self-administered medications include topical podofilox (0.5%, Condyllox) or imiquimod (5%, Aldara). Podofilox is applied twice daily for 3 days, repeated weekly for 4 weeks and imiquimod is applied three times per week for up to 16 weeks. It is primarily an immune modulator. Providers may instead choose in-office application of trichloroacetic acid (Tri-Chlor), 5-fluorouracil<sup>1</sup> (1%, Fluoroplex or 5%, Efudex),<sup>1</sup> or podophyllin. Podophyllin and 5-fluorouracil should not be used in women who could become pregnant. Surgical ablative therapies include CO<sub>2</sub> laser vaporization and use of the Cavitron ultrasonic aspirator (CUSA), especially for extensive disease.

### Intraepithelial Neoplasms of the Vulva

#### Vulvar Intraepithelial Neoplasia

Vulvar intraepithelial neoplasia (VIN) is a dysplastic condition of the squamous epithelium whose incidence is increasing, especially in younger women. There are two pathologically distinct types of VIN, usual and differentiated types.

The usual type has a strong association with HPV infections and thus shares similar risk factors with cervical intraepithelial neoplasias (CIN). These risk factors include early first intercourse, multiple sexual partners, smoking, and immunosuppression. Up to 22% of women have concurrent CIN lesions and up to 71% have had a previous, concomitant or subsequent history of vaginal intraepithelial neoplasia. Differentiated VIN is not associated with HPV and is found in relation to vulvar dermatoses such as lichen sclerosis. Differentiated VIN typically occurs in older women with a mean age of 67 years compared to 47.8 years in usual type VIN. Symptoms of both types include pruritus (most common), pain, a noticeable lesion, and discoloration. Most patients with HPV-related disease have multifocal lesions. Typical findings are raised white, gray, red, or mottled lesions; application of 4% acetic acid for several minutes can help identify faint lesions and outline abnormal vascular patterns. Diagnosis of VIN is made by punch biopsies through full thickness of the epithelium to rule out invasion. Usual and differentiated VIN have very different cancer progression risks, 5.7% for HPV-mediated VIN and 32.8% for differentiated VIN. Differentiated VIN, also, has a shorter time to progression, 22.8 months compared to 41.4 months.

Treatment of VIN can be categorized into excisional and ablative therapies. Management should be individualized to each patient taking into account risk of progression, distribution of disease and histologic features on biopsy. Often a combination of medical and surgical management is appropriate. Patients at risk for microinvasion (unifocal disease, raised lesions, older age, and prior radiation) should have the lesion excised completely if possible. Skinning vulvectomy is rarely used because of psychological and sexual consequences related to scarring and disfigurement.

The ablative therapies can be divided into mechanical and chemical. The mechanical method most commonly used is the CO<sub>2</sub> laser, although use of the CUSA is also described. Both can ablate large or multifocal lesions successfully with an excellent cosmetic and functional outcome. The chemical method most commonly used is topical 5-fluorouracil (5%, Efudex).<sup>1</sup> Because of its teratogenic potential, it should not be used in women who could become

**TABLE 1** Recurrence of Vulvar Intraepithelial Neoplasia III

TREATMENT METHOD	% RECURRENCE
Chemical ablation	20–40
Mechanical ablation	20–40
Wide local excision	
Negative margin	15–25
Positive margin	30–45

pregnant. It can be applied on two consecutive nights weekly for 10 weeks. An alternative ablative therapy is use of imiquimod<sup>1</sup> (Aldara), as described earlier. Because of the irritation caused by these topical therapies, many patients have problems with treatment compliance. Residual disease should be excised to rule out invasion.

Patients with VIN frequently have recurrent disease, regardless of the treatment method used (Table 1). Continued smoking increases this risk, so patients should be counseled in smoking cessation. In those patients whose cancers recur and are retreated, subsequent 5-fluorouracil prophylaxis, with a single application biweekly, is used successfully to minimize further recurrences.

#### Paget's Disease

Paget's disease of the vulva is an uncommon condition characterized by a patchy, eczematoid lesion that frequently covers much of the vulva. Most patients are postmenopausal and present with complaints of pruritus. Although Paget's disease is an in situ disease process, 15% to 25% of patients have an underlying malignancy, usually an adenocarcinoma of the apocrine glands but occasionally an invasive Paget's. In addition, up to 30% of patients have a synchronous adenocarcinoma of the breast, colon, rectum, or upper genital tract. Screening for these cancers is therefore recommended. To assess for invasion, the lesion should be excised via wide local excision or simple vulvectomy with at least 5 mm of the adjacent subcutaneous tissue. Achieving negative margin status is frequently difficult. However, the risk of recurrence is approximately 30% whether margins are negative or positive. Thus expectant management, reserving treatment for symptomatic recurrences, is usually recommended.

#### Invasive Vulvar Lesions

Less than 5% of gynecologic cancers arise on the vulva. Over 90% are squamous cell carcinomas. The etiology of this type appears mixed. The differentiated type is more common, occurs in older women (age 60–69, mean age 65) and is associated with vulvar dystrophies. The classic or usual type is predominantly associated with HPV-16. These women are slightly younger (age 45–52 years) and present with earlier stage disease. Other histologic types are melanomas (5%–10%), basal cell carcinomas (2%–3%), adenocarcinomas (1%), and sarcomas (1%–2%). Most patients present with a combination of symptoms, including pruritus, discomfort, and complaints of a mass. Examination frequently reveals a suspicious lesion, which should be biopsied for diagnosis. Vulvar cancers typically spread by local extension and lymphatic dissemination. Factors that influence dissemination include tumor size (Table 2), depth of invasion (Table 3), lymphovascular space invasion, and tumor grade. Staging is surgical and classified using the tumor, nodes, and metastasis (TNM) system as well as the International Federation of Gynecology and Obstetrics (FIGO) system (Table 4).

#### Squamous Cell Carcinomas and Adenocarcinomas

Surgical management of squamous cell carcinomas and adenocarcinomas depends on the size, depth of invasion, and location of the lesion. The vulvar lesion is managed with a radical excision. Management of the groins is based on depth of invasion. Lesions with invasion of less than 1 mm (Stage IA) have minimal risk of lymphatic spread (<1%) and do not require lymphadenectomy.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Incidence of Regional Node Metastases by Tumor Diameter

TUMOR DIAMETER (CM)	% POSITIVE INGUINAL NODES
<1	1–15
5–20	
25–35	
35–50	
≥50	≥50

**TABLE 3** Incidence of Regional Node Metastases by Depth of Tumor Invasion

DEPTH OF INVASION (MM)	% POSITIVE INGUINAL NODES
<1	1–5
1–3	10–15
3–5	15–30
5–10	30–45

All others require surgical assessment of the lymph nodes. Lesions less than 2 cm in size of the primary tumor, greater than 2 cm from the vulvar midline and are of squamous histology require only unilateral lymphadenectomy. Those without these characteristics or have palpable lymph nodes of the contralateral side require bilateral assessment. This surgical approach is associated with significant morbidity including disfigurement, wound breakdown, and problems with lymphocysts and chronic lymphedema. For patients with very large lesions or lesions in sensitive areas such as the clitoris, preoperative radiation, followed by less radical excision of residual disease, may minimize problems with the vulvar wound. Current investigations are ongoing in the use of sentinel lymph node dissections as a method of minimizing the groin morbidity without sacrificing survival. Positive vulvar margins or metastases to lymph nodes are managed with postoperative radiation. Survival depends on stage at diagnosis (Table 5).

### Verrucous Carcinoma

Verrucous carcinoma is a large exophytic tumor that resembles giant condyloma acuminatum. It is a variant of squamous carcinomas but has an excellent prognosis because of the lack of metastases. Verrucous carcinomas have a high tendency to recur and should be managed with radical local excision.

### Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy. Most patients have disease on the mucosal surfaces of the vulvar introitus, clitoris, and labia minora. The vulvar lesion is treated by radical excision, but management of the groins is controversial. The risk of spread is significant with a tumor thickness greater than 0.75 mm, but survival at 5 years is only approximately 10% with groin node metastases. Some argue against node dissection for this reason. However, given some long-term survivors with modern melanoma therapy, either lymphadenectomy or sentinel lymph node dissection, as is done for other cutaneous melanomas, appears indicated.

### Basal Cell Carcinoma

Basal cell carcinomas typically occur in elderly white women, are commonly located on the labia majora, and have characteristics similar to basal cell carcinomas at other sites. Treatment is wide local excision only because metastases are rare. Basal cell carcinomas are prone to local recurrence, however. A malignant squamous

**TABLE 4** Staging Vulvar Carcinoma

TNM CATEGORIES	FIGO STAGES	
T Primary tumor		
T0		No evidence of primary tumor
Tis		Carcinoma in situ
T1	I	Confined to vulva
T1a	IA	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm
T1b	IB	Lesions >2 cm in size OR any size with stromal invasion >1.0 mm, confined to the vulva or perineum
T2	II	Tumor of any size with extension to adjacent perineal structures (lower/distal 1/3 urethra, lower/distal 1/3 vagina, anal involvement)
T2	III	Tumor of any size with or without extension to adjacent perineal structures (lower/distal 1/3 urethra, lower/distal 1/3 vagina, anal involvement) with positive inguino-femoral lymph nodes
T3	IVA	Tumor of any size with extension to any of the following: upper/proximal 2/3 of urethra, upper/proximal 2/3 vagina, bladder mucosa, rectal mucosa, or fixed to pelvic bone
T3	IVB	Any distant metases including pelvic lymph nodes
N Regional lymph nodes		
N0		No lymph node metastases
N1		One or two regional lymph nodes with the following features:
N1b	III Ai	One lymph node metastasis, ≥ 5 mm
N1a	III Aii	One to two lymph node metastases, < 5 mm
N2	IIIB	Regional lymph node metastasis with the following features:
N2b	IIIBi	Two or more lymph node metastases, ≥ 5 mm
N2a	IIIBii	Three or more lymph node metastases, <5 mm
N2c	IIIC	Lymph node metastasis with extracapsular spread
N3	IVA	Fixed or ulcerated regional lymph node metastasis
M Distant metastases		
M0		No distant metastases
M1	IVB	Distant metastasis (including pelvic lymph node metastasis)

Abbreviations: TNM = tumor, node, metastasis; FIGO = International Federation of Gynecology and Obstetrics.

**TABLE 5** Survival Rate by FIGO Stage for Patients With Invasive Squamous Cell Vulvar Cancer

FIGO STAGE	OVERALL SURVIVAL (PERCENT)		
	One year	Two years	Five years
I	96.4	90.4	78.5
II	87.6	73.2	58.8
III	74.7	53.8	43.2
IV	35.3	16.9	13.0

Abbreviation: FIGO = International Federation of Gynecology and Obstetrics.

component must be ruled out because it should be managed as a squamous cell carcinoma.

### Sarcomas

Leiomyosarcoma is the most common vulvar sarcoma and usually arises in the labia majora. Malignant fibrous histiocytoma is the second most common. Management of these lesions is radical vulvar excision.

## VULVOVAGINITIS

Method of

Heather L. Paladine, MD, MEd; and Urmi Desai, MD, MS

### CURRENT DIAGNOSIS

- The most common causes of vulvovaginitis are bacterial vaginosis, candidal vulvovaginitis, and *Trichomonas* infection.
- Vulvovaginitis should be diagnosed by a combination of patient history, physical examination findings, and office-based or laboratory testing. Patients should not be treated presumptively based on history and physical examination.
- Bacterial vaginosis is diagnosed based on at least three of four of the Amsel criteria: fishy vaginal odor spontaneously or with KOH testing; vaginal pH above 4.5; thin, homogeneous vaginal discharge; and clue cells on saline microscopy.
- Vulvovaginal candidiasis is diagnosed based on symptoms of a thick whitish discharge, itching, and/or discomfort together with budding or pseudohyphae on KOH microscopy or positive fungal culture.
- The gold standard for *Trichomonas* diagnosis is nucleic acid amplification testing.

### CURRENT TREATMENT

- Treatment of bacterial vaginosis is recommended for symptomatic women, and both oral and topical metronidazole (Flagyl tablet),<sup>1</sup> 500 mg PO MetroGel (75%) or topical clindamycin (Cleocin 2%) are first-line treatments for both pregnant and nonpregnant women.
- First-line treatment for symptomatic women with vulvovaginal candidiasis includes either oral fluconazole (Diflucan) or topical azole therapy for nonpregnant women; for pregnant women, topical therapy is preferred.
- First-line therapy for *Trichomonas* infection includes a 1-week course of metronidazole.
- Patients should be adequately counseled about treatment regimens for vaginitis, including potential weakening of condoms by oil-based topical therapies, and the importance of avoidance of sexual intercourse until treatment of bacterial vaginosis or *Trichomonas* is complete. The Centers for Disease Control and Prevention (CDC) no longer recommends that patients abstain from drinking alcohol while taking oral metronidazole.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

The term *vulvovaginitis* includes conditions that result in irritation of the vagina or vulva, causing symptoms of itching, burning, pain, odor, or discharge. Vulvovaginitis is a common condition in women's health, accounting for about 10% of office visits each year and affecting almost every woman at some point in her life. The three most common causes of vulvovaginitis are bacterial vaginosis (BV, accounting for up to 50% of cases in which a diagnosis is made), vulvovaginal candidiasis (VVC, accounting for 30% of cases), and *Trichomonas* (accounting for 15% to 20% of cases). The remaining diagnoses include genitourinary syndrome of menopause (GSM, formerly called *atrophic vaginitis*), inflammatory vaginitis, and allergic/irritant vaginitis. A specific cause is not found in up to 30% of patients.

### Risk Factors

Risk factors for vulvovaginitis vary by condition. Although BV is not a sexually transmitted infection, it occurs almost exclusively in women of reproductive age who are sexually active and more commonly in women with new or multiple sexual partners. BV is found more often in women who smoke cigarettes or douche.

VVC is more common in women who are immunosuppressed, such as those who have HIV or diabetes or are pregnant. Recent antibiotic use is also a risk factor.

*Trichomonas* is a sexually transmitted infection and is more likely to occur in women who have other sexually transmitted infections, who have multiple sexual partners, or who have had unprotected intercourse. As with many sexually transmitted infections, disparities exist in the prevalence of *Trichomonas*, with infections more commonly occurring in nonwhite, low-income, and formerly incarcerated people.

### Pathophysiology

In women of reproductive age, the normal vaginal environment is acidic, with a pH of less than 4.6. This is thought to be caused by the prevalence of lactobacilli, which produce lactic acid, as part of the normal vaginal flora; however, the exact mechanism is unclear. BV represents a shift in the normal vaginal flora to anaerobic bacteria. The mechanism of this shift is also not entirely clear but is associated with risk factors such as douching and intercourse, which may change the vaginal pH.

**TABLE 1** Diagnosis of Vulvovaginitis

CONDITION	SYMPTOMS	EXAMINATION FINDINGS	PH	MICROSCOPY FINDINGS
Normal	Discharge changes with menstrual cycle	Thin, clear or whitish discharge	Normal (4–4.5)	Epithelial cells, lactobacilli
Bacterial vaginosis	Fishy odor, vaginal discharge, vaginal discomfort/dyspareunia	Homogenous gray/white discharge	Elevated ( $\geq 4.6$ )	Clue cells on wet mount
Vulvovaginal candidiasis	Vulvar irritation or itching, vaginal discharge	Vulvar excoriations or erythema Thick, clumpy white discharge	Normal (4–4.5)	Pseudohyphae or budding yeast on KOH examination
<i>Trichomonas</i>	Foul-smelling discharge, vaginal pain or discomfort	Cervical inflammation with “strawberry cervix,” yellow-green frothy vaginal discharge	Elevated ( $\geq 4.6$ )	Mobile trichomonads on wet mount, white blood cells
Genitourinary syndrome of menopause (formerly <i>atrophic vaginitis</i> )	Vulvar itching, vaginal pain or discomfort, dyspareunia, vaginal dryness	Vulvar excoriations, clear vaginal discharge, thin friable mucosa with loss of vaginal rugae	Elevated ( $\geq 4.6$ )	May have white blood cells, parabasal cells, decreased lactobacilli
Irritant/allergic vaginitis	Vulvar or vaginal discomfort or pain	Vulvar or vaginal erythema, fissures, lichenification	Elevated ( $\geq 4.6$ )	May have white blood cells, parabasal cells, decreased lactobacilli
Inflammatory vaginitis	Vulvar or vaginal discomfort, pain, or burning Vaginal discharge	Purulent vaginal discharge Vaginal erythema or rash	Elevated ( $\geq 4.6$ )	Many white blood cells, parabasal cells, decreased lactobacilli

VVC is caused by infection with species of candidal fungi, most commonly *Candida albicans*. Some 10% to 30% of women may have candida organisms among their normal vaginal flora. Candidal infections result from an interaction among biologic, genetic, and environmental factors leading to differences in the host immune response, host susceptibility, and the virulence of different strains of *Candida*.

*Trichomonas* is a protozoan infection. The risk factors as already described are similar to those for other sexually transmitted infections.

### Prevention

Although previous studies have defined risk factors for BV, it is not known whether avoiding these risk factors (such as douching or unprotected intercourse) will reduce the risk. Studies that have looked at the prevention of recurrent BV through treatment with probiotics such as lactobacilli or other methods to maintain an acidic vaginal pH have not been conclusive.

Routine testing for conditions such as HIV or diabetes is not recommended in women with VVC unless they have other risk factors. Women who are prone to develop VVC after taking antibiotics can use topical or oral antifungal medications during their treatment with antibiotics. Although probiotics are commonly used for the prevention and treatment of VVC, they have not been well studied.

*Trichomonas* is a sexually transmitted infection; therefore prevention includes condom use or being in a monogamous relationship.

### Clinical Manifestations

Table 1 includes symptoms and physical examination findings for the common causes of vulvovaginitis. These symptoms can cause significant feelings of shame, distress, and decreased quality of life, especially in women with recurrent infections.

### Diagnosis

The diagnosis of vulvovaginitis is unreliable based on history and physical examination findings alone and should include office-based or laboratory testing to confirm. There is a risk of misdiagnosis or delay in diagnosis with presumptive treatment, as patients may get temporary relief of vulvovaginal symptoms with

**TABLE 2** Amsel Criteria

CRITERION	POSITIVE RESULT
Vaginal discharge	Thin homogeneous discharge
Odor of discharge	Fishy odor on testing with KOH
Vaginal pH	pH $\geq 4.6$
Microscopy	Clue cells on saline microscopy

Three positive criteria are needed for a diagnosis of bacterial vaginosis.

topical antifungals even if they do not have a fungal infection. Although newer laboratory tests have become available for the diagnosis of BV and VVC, the American College of Obstetricians and Gynecologists continues to recommend testing with history, examination, microscopy, and pH testing unless microscopy is not available. The newer tests include DNA testing for *Gardnerella vaginalis* or for the presence of vaginal sialidase activity for the diagnosis of BV as well as DNA testing for *Candida* species. The newer tests are also less cost-effective. Table 1 also includes pH and microscopy findings for causes of vulvovaginitis.

BV is traditionally diagnosed via the Amsel criteria (Table 2), although Gram stain is considered the gold standard. A positive diagnosis requires three out of four criteria: fishy vaginal odor or positive odor on testing of vaginal discharge with 10% potassium hydroxide (KOH); vaginal pH above 4.5; a thin, homogeneous vaginal discharge; and clue cells (epithelial cells with adherent bacteria (Figure 1) on microscopic examination of vaginal discharge with normal saline (wet mount).

VVC is diagnosed based on the combination of clinical signs and symptoms and either microscopy or fungal culture of vaginal discharge. Microscopy has a sensitivity of 50% to 70% for candidal vulvovaginitis; therefore fungal culture is recommended when microscopy is negative in a patient with typical symptoms. Figure 2 demonstrates microscopy results with KOH that are positive for yeast. Fungal culture can also identify non-*albicans* species of *Candida*, which may be more difficult to treat.

**Figure 1** Clue cells on saline microscopy. From Brunzel NA: *Fundamentals of urine & body fluid analysis*, ed 4, St. Louis, 2018, Elsevier.

**Figure 2** Candidal pseudohyphae on KOH microscopy. From Herran CP, Nucci MR: *Gynecologic pathology: a volume in the series foundations in diagnostic pathology*, ed 2, Philadelphia, 2021, Elsevier.

Nucleic acid amplification testing is recommended for the diagnosis of *Trichomonas* as microscopy is only 50% to 60% sensitive. Commercial DNA probe tests and a point-of-care antigen detection test are also available. Sensitivities may be lower with the newer tests, although this varies by test. [Figure 3](#) shows positive saline microscopy for *Trichomonas*.

### Differential Diagnosis

In addition to BV, VVC, and *Trichomonas*, other less common conditions can result in vulvovaginal symptoms. GSM was formerly known as *atrophic vaginitis* and results from a decrease in estrogen levels following menopause. Women who are breastfeeding or using progestin-only contraception also have a relative estrogen deficiency and may experience similar symptoms. GSM is characterized by vaginal dryness and discomfort and may also include urinary tract symptoms and clear vaginal discharge. GSM is a presumptive diagnosis made on characteristic examination findings in a postmenopausal woman once other causes of vaginitis have been excluded.

Vulvovaginitis may be caused by a reaction to irritant or allergen exposure. Triggers can include latex (used in condoms), spermicides, and chemicals in sanitary pads or toilet paper. This is

**Figure 3** *Trichomonas* on saline microscopy. From Mandell GL, Bennett JE, Dolin R: *Principles and practice of infectious diseases*, ed 7, Philadelphia, 2010, Churchill Livingstone Elsevier.

also a diagnosis of exclusion. In unclear cases, referral to an allergist for patch testing may be helpful.

Inflammatory conditions are thought to be underdiagnosed and may be responsible for many of the cases of vulvovaginitis that were not previously given a diagnosis. They occur more commonly in women who are perimenopausal. The patient has a purulent vaginal discharge with vulvovaginal erythema or rash, and microscopy characteristically demonstrates many white blood cells. The etiology is thought to be autoimmune.

### Treatment

#### Bacterial Vaginosis

Treatment of bacterial vaginosis is recommended to alleviate symptoms but may also be helpful in reducing susceptibility to other sexually transmitted diseases including HIV and those caused by *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis*. Treatment also reduces the risk of recurrence. Additionally, in pregnant women, treatment has been associated with potential decreases in adverse outcomes including late miscarriages and poor neonatal outcomes, although it may not have a significant impact on the prevention of preterm labor, as may have been thought in the past. Treatment is recommended for all symptomatic women. Both initial oral and topical therapies are acceptable treatments in pregnancy.

Initial and alternative treatment regimens are presented in [Table 3](#); considerations in choosing regimens include patient preference and cost. Of note, secnidazole (Solosec) is a newer oral agent that provides for one-time dosing; however, it may be cost-prohibitive for patients. The Centers for Disease Control and Prevention (CDC) no longer recommends avoidance of alcohol while patients are taking oral metronidazole. The previous warning was based on laboratory experiments and not on clinical data. Patients should also be counseled that oil-based topical therapies including clindamycin may weaken latex condoms or diaphragms. Additionally, to prevent recurrent infection, patients should be counseled to avoid sexual intercourse until after completion of therapy and to avoid douching.

#### Vulvovaginal Candidiasis

The rationale for the treatment of vulvovaginal candidiasis is relief of symptoms. Treatment regimens for VVC are listed in [Table 4](#) for initial treatment and treatment of recurrence. In non-pregnant patients, the choice between oral and topical azoles can be based on patient preference. Those patients who are prescribed topical therapies should be counseled that topical azole preparations may be oil based and can weaken latex condoms. Topical therapies may cause local irritation or hypersensitivity reactions, although systemic effects are not of concern. Oral azoles can cause nausea, abdominal pain, headache, and rarely elevations in

**TABLE 3** Treatment of Bacterial Vaginosis

Initial regimens	Metronidazole (Flagyl) <sup>1</sup> 500 mg PO bid for 7 days OR Metronidazole 0.75% gel (MetroGel), one full applicator (5 g) intravaginally daily for 5 days OR Clindamycin 2% cream (Cleocin), one full applicator (5 g) intravaginally hs for 7 days
Alternative regimens	Secnidazole (Solosec) 2 g PO once Tinidazole (Tindamax) 2 g PO daily for 2 days OR Tinidazole 1 g PO once daily for 5 days OR Clindamycin <sup>1</sup> 300 mg PO bid for 7 days OR Clindamycin ovules 100 mg intravaginally hs for 3 days
Pregnancy	Either oral or vaginal regimens suggested in initial treatment section
Treatment of recurrence	First recurrence: retreat of same regimen or trial of alternative initial regimen Multiple recurrences: Metronidazole 0.75% gel, intravaginally twice weekly for 4 to 6 months <sup>3</sup>

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

liver function tests. For pregnant patients, only topical therapies should be prescribed.

For those with severe VVC or with immunocompromise, longer treatment may be necessary, such as a 7- to 14-day course.

For recurrent VVC (four or more episodes within a year), longer duration of initial therapy followed by maintenance therapy is recommended. Non-*albicans* VVC should also be considered and appropriate diagnostic testing performed to guide treatment, which may include a 7- to 14-day course of an azole topical or oral regimen (other than fluconazole [Diflucan]) and potentially a 2-week course of treatment with boric acid<sup>6</sup> if recurrent.

### Trichomonas

The rationale for the treatment of *Trichomonas* infection includes a decrease of symptoms and reduced transmission to sexual partners. *Trichomonas* infection in pregnant women is associated with adverse outcomes including preterm birth and low-birth-weight infants; however, treatment has not shown a definite reduction in these outcomes. For patients with HIV, *Trichomonas* infection is associated with pelvic inflammatory disease; thus screening and treatment can help prevent this complication. Regimens for initial therapy and treatment of recurrence are listed in Table 5. The CDC no longer recommends single-dose treatment for *Trichomonas* infection in women; a 7-day course has been shown to be more effective.

Persistent or recurrent *Trichomonas* infection is often caused by reinfection. When patients are being counseled about treatment, they should be advised to avoid intercourse until treatment is completed, symptoms have resolved, and partners have been treated. All patients diagnosed with *Trichomonas* should be asked to inform partners of the need for presumptive treatment. Additionally, patients should be retested within 3 months of diagnosis to ensure adequate treatment and address potential reinfection. In cases in which treatment-resistant infection is suspected, a 1-week regimen should be attempted. If the infection still persists, further testing should be implemented according to guidance from the CDC.

<sup>6</sup>May be compounded by pharmacists.

**TABLE 4** Treatment of Vulvovaginal Candidiasis

Initial regimens	<i>Topical azole therapy:</i> Clotrimazole (Gyne-Lotrimin) 1% cream 5 g intravaginally daily for 7 to 14 days OR Clotrimazole 2% cream 5 g intravaginally daily for 3 days OR Miconazole 2% cream 5 g intravaginally daily for 7 days OR Miconazole 4% cream 5 g intravaginally daily for 3 days OR Miconazole 100 mg vaginal suppository, one suppository daily for 7 days OR Miconazole 200 mg vaginal suppository, one suppository for 3 days OR Miconazole 1200 mg vaginal suppository, one suppository for 1 day OR Tioconazole (Vagistat) 6.5% ointment 5 g intravaginally in a single application  <i>Prescription intravaginal agents:</i> Butoconazole (Gynazole) 2% cream (single-dose bioadhesive product), 5 g intravaginally in a single application OR Terconazole (Terazol) 0.4% cream 5 g intravaginally daily for 7 days OR Terconazole 0.8% cream 5 g intravaginally daily for 3 days OR Terconazole 80 mg vaginal suppository, one suppository daily for 3 days OR Fluconazole (Diflucan) 150 mg PO once
Alternative regimens	N/A
Pregnancy	Topical azole therapy applied intravaginally for 7 days
Treatment of recurrence	Topical azole therapy for 7 to 14 days OR Fluconazole 150 mg every third day for three doses <sup>3</sup> For maintenance: Oral fluconazole (100, 150, or 200 mg) weekly for 6 months <sup>3</sup> ; consider topical treatment if oral is not feasible

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

**TABLE 5** Treatment of Trichomonas Infection

Initial regimens	For women: Metronidazole (Flagyl) 500 mg PO bid for 7 days For men: Metronidazole 2g PO in a single dose
Alternative regimens	Tinidazole 2 g orally in a single dose
Pregnancy	Metronidazole 500 mg PO bid for 7 days
Treatment of recurrence	Trial of metronidazole, 500 mg bid for 7 days <i>If metronidazole 500 mg bid for 7 days fails:</i> Trial of metronidazole, 2 g daily for 7 days <i>If above regimens fail:</i> Consider susceptibility testing (contact Centers for Disease Control and Prevention)

## Noninfectious Vaginitis

Treatment of genitourinary syndrome of menopause includes low-dose vaginal estrogen therapy or topical lubricant therapy for less severe symptoms. Inflammatory vaginitis is still not well understood, although long-term maintenance therapy with topical clindamycin<sup>1</sup> or steroids may be helpful.

---

<sup>1</sup>Not FDA approved for this indication.

## Pregnancy and Antepartum Care

### ANTEPARTUM CARE

Method of

Matthew K. Cline, MD; and Natawadee Young, MD

### CURRENT DIAGNOSIS

- Pregnancy evaluation should begin 3 to 6 months before conception with optimization of underlying medical conditions, update of immunizations, and commencement of prenatal vitamins with 400 µg of folic acid.<sup>1</sup>
- Preconception counseling with a specialist in high-risk pregnancies should be considered in all patients with underlying medical conditions, such as diabetes and hypertension.
- Early ultrasound (< 13 weeks) assists with establishment of accurate estimated date of confinement and is an essential task in the first prenatal visit.
- The first prenatal visit should include a review of the medical and obstetric histories, current medications, allergies, herbal remedies, supplements, and tobacco, alcohol, and drug use.
- Prenatal laboratory studies should be done at the first visit after a pregnancy is confirmed with a urine pregnancy test. These studies include hemoglobin, platelet count, blood and Rh type and antibody screening, rubella status, hepatitis B and C screening, syphilis screen, and a urine culture. All women should be screened for HIV. High-risk patients should be screened for gonorrhea and chlamydia.
- Genetic screening should be offered based on ethnic history.
- Offer aneuploidy screening to all women in the first trimester along with counseling about risks and benefits. These tests aid in diagnosis of chromosome abnormalities. If a patient opts for a first-trimester screen, it is important to perform an alpha-fetoprotein (AFP) screen in the second trimester to screen for neural tube defects. All women should be offered amniocentesis or chorionic villous sampling for genetic testing with appropriate counseling.
- Appropriate weight gain in pregnancy depends on maternal body mass index (BMI) before pregnancy. In patients with a normal BMI, a 25- to 30-pound weight gain is recommended. Underweight patients are encouraged to gain 30 to 35 pounds, and overweight patients are encouraged to gain no more than 20 pounds.
- Prenatal visits should begin at 8 to 12 weeks' gestation and continue monthly until 28 weeks. Visits should then be every 2 weeks until 36 weeks and then weekly. Each visit should include assessment of maternal weight, blood pressure (BP), fundal height measurement, documentation of fetal heart tones, and review of symptoms of preterm labor and preeclampsia.
- All patients should undergo a glucose challenge test at 24 to 28 weeks. This is done nonfasting by administering a 50-g load of glucose and obtaining a serum sample 1 hour after administration. A level greater than 140 mg/dL is considered abnormal, and a 3-hour glucose tolerance test is indicated (which is done after a 12-hour fast with a 100-g oral glucose load). If a woman demonstrates abnormalities in two of the four values, gestational diabetes is diagnosed.

<sup>1</sup>Not FDA approved for this indication.

### CURRENT THERAPY

- Administration of the inactivated influenza vaccine (Fluzone, Fluvirin, Fluarix) is recommended in all pregnant patients, regardless of trimester, who will be pregnant (or up to 3 months postpartum) during the flu season.
- Additionally, administer Tdap vaccine (Adacel, Boostrix) in each pregnancy given between 27 and 36 weeks or immediately postpartum in order to decrease rates of pertussis in this age group.
- Vaccination during pregnancy for protection against Covid-19 is a rapidly changing area of preventive therapy. The most updated recommendations can be accessed at the CDC website at <https://www.cdc.gov/coronavirus/2019-ncov/vaccines/recommendations/pregnancy.html>.
- Folic acid supplementation<sup>1</sup> should begin before conception. The recommended dose is 400 µg daily and is usually given as a prenatal vitamin. In patients with a previous pregnancy complicated by a neural tube defect, 4 mg daily<sup>3</sup> is recommended to decrease the chance of recurrence of a neural tube defect.
- All patients with HIV should be treated with appropriate HAART (highly active anti-retroviral therapy) for the patient and her HIV viral type throughout the pregnancy.
- Intrapartum zidovudine (Retrovir) is recommended for all patients with HIV whose HIV RNA load is ≥ 50 copies/ml or who have concerns with adherence to HAART therapy. Consideration of cesarean delivery is appropriate based on viral load evaluation.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

### Antepartum Care

Ideally, antepartum care commences 3 to 6 months before conception with the recommendation that women who are sexually active and not using contraception should begin taking daily multivitamin or folic acid supplements. The most convincing trials of this were performed in Europe and China when it was concluded that women of reproductive age should take multivitamin supplements containing 0.4 mg of folate daily to reduce the incidence of neural tube defects. Women with histories of children with neural tube defects or other anomalies should increase this dose to 4 mg<sup>3</sup> of folate in the periconceptional period to reduce risks of recurrence.

Preconception counseling should also include an accurate assessment of preexisting maternal medical conditions. This is the ideal time to stress changes in factors that respond to early intervention: quitting smoking, refraining from alcohol or drug abuse, treating gum disease, and avoiding teratogens. Alcohol is a known teratogen. Immunization status should be reviewed and vaccines should be administered as appropriate. Special consideration is given to patients with thyroid disease. Concern focuses on associations with low intelligence quotients (IQs) in children conceived by hypothyroid mothers. Patients with diabetes should

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

**BOX 1** Potential Indications for High-Risk Referral

- Current disease involving renal, cardiac, or endocrine systems
- Fetal anomalies (in previous pregnancies or first-degree family relatives)
- History of preterm delivery
- Incompetent cervix or recurrent miscarriages
- Isoimmunization
- Known carrier of genetic disorder
- Multiple gestation
- Placenta previa after 28 weeks
- Prior intrauterine fetal demise or stillbirth
- Systemic diseases such as hypertension, diabetes, or asthma
- Third-trimester bleeding

be counseled that the increased risk of birth defects is directly related to the level of glucose control at conception.

High-risk obstetric referrals may be offered to women with potential for obstetric complications suggested by conditions listed in **Box 1**. Identification of the high-risk patient is critical to minimizing adverse outcomes.

In most cases, a woman's pregnancy is a normal event that is complicated by potentially dangerous disease in a minority of cases. The physician who manages pregnant patients must follow the normal changes that occur during antepartum care, so that abnormalities can be recognized and treated appropriately. Additionally, routine prenatal care offers multiple opportunities for patient education, primary intervention, and appropriate monitoring of the low-risk pregnancy in the setting of the family and community. For some women, antepartum care is part of their own continuum in a long-term primary care relationship with caregivers.

### Timeline of Routine Antepartum Care

#### First Visit and Early Care

##### History

After pregnancy is confirmed, it is extraordinarily important to determine the duration of pregnancy and the estimated date of confinement (EDC). Further care is heavily predicated on this estimate. The history begins with ascertaining the first day of the last normal menstrual period and calculating the EDC by assuming duration of pregnancy averages 280 days (40 weeks). Because a first-trimester dating ultrasound (US) is accurate to within 5 days at confirmation or determination of an accurate EDC, its value cannot be overestimated.

The documentation of prior obstetric history includes prior complications, route of delivery, and estimated birth weights. Maternal medical disorders are often exacerbated by pregnancy; cardiovascular, renal, and endocrine disorders require evaluation and counseling concerning possible treatments required. A history of previous gynecologic surgery, including cesarean delivery, is important to consider. A family history of twinning, diabetes mellitus, familial disorders, or hereditary disease is relevant.

Current medications (prescription and nonprescription) are reviewed, along with any herbals or supplements. Certain prescription medications are known teratogens and should be discontinued. Examples include isotretinoin (Accutane), tetracycline (Sumycin), quinolone antibiotics (ciprofloxacin [Cipro], levofloxacin [Levaquin]), "statin" cholesterol-lowering medications such as atorvastatin (Lipitor) and rosuvastatin (Crestor) and warfarin (Coumadin). Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) should not be used in pregnancy because they can be associated with fetal renal agenesis.

It is important to determine the pregnant patient's risks for developing preeclampsia during the first trimester prenatal visit because starting low dose aspirin<sup>1</sup> (81 mg) between 12 to 28

weeks (ideally before 16 weeks' gestation) can prevent morbidity and mortality from preeclampsia. One or more of the following high-risk factors is an indication for beginning low dose aspirin after 12 weeks: a history of previous preeclampsia, multifetal gestation, renal disease, autoimmune disease, diabetes, and chronic hypertension. Consideration of low dose aspirin should be given for patients with more than one of moderate-risk factors for preeclampsia including obesity, advanced maternal age, history of low birth weight infants or adverse birth outcomes, and low socioeconomic status or African American race.

Open discussion of substance abuse (alcohol, tobacco, and illicit drugs) is an integral part of the patient interview. Counseling patients about smoking cessation is vital in early pregnancy. Smoking increases the risk of fetal death or damage in utero. It is also associated with increased risk of placental abruption and placenta previa, each of which put both mother and child at risk, along with premature birth. The interest that pregnant women have in delivering a healthy infant can be a potent motivator for change at this point.

Opioid use in pregnancy has escalated in the last decade. Early screening for opioid use, misuse, and for opioid use disorder along with brief intervention and referral is recommended for all pregnant women. Pregnant women with opioid use disorder should be referred to psychosocial resources and to a qualified clinic or treatment center that is able to assist in managing the patient with methadone or buprenorphine throughout the pregnancy and postpartum period. Medically assisted withdrawal is currently not recommended in pregnancy due to the high risk for relapse and the associated harms that occur with addiction. Patients and care teams should be prepared for the risk of neonatal abstinence syndrome if there is continued opioid or other illicit drug use during pregnancy.

#### Domestic Violence Screening and Counseling

Pregnancy is also a time of increased incidence of domestic or intimate partner violence, and because of this, it is appropriate to screen patients about the safety of their homes and relationships starting at the first prenatal visit. The United States Preventive Services Task Force (USPSTF) gives screening for domestic or intimate partner violence a "B" rating, supporting its use in routine prenatal care. A large evidence review supports benefit to patients being screened with one of many possible screening tools. The Personal Violence Screen consists of three "Yes" or "No" questions that can be quickly administered to a patient in private, and a positive result is one or more "Yes" responses:

1. Have you been hit, kicked, punched, or otherwise hurt by someone in the past year?
2. Do you feel unsafe in your current relationship?
3. Is there a partner from a previous relationship who is making you feel unsafe now?

A positive screen should be followed by specific referral to local resources for the patient to reach a safe environment and continued support. Each office should evaluate local resources and have a prepared contact list for these patients to use as their next step to safety.

#### Examination

Physical examination begins with a thorough general examination to assess maternal well-being, including BMI and BP. The BMI is calculated by dividing weight in kilograms by height in meters squared. The BMI of a patient is categorized as underweight (under 19.8), normal weight (19.8 to 25), overweight (25 to 30), or obese (over 30).

Breast examination may be significant for changes in pregnancy that result from hormonal responses by the mammary ducts. These changes include engorgement and vascular prominence, occasionally resulting in mastodynia. Enlargement of areolar sebaceous glands occurs between 6 and 8 weeks' gestation.

A pelvic examination is performed with attention to the adequacy of pelvis and evaluation for adnexal masses. Numerous changes in the pelvic organs occur in pregnancy. For example, congestion of the pelvic vasculature (Chadwick's sign) causes bluish discoloration of the vagina and cervix. Softening of the cervix

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** U.S. Preventive Services Task Force Recommendations for Pregnancy

**Grade A** = The USPSTF recommends the service. There is high certainty that the net benefit is substantial. Screening/actions in pregnancy in this category include the following:

- Screen for hepatitis B infection in all pregnant women.
- Screen for HIV infection in all pregnant women.
- Screen for syphilis in all pregnant women.
- Screen for cervical cancer in all women between 21 and 65 who have a uterus.
- Ask about smoking and provide augmented, pregnancy-tailored counseling for those who smoke and are pregnant.
- All women planning or capable of pregnancy should take 400–800 µg of folic acid daily.
- Screen all women at the first visit by Rh(D) typing and antibody screen.

**Grade B** = The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial. Screening/actions in pregnancy in this category include the following:

- Screen for asymptomatic bacteriuria at 12 to 16 weeks or at first prenatal visit.
- Screen for chlamydia in pregnant women 24 and younger or at high risk.
- Screen for gonorrhea if at high risk of infection.
- Screen for Hepatitis C in all persons aged 18–79.
- Provide intervention during pregnancy and after birth to support breast-feeding.
- Screen for alcohol misuse and provide behavioral counseling interventions to reduce its misuse.
- For women at high risk of preeclampsia, start low-dose aspirin<sup>1</sup> at 81 mg/day after 12 weeks of gestation.
- Screen for gestational diabetes mellitus (GDM) in asymptomatic pregnant women after 24 weeks of gestation.
- Screen for depression in pregnant and postpartum women.
- Screen women of childbearing age for intimate partner violence (IPV), such as domestic violence, and provide or refer women who screen positive to intervention services.
- Screen throughout pregnancy for preeclampsia by blood pressure measurement.
- Repeat Rh(D) antibody testing for all unsensitized women at 24–28 weeks.

**Grade C** = Clinicians may provide this service to selected patients depending on individual circumstances. However, for most individuals without signs or symptoms there is likely to be only a small benefit from this service.

**Grade D** = The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.

- Screen for bacterial vaginosis in asymptomatic pregnant women at low risk for preterm birth.
- Screen for herpes simplex with serology in asymptomatic pregnant women.

**Grade I** = The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service.

- Screen for iron deficiency anemia in asymptomatic pregnant women.
- Screen for illicit drug use in pregnancy.
- Screen for elevated blood lead levels in asymptomatic pregnancy women.

Listing of all topics is available at <https://www.uspreventiveservicestaskforce.org/BrowseRec/Index/browse-recommendations>.

Abbreviation: USPSTF = U.S. Preventive Services Task Force.

<sup>1</sup>Not FDA approved for this indication.

due to increased vascularity of the cervical tissue (Goodell's sign) can occur as early as 4 weeks.

Portable devices using Doppler will reliably detect fetal heart tones at a normal rate of 120 to 160 beats per minute as early as 11 weeks.

### Laboratory Studies

Routine laboratory studies and screenings in pregnancy are listed in Table 1, along with their USPSTF level of recommendation.

### Other Studies

Aneuploidy screening for common chromosomal abnormalities should be offered to all women, with counseling about risks and benefits. Current strategies include either cell free DNA aneuploidy screening or the more traditional maternal serum biomarker tests (PAPP-A/b-HCG) with or without nuchal translucency measurement. Invasive diagnostic testing for fetal chromosomal disorders through either chorionic villus sampling or amniocentesis is offered to all women, but especially if patients have increased risk or if the screening tests are abnormal. Second trimester screening for neural tube defects with maternal serum alpha fetoprotein is offered to all women. Second trimester fetal anatomy ultrasound evaluation is also offered around 20 weeks of gestation. Women may decline all screening and testing options after informed counseling.

Cell-free DNA screening was utilized primarily after 10 weeks in high-risk women such as those with prior aneuploidy, or older than age 35. However, there is now evidence using cell-free DNA screening in the general population, and results appear to be comparable. It has the highest detection rate (DR) for Down syndrome in high-risk women (98% DR with positive screening rates of less than 0.5%, positive predictive value of 93%). Positive predictive values are lower for trisomy 18 (64%), trisomy 13(44%), and sex chromosome aneuploidies (39%). However, it must be emphasized that for younger or low-risk women, false positive rates will be higher because of a lower pretest probability in these populations. In addition, the test cannot distinguish between fetal and maternal DNA, and causes of false positive screening tests can include placental mosaicism, a resorbing twin, or even maternal malignancy or aneuploidy. For this reason, ACOG recommends diagnostic testing with CVS or amniocentesis after a positive cell-free DNA screen prior to decisions about termination of the pregnancy. Cell-free DNA screening testing after a positive first trimester screen can also add additional information prior to diagnostic invasive tests. Appropriate pre and posttest counseling is important due to these evolving issues.

Chorionic villus sampling (CVS) (done at 10–12 weeks' gestation) or amniocentesis (performed at 14–16 weeks' gestation) should be offered to women older than 35 years, to those with abnormal first-trimester screens or second trimester "quad" screens, and to those with significant family history of genetic disease. From either test, fetal cells grown in culture may be subjected to chromosomal, metabolic, or DNA study for trisomy 13, 18, or 21 or abnormal numbers of sex chromosomes. CVS cannot be used for diagnosis of neural tube defects, but amniocentesis can accurately diagnose open neural tube defects or open abdominal defects by measuring amniotic fluid AFP.

Patients with tuberculosis exposure may be assessed for active tuberculosis with skin testing (if not vaccinated with Bacillus Calmette-Guérin [BCG]) and chest x-ray with abdominal shielding. Serologic assessment for toxoplasmosis, cytomegalovirus, and varicella immunity are not routinely indicated.

Currently it is recommended that all pregnant couples of Caucasian background be screened for being carriers of cystic fibrosis genes. Additionally, screening for genetic disorders should be undertaken if concern exists based on racial or ethnic background (hemoglobinopathies,  $\beta$ -thalassemia,  $\alpha$ -thalassemia, Tay-Sachs disease) or familial background (cystic fibrosis, fragile X, Duchenne's muscular dystrophy).

### Education

Several areas are appropriate for routine education during the first prenatal visit, and may be provided by handouts, nursing instruction, or directly by the physician. These will vary based on the patient's individual knowledge and prior experience, but at a minimum should include discussions of the following:

- Common discomforts of pregnancy and safe methods to relieve them
- Foods to avoid during pregnancy and safe food preparation
- Avoidance of tobacco, ethanol, and nonprescribed drugs throughout pregnancy

- Limitations on travel and importance of proper seatbelt use
- Danger signs of pregnancy and reasons to call or be seen after hours
- Availability of birth education classes, tours, and other educational resources

### Follow-up

Follow-up visits are scheduled once monthly until 28 weeks' gestation, and then patients are followed twice monthly until 36 weeks. Visits are then scheduled at weekly intervals until delivery. At each visit, weight, BP, fetal heart tones, and fundal height are noted. In the last 6 weeks of pregnancy, assessing fetal position is also appropriate.

Interval history includes questions about diet, sleeping patterns, and fetal movement. Warning signs such as bleeding, contractions, leaking of fluid, headache, or visual disturbances are reviewed.

### 15 to 20 Weeks' Gestation

#### Interval History

At each visit, it is appropriate to ask about specific symptoms: headache, dysuria, swelling, vaginal discharge, any bleeding, pelvic pain, and nausea or vomiting. The nausea and vomiting of the first trimester usually begins to decrease after 12 to 14 weeks. By this point in the pregnancy, the patient is usually feeling well. The other items above, if present, may indicate reasons for a targeted examination to evaluate for the cause, such as a speculum examination with wet prep for an increased symptomatic discharge (though the physiologic discharge of pregnancy has often become evident by this point, it should be asymptomatic).

#### Alpha-Fetoprotein and Aneuploidy Testing

For patients who received first-trimester aneuploidy screening, maternal serum AFP testing should be offered for all pregnancies at 16 to 20 weeks as a means of screening for open neural tube defects. High levels of AFP are associated with various fetal anomalies, including neural tube defects, multiple gestations, and ventral wall defects. Unexplained elevation of AFP has been associated with poor fetal growth, fetal loss, and preeclampsia. In cases with unexplained elevation of AFP, maternal and fetal surveillance should be increased. Low levels of AFP are associated with increased risk of Down syndrome.

For those who did not have the first trimester screen, a "quad screen" with multiple analytes can be done at this time to screen for aneuploidy such as trisomy 21, 18, and 13 as well. The interpretation of this test depends on the gestational age; even if timed correctly, it is known to have a moderate level of false-positive results. Therefore the first step after an abnormal AFP or quad screen is to refer for a detailed ultrasound to confirm gestational age and assess fetal anatomy. If the results of the screening remain abnormal, definitive testing via amniocentesis is recommended.

#### Physical Findings

Interval changes in the physical examination now include the start of colostrum secretion, which can begin as early as 16 weeks' gestation. The mother might detect fetal movements (quickening) at around 18 to 20 weeks. The uterus is palpable at 20 weeks at the umbilicus.

Chloasma is darkening of the skin over the forehead, bridge of the nose, or cheekbones and is more obvious in those with dark complexions. It can begin to manifest at this time, and is intensified by exposure to sunlight. Darkening of the skin in the areolae and nipples becomes more accentuated. A darkened line appears in the lower midline of the abdomen from the umbilicus to the pubis (linea nigra). The basis of these changes is stimulation of melanophores by increased melanocyte-stimulating hormone.

At 15 to 20 weeks, abdominal enlargement can appear more rapid as the uterus rises out of the pelvis and into the abdomen.

### Ultrasonography

Sonography has long established itself as the single most useful technology in monitoring pregnancy and diagnosing complications. It is for this reason that an anatomic US is offered at 18 to 20 weeks to evaluate growth, placentation, amniotic fluid volume, and fetal anatomy. If earlier dating of the pregnancy is uncertain, this is an opportunity to confirm or refute prior estimates. If anomalous conditions are discovered or the patient has a history of diabetes, advanced maternal age, or has prior children with anomalies, more comprehensive US becomes necessary.

### 20 to 35 Weeks' Gestation

#### Interval History

This period in the middle trimester of the pregnancy is often the time when patients feel their best: the challenges of nausea and vomiting from the first trimester are usually past. Patients should be asked about diet and activity, fetal activity (which should continue to increase throughout this period), and any symptoms that might suggest preeclampsia, such as hand or face swelling, visual changes, or severe headaches. Vaginal secretions do increase during this period but any bleeding or leakage of a large amount of fluid, along with any uterine rhythmic contractions, should also prompt a call or evaluation of the patient.

#### Physical Findings

The uterus should be palpable at the umbilicus at 20 weeks, and from this period until 34 weeks the measurement in centimeters from the fundus to the symphysis pubis should correspond to the gestational age in weeks. Measurements that are more than 2 cm below the expected size should raise suspicion for oligohydramnios, intrauterine growth restriction, fetal anomalies, or an abnormal fetal position. Conversely, measurements more than 2 cm larger than expected may indicate multiple gestation, polyhydramnios, or fetal macrosomia. These rules apply for the gestational ages of 20 to 34 weeks. Either situation can be evaluated with maternal US examination and consultation with a maternal-fetal-medicine specialist.

New physical examination findings at this time include the onset of stretch marks (striae) of the breasts and abdomen. These are caused by separation of underlying collagen tissue, a response to increased adrenocorticosteroid. The ligamentous structures of the pelvis also undergo slight but definite relaxation of the joints, a progesterone effect. As the uterus enlarges, it often rotates to the right. Braxton-Hicks contractions, characterized as painless uterine tightening, increase in regularity. The fetal outline can be easily palpated through the maternal abdominal wall.

#### Laboratory Studies

Increased surveillance for preeclampsia should occur in any patient with a previous history of preeclampsia or chronic hypertension predating the pregnancy. Newer guidelines require only two blood pressures 4+ hours apart that are 140/90 or greater for the diagnosis of preeclampsia along with 1+ urinary protein, a urinary protein to creatinine ratio of 0.3 or greater, or >300 mg of protein in a 24-hour urine collection. Further evaluation for patients with elevated BP (>140/90) should include evaluation for symptoms or findings that are consistent with severe features: headaches, visual changes, pulmonary edema, RUQ pain or epigastric pain, BP of 160 or higher systolic or 110 or higher diastolic on two occasions 4 hours apart, or laboratory evidence of thrombocytopenia (platelets below 100,000), liver transaminases elevated to at least twice the normal level, a serum creatinine that has doubled or is greater than 1.1. If any severe feature is present, the diagnosis of preeclampsia does not require proteinuria. Once the diagnosis of preeclampsia is made, management will be based on gestational age as well as presence of severe features. For additional details, please see chapter "Hypertension in Pregnancy."

A complete blood count (to screen for anemia) and a nonfasting 1-hour glucose tolerance test (after ingestion of 50 g of glucose) are scheduled to detect patients at risk for developing gestational diabetes at 24 to 28 weeks. If the screening test is abnormal, a

- Burning with urination
- Chills or fever
- Prolonged vomiting or inability to keep liquids down
- Pronounced decrease in fetal movements
- Rhythmic cramping pains (> 4/hr)
- Rupture of membranes
- Severe abdominal, pelvic, or back pain
- Signs of preeclampsia (headache, edema, right upper quadrant pain, visual changes)
- Vaginal bleeding (though spotting may occur after any pelvic examination)

3-hour test is performed with 100 g of glucose to confirm the diagnosis. Two or more abnormal values on this test are considered diagnostic of gestational diabetes mellitus.

A repeat Rh antibody is checked at 28 weeks' gestation in Rh-negative mothers. Those who remain unsensitized at 28 weeks' gestation receive a first dose of Rho(D) immune globulin (RhoGAM) of 300 µg to prevent maternal isoimmunization to fetal red blood cells. (This should also be given at any point after the first 12 weeks of pregnancy in the setting of significant maternal trauma in an Rh-negative mother. If there is suspicion of a significant fetal-maternal hemorrhage, a Kleihauer-Betke test can be used to quantitate the amount of fetal blood in the maternal circulation in order to increase the dose of RhoGAM appropriately.)

#### Follow-up

Return visits at 2-week intervals are initiated beginning at 28 weeks, and the patient is oriented to the labor and delivery ward. Precautions are given regarding the onset of conditions listed in [Box 2](#). The onset of any of these should prompt immediate medical attention.

### 36 to 41 Weeks' Gestation

#### Physical Findings

Patients often note increased vaginal discharge at this time in their pregnancy, a physiologic consequence of hormone stimulation. The discharge consists mainly of epithelial cells and cervical mucus and is treated with reassurance. Discharge accompanied by itching, burning, or malodor should be evaluated with a wet prep and any abnormalities treated.

#### Laboratory Studies

Vaginal and rectal rapid molecular tests are collected to evaluate for the presence of group B streptococci (GBS) at 36 0/7 to 37 6/7 weeks. GBS organisms are implicated in preterm labor, amnionitis, endometritis, and wound infection. If tests are positive, the patient will be given antibiotic prophylaxis during active labor to protect the newborn against vertical transmission and the resulting infection that could occur. If a patient has a positive urine testing during the pregnancy of over 100,000 colony-forming units of GBS, she is treated at the time of that culture but also assumed to be heavily colonized and given intrapartum antibiotics without performing the vaginal/rectal cultures at 36 0/7 to 37 6/7 weeks.

#### Follow-up

Follow-up visits are planned on a weekly basis with emphasis on weight gain, BP, and signs of preeclampsia. Review of precautions regarding infection, pregnancy loss, and symptoms of preeclampsia completes the visit.

### Late Term and Postterm Gestation

About 6% of pregnancies continue beyond 42 weeks and are considered postterm. The period between 41 0/7 and 41 6/7 weeks is

named late term pregnancy. Due to increased perinatal morbidity and mortality beginning at 41 0/7 weeks, guidelines recommend elective induction of labor at 41 weeks after shared decision-making with patients. Should the patient decline induction, then experts recommend fetal surveillance twice weekly between 41 and 42 weeks gestation with nonstress testing, amniotic fluid measurement, or the biophysical profile, followed by induction of labor at 42 weeks gestation.

### Common Concerns of the Antenatal Period

#### Bleeding

About one-half of pregnant women experience some form of bleeding during the pregnancy; often this is benign. Patients also have a heightened awareness of symptoms that previously may have gone unnoticed in the nonpregnant state. Efficient and competent evaluation, followed by compassion and reassurance when prudent, allays many fears and provides clear direction. Spotting due to bleeding at the implantation site occurs from the time of implantation (about 6 days after fertilization) until 29 to 35 days after the last menstrual period in many women. Usually, cardiac activity on US and appropriate β-hCG levels confirm a viable early pregnancy. First-trimester bleeding may be a sign of spontaneous miscarriage or ectopic pregnancy and deserves further evaluation, often with a pelvic examination and US. Vaginal bleeding in late pregnancy is covered in other chapters.

#### Nausea

Nausea is a common symptom that occurs in most pregnancies. It is heightened before 14 weeks' gestation and is largely benign. The etiology is not well understood but likely is related to elevating levels of β-hCG. Nausea of pregnancy can occur at any time during the day. Aggravating factors vary with the individual patient; success varies with interventions designed to reduce symptoms.

Uncomplicated nausea may be responsive to small nonfatty portions at mealtime. Pyridoxine (vitamin B<sub>6</sub>)<sup>1</sup> tablets 12.5 mg three times daily with 12.5 mg of doxylamine (Unisom)<sup>1</sup> twice a day are safe in pregnancy and may be helpful. A combination product of doxylamine 10 mg and pyridoxine 10 mg (Diclegis) is approved by the FDA for the treatment of nausea and vomiting of pregnancy in women who do not respond to conservative management. Antiemetic drugs in the outpatient setting are the next step; ondansetron (Zofran, FDA category B)<sup>1</sup> 4 to 8 mg up to three times a day and meclizine (Antivert, FDA category B)<sup>1</sup> 12.5 to 25 mg three times a day are agents with the best safety profile.

Inability to control protracted vomiting in conjunction with clinical dehydration can require hospitalization for IV fluids and treatment of hyperemesis gravidarum. Extreme nausea and vomiting that persists beyond 18 to 20 weeks' gestation may be a sign of multiple gestation, thyroid disease, molar pregnancy, or liver or pancreatic disease.

#### Nutrition and Weight Gain

The mother's nutrition is a vital factor in the development of the fetus from preconception through the postpartum period. Therefore, the pregnant woman should be advised to eat a balanced diet and should be informed of the additional 300 kcal/day needed during pregnancy. The American College of Obstetricians and Gynecologists (ACOG) recommends a target weight gain of 22 to 27 pounds (10–12 kg) during pregnancy. It also advises that underweight women might need to gain more and obese women should gain less. Nutritional requirements for protein are 80 g/day, for calcium are 1500 mg/day, for iron are 30 mg/day, and for folate are 0.4 mg/day (4 mg/day in some cases, such as those patients with previous baby with neural tube defects). Patients with seizure disorders managed with valproic acid (Depakene) or carbamazepine (Tegretol) are also at risk for birth defects and might benefit from the higher dose of folate.

<sup>1</sup>Not FDA approved for this indication.

## Heartburn

Heartburn in the form of reflux esophagitis is caused by the enlarging uterus displacing the stomach and by progesterone's relaxation of the lower esophageal sphincter. Treatment consists of taking antacids, decreasing exacerbating factors such as spicy foods, eating more frequently but in smaller quantities, limiting eating before bedtime, and taking H<sub>2</sub>-blockers.

## Urinary Symptoms

Urinary frequency, nocturia, and bladder irritability are common complaints due to progesterone-mediated relaxation of smooth muscle and subsequent altered bladder function. Later in pregnancy, urinary frequency becomes even more prominent from pressure on the bladder by the enlarging uterus and the fetal presenting parts, such as when the fetal head descends into the pelvis.

Dysuria, however, is often a sign of infection that requires antibiotic treatment. Bacteriuria combined with urinary stasis from altered bladder function predisposes the patient to pyelonephritis. Although simple urinary tract infections are treated on an outpatient basis, pyelonephritis remains the most common nonobstetric cause for hospitalization during antenatal care.

Patients with a diagnosis of pyelonephritis require hospitalization, aggressive fluid replacement, and IV antibiotics until they remain afebrile for longer than 24 hours. Close monitoring of maternal respiratory status is important because these women are at risk for acute respiratory distress syndrome (ARDS) and renal failure as well as a significant increase in preterm labor and delivery. All patients should complete a 14-day course of antibiotic treatment. After treatment has been completed, suppressive therapy should be continued until delivery.

## Infection

Two infections of special note are HIV and bacterial vaginosis (BV). HIV transmission to the newborn can be reduced significantly with appropriate infectious disease and maternal-fetal medicine specialty management. Although all symptomatic pregnant women with BV should be treated, evidence is inconclusive for screening and treating asymptomatic women, even those with a high risk history of prior preterm delivery or PPRM. Because of well-documented safety and efficacy of oral<sup>1</sup> and vaginal metronidazole, and vaginal clindamycin cream, any of these three are considered first-line for treatment in pregnancy.

*Chlamydia trachomatis* is an obligate intracellular bacterium and is the most common sexually transmitted bacterial infection in women of reproductive age. It may be associated with urethritis, mucopurulent cervicitis, and acute salpingitis, or it may be clinically silent. Perinatal transmission is clearly associated with neonatal conjunctivitis (leading to blindness) and pneumonia and is likely associated with preterm delivery, premature rupture of membranes, and perinatal mortality. Diagnosis is confirmed by nucleic acid amplification testing (NAAT) during routine screening. Doxycycline should be avoided in pregnancy, and erythromycin is associated with gastrointestinal upset, so treatment with azithromycin (Zithromax 1000 mg as single dose) is often the best choice in pregnancy.

Gonococcal infection is associated with concomitant chlamydia infection in about 40% of infected pregnant women. It is usually limited to the lower genital tract, including the cervix, urethra, and periurethral or vestibular glands. Because of an association between gonococcal cervicitis and septic spontaneous abortion, and because preterm delivery, premature rupture of membranes, and postpartum infection are more common with gonococcal infection, routine cultures are appropriate at the first antenatal visit. Because some strains have rendered some  $\beta$ -lactam drugs ineffective for therapy, the recommendation for uncomplicated gonococcal infection is intramuscular ceftriaxone (Rocephin) 250 mg plus azithromycin (Zithromax) 1 g orally as a single dose.

Vaginosis due to *Candida albicans* can become symptomatic with caseous white discharge and vaginal itching or burning, and it may be associated with red satellite lesions on the vulva.

Marked inflammation of the vagina and introitus may be noted. Topical application of over-the-counter antifungal creams such as miconazole nitrate (Monistat) or nystatin (Mycostatin) is generally helpful in controlling the imbalance of vaginal flora, but this requires a 7-day regimen to achieve adequate cure rates. A single dose of fluconazole (Diflucan), 150 mg by mouth, is another appropriate choice, but only after the first trimester.

*Trichomonas vaginalis* can be found in 20% to 30% of pregnant patients, but only a small number complain of discharge or irritation. This flagellated, oval, motile organism can be seen on normal saline wet prep and is evident clinically by presence of a foamy or greenish discharge accompanied by multiple cervical petechiae. The CDC now recommends highly sensitive and specific nucleic acid amplification test (NAAT) in testing for trichomonads (95.3–100% sensitive, 93.2–100% specific for the APTIMA T. vaginalis test), as wet prep microscopy is rather insensitive (51–65%). There are also several new point-of-care tests that are now FDA-approved using antigen detection or DNA hybridization probe technology that have results available in as little as 10 minutes (OSOM *Trichomonas* rapid test) to 45 minutes (Affirm VP III). Treatment is oral metronidazole (Flagyl) as a single 2-g dose for the patient and her partner (though most states support expedited partner treatment, each practitioner will need to individualize this approach).

Rubella, also known as German measles, is directly responsible for spontaneous miscarriage and severe congenital malformations. Although large epidemics of rubella are nonexistent in the United States because of immunization, the disease can still affect up to 25% of susceptible women. Absence of rubella antibody indicates susceptibility. Vaccination involves an attenuated live virus (MMR) and therefore is avoided in pregnancy. Vaccination of nonpregnant susceptible women (including those during the postpartum period) and hospital personnel continues to be the mainstay of therapy. Detection by immunoglobulin M (IgM)-specific antibody confirms recent infection.

Varicella-zoster virus, the etiologic agent of childhood chickenpox, is a DNA herpes virus that remains latent in the dorsal root ganglia and may be reactivated years later to cause herpes zoster or shingles. Infection early in pregnancy can lead to severe congenital malformations, including chorioretinitis, cerebral cortical atrophy, hydronephrosis, and cutaneous and bony leg defects. Varicella-zoster immunoglobulin (VariZIG) (30–40 kg: 500 U;  $\geq 40.1$  kg: 625 U) can attenuate varicella infection if given to an exposed, nonimmune pregnant woman within 96 hours of her exposure to a patient with active varicella.

Genital herpes simplex virus (HSV) can present at any gestational age and is characterized by multiple, painful genital ulcers or vesicles; the diagnosis can be confirmed (if not in labor) through use of PCR laboratory testing. If active genital lesions are noted in labor, cesarean delivery is indicated because the fetus is at risk for acquiring the virus during passage through the birth canal. For HSV outbreaks remote from term, acyclovir (Zovirax) and its derivatives can shorten the course of an outbreak. For those with a history of active herpes during or preceding pregnancy, prophylaxis with acyclovir or similar approved antiviral medications from 36 weeks onward can decrease the chance of an outbreak at term and the need for a cesarean delivery.

*Influenza* can occur during pregnancy, and because the risk of secondary complication such as pneumonia is increased during the antepartum period, influenza vaccination is recommended for all patients in any trimester who are pregnant or up to 3 months postpartum during the local influenza season. Rapid testing of nasal or throat swabs can ascertain the diagnosis of influenza. Though oseltamivir (Tamiflu) and zanamivir (Relenza) are both FDA category C in pregnancy, no toxic effects have been observed in animal trials, so these are the preferred agents. These agents need to be started as soon as possible to provide the most benefit in symptom duration and severity. Similarly, Covid-19 (SARS-CoV2) infection can confer a higher risk of severe illness to pregnant patients. Current CDC guidelines recommend vaccination (preferably with mRNA vaccines) due to data demonstrating vaccine safety and efficacy.

<sup>1</sup>Not FDA approved for this indication.

### Varicose Veins

Pressure by the enlarged uterus on venous return from the legs and progesterone-mediated vasodilation can lead to prominent varicosities and edema of the legs or vulva. Any concern for deep vein thrombosis should be ruled out with duplex ultrasound imaging. Benign varicosities almost invariably return to normal after delivery, thus limiting the need for intervention in the antepartum period, though their symptoms may be decreased through the wearing of support hose. Edema of the lower extremities is common, responds to elevation, and must be differentiated from facial or hand edema accompanying preeclampsia. Hemorrhoids are manifestations of the varicosities of the rectal veins. Treatment focuses on stool softeners, sitz baths, and over-the-counter topical preparations. If a hemorrhoid becomes firm and tender, evaluation for possible treatment by opening and removing the thrombus can provide immediate relief.

### Constipation

Bowel transit time and relaxation of intestinal smooth muscle are both increased due to progesterone effects, resulting in overall slowing of bowel function. If pronounced, this can lead to constipation. Dietary management of this condition is centered on recommendations for increased fluids and high-fiber foods; stool softeners, such as docusate (Colace), can also be used in pregnancy. Enemas and laxatives are not recommended.

### Upper Extremity Discomfort

Periodic numbness and tingling of the fingers is due to exacerbations of carpal tunnel compression exacerbated by tissue edema. Splinting of the affected hand at night may help, along with stretching exercises of the wrist and neck that can be done throughout the day. Most of these symptoms resolve after delivery.

### Backache and Pelvic Discomfort

Endocrine relaxation of ligamentous structures coupled with an offset center of gravity create exaggerated lordotic spinal curve, joint instability, and back pain. Most women experience some form of this discomfort as pregnancy progresses. Advice given for improvements in posture, local heat, acetaminophen (Tylenol), and massage may be helpful. Minimizing the time spent standing can have a positive effect. Round ligament pain usually occurs during the second trimester and is described as sharp bilateral or unilateral groin pain. It may be exacerbated by change in position or rapid movement and might respond to similar measures. These routine aches and pains of pregnancy must be differentiated from rhythmic cramping pains originating in the back or uterus. The latter may be a sign of preterm labor requiring appropriate evaluation.

### Leg Cramps

Leg cramps in the form of recurrent muscle spasms in pregnancy are believed to be due to lower levels of serum calcium or higher levels of serum phosphorus. The calves are most commonly involved and attacks are more frequent at night and in the third trimester. There are no data from controlled trials to show benefit over placebo for treatment targeted toward reduced phosphate and increased calcium or magnesium intake. Local heat, putting the affected muscle on stretch, acetaminophen, and massage can be helpful in acute events.

### Intercourse

In general, intercourse is considered safe in pregnancy. The exception to this rule is found in patients who have a known placenta previa, are experiencing uterine bleeding, or have postcoital cramps and spotting. It may be wise to avoid intercourse in couples who are at risk for special circumstances. Firmer recommendations can be made in instances of placenta previa or known rupture of membranes; in these instances intercourse should not occur.

### Dental Care

Ideally, women should have dental care completed before conception. However, dental procedures under local anesthesia may be

carried out at any time during the pregnancy. Use of nitrous oxide inhalants is to be avoided, however. Long procedures should be postponed until the second trimester. Antibiotics are appropriate as needed for dental infections and in cases of rheumatic heart disease or mitral valve prolapse with regurgitation.

### X-rays, Ionizing Radiation, and Imaging

The adverse effects of ionizing radiation are dose dependent, but there is no single diagnostic procedure that results in a dose of radiation high enough to threaten the fetus or embryo. Diagnostic radiation of less than 5000 mrad is considered by ACOG to have minimal teratogenic risk, and if medically indicated, x-ray imaging may be performed safely (with appropriate abdominal shielding). Patients receiving dental x-rays are additionally protected by a lead apron. Still, the need for x-ray films should be evaluated for risks and potential benefits in the individual pregnant patient to conservatively protect the mother and fetus from theoretical genetic or oncogenic risk. Magnetic resonance imaging (MRI) is considered safe due to its mechanism of action, which is a non-ionizing form of radiation. Radioactive iodine (<sup>131</sup>I) is contraindicated in pregnancy.

### Immunization

Live virus vaccines must be avoided during pregnancy because of possible effects on the fetus. These include measles, mumps, rubella (MMR), yellow fever (YF-Vax), and varicella (Varivax) vaccinations. The risks to the fetus from the administration of rabies vaccine (RabAvert, IMOVAX) are unknown.

Diphtheria and tetanus toxoid with pertussis (Tdap) is recommended between 27 and 36 weeks by the CDC and ACIP to decrease the risk of whooping cough in the newborn infant. The hepatitis B vaccine (Engerix B, Recombivax HB) series is safe and may be given in pregnancy to women at risk. The inactivated influenza vaccine (Fluzone, Fluvirin, Fluarix) is also recommended in all women during any trimester they will be pregnant during the flu season (or up to 3 months postpartum during flu season).

### Tests of Fetal Well-Being

A primary goal in antepartum care is the competent management of patient care extended to both mother and baby in order to reduce the risk of fetal demise after 24 weeks, ensure optimal conditions for term delivery after 37 weeks, and intervene for evolving conditions threatening the well-being of either patient. Any pregnancy that may be at increased risk for antepartum fetal compromise is a candidate for tests of fetal well-being performed weekly, beginning at 28 to 32 weeks. Some conditions requiring antepartum testing are listed in [Box 3](#).

### Nonstress Test

The nonstress test (NST) consists of fetal heart rate monitoring in the absence of uterine contractions. A reactive tracing is one in which heart rate accelerations of 15 beats/min above the baseline of 120 to 160 beats/min are of at least 15 seconds' duration. Two of these accelerations must be observed in a 20-minute period.

#### BOX 3 Conditions That Prompt Enhanced Fetal Surveillance

- Decreased fetal movements
- Fetal growth restriction
- Hypertensive disorders
- Insulin-dependent diabetes mellitus
- Multiple gestation with discordant fetal growth
- Oligohydramnios or polyhydramnios
- Postterm pregnancy
- Prior loss or stillbirth

False-positive nonreactive tracings are more common before 28 weeks' gestation.

### Biophysical Profile

The biophysical profile (BPP) consists of an NST with ultrasound observations. A total of 10 points is given for the following elements (2 points each):

- Reactive NST
- Presence of fetal breathing movements of 30 seconds or more in 30 minutes
- Fetal movement defined as three or more discrete body or limb movements within 30 minutes
- Fetal tone defined as one or more episodes of fetal extremity extension and return to flexion
- Quantification of amniotic fluid volume, defined as a pocket of fluid that measures at least 2 cm by 2 cm

The results of a BPP are usually reported out of 8 points if done without the NST, and out of 10 points if done with an NST. Scores of 8 or 10 points (out of 10) are considered reassuring, with retesting indicated in 4 to 7 days depending on the original indication for the testing. A score of 6 points is borderline; testing should be repeated in 24 hours. Scores of 4 or 2 points are nonreassuring and should prompt additional testing, treatment, or planning for delivery depending on the setting.

## ECTOPIC PREGNANCY

Method of

Christina M. Kelly, MD

### CURRENT DIAGNOSIS

- Vaginal bleeding and abdominal pain in the first trimester of pregnancy raise concern for ectopic pregnancy, but a normal intrauterine pregnancy (IUP) or early pregnancy loss could exist.
- High-resolution transvaginal ultrasound (TVUS) and measurement of serum  $\beta$ -human chorionic gonadotropin (hCG) are the best initial steps in determining whether a pregnancy is ectopic.

- A single hCG value is not diagnostic of pregnancy location, viability, or gestational age. It can determine whether the level is in the discriminatory zone.
- If the hCG is above the discriminatory zone (3000–3500 mIU/mL), absence of a gestational sac with a yolk sac or embryo visualized in the uterus is highly suggestive of a nonviable gestation, either an early pregnancy loss or an ectopic pregnancy.
- If the initial hCG is below the discriminatory zone and there is no ultrasound evidence of ectopic pregnancy, patients should be followed up with repeat hCG levels every 48 hours. There is not a universal method to predict an expected minimal rise for serial hCG levels for a viable IUP. Rather, it is dependent on the initial hCG level. Updated guidelines about the appropriate hCG patterns help guide decision making and determine whether additional diagnostic interventions are needed.
- If definitive findings of an intrauterine or ectopic pregnancy are not present on TVUS in a pregnant patient with a positive hCG level, a pregnancy of unknown location exists. Serial monitoring is needed to either establish a definitive diagnosis or reasonably exclude an IUP before an ectopic pregnancy is diagnosed and treated. Uterine aspiration can be considered to confirm the diagnosis of early pregnancy loss or ectopic pregnancy based on the presence or absence of chorionic villi.

### CURRENT THERAPY

- Surgical management of ectopic pregnancy is indicated when a patient is hemodynamically unstable, exhibits signs of intraperitoneal bleeding, reports symptoms concerning for a ruptured ectopic mass, or has a contraindication to methotrexate.
- For a patient who is clinically stable and has a nonruptured ectopic pregnancy, either surgical or medical management of ectopic pregnancy are safe and effective options. For the patient to make an informed choice, a shared decision-making model can be used that reviews the risks for and benefits of both approaches and considers the clinical features of the ectopic pregnancy, stability of the patient, future fertility plans, and additional patient characteristics that would preclude one approach or the other.
- Medical management with systemic methotrexate (not approved by the Food and Drug Administration) requires regular patient follow-up for laboratory and office visits until hCG levels are undetectable.
- Medical management with methotrexate is most effective when ectopic pregnancies are less than 4 cm on TVUS,
- Pretreatment hCG levels are less than 5000 mIU/mL, and fetal cardiac activity is not detected on TVUS.
- Expectant management of ectopic pregnancy may be considered in special circumstances, such as an asymptomatic and informed patient with reliable social resources in the setting of decreasing hCG levels that indicate pregnancy resolution.

An ectopic pregnancy is a potentially serious threat to the general and reproductive health of a pregnant person. Despite vast improvements in the clinical care of patients with ectopic pregnancy over recent years, diagnostic challenges and therapeutic controversies regarding this condition still exist. The objective of this chapter is to provide an overview of the epidemiology, diagnosis, and contemporary management of ectopic pregnancy. The chapter focuses on ectopic pregnancies that implant in the fallopian tube, which represent greater than 95% of all ectopic pregnancies.

## Epidemiology

Of all pregnancies in the United States, approximately 1% to 2% are diagnosed as ectopic. The current incidence of ectopic pregnancy is difficult to calculate accurately because of the lack of tracking in both the hospital and outpatient settings, but recent studies estimate that over the last 25 years, it has increased six-fold. This rise may be the result of enhanced diagnostic capabilities, increased incidence of sexually transmitted infections and other risk factors, expanded use of infertility treatments, and heightened awareness of health professionals.

Ectopic pregnancy is the leading cause of maternal mortality in the first trimester of pregnancy in the United States, accounting for 2.7% of pregnancy-related deaths, and there should be continued high suspicion for at risk patients. However, the ectopic-related mortality rate is declining despite the increase in incidence. Between 1980 and 2007, 876 deaths were attributed to ectopic pregnancy, which represented a 56.6% decline in mortality rate between 1980 to 1984 and 2003 to 2007. However, age and racial disparities still persist. The ectopic pregnancy mortality ratio was 6.8 times higher for Black people compared with whites and 3.5 times higher for patients over 35 years old compared with those younger than 25 years old.

## Pathophysiology

Damage to the fallopian tube and fallopian tube dysfunction are the primary factors associated with development of ectopic pregnancy. Normal embryo transport can be disrupted by damage to the structural integrity of the mucosal portion of the fallopian tube. Intratubal scarring secondary to infection or trauma could lead to trapping of a conceptus within intratubal adhesions or diverticula. Alteration of the hormonally mediated events leading to implantation, as sometimes occurs in treatments for infertility, offers another mechanism for consideration. A change in the estrogen-to-progesterone ratio could theoretically affect smooth muscle activity in the fallopian tube, immobilizing ciliary activity.

## Risk Factors

Half of all patients with ectopic pregnancy will not report any known risk factors; therefore the absence of risk factors should not decrease clinical suspicion. However, identification of clinical and historical risk factors for ectopic pregnancy could aid in early diagnosis. The most significant historical risk factors include prior ectopic pregnancy, prior fallopian tube surgery, infertility treatment, and hospitalization for pelvic inflammatory disease (PID). History of prior ectopic pregnancy is the strongest of these. Major clinical risk factors include pain or moderate-to-severe vaginal bleeding at presentation. Less significant risk factors are tobacco use and age >35 years old. Up to 53% of pregnancies that occur with a copper or progestin-releasing intrauterine device (IUD) in place are ectopic; however, the overall failure rate IUDs is less than 1%.

## Diagnosis and Clinical Manifestations

Although some patients present acutely with a ruptured ectopic pregnancy and hemoperitoneum, the vast majority (up to 80%) of ectopic pregnancies are diagnosed in stable patients who can be managed in the outpatient setting. Therefore reproductive-age people who present with symptoms of vaginal bleeding or abdominal discomfort need to be tested for pregnancy. If a patient is found to be pregnant, then their pregnancy needs to be differentiated as an ectopic pregnancy, a nonectopic gestation at risk for early pregnancy loss (EPL), or a normally developing IUP. The use of TVUS and hCG assays represent the current standard for this differentiation and for accurate and timely diagnosis of ectopic pregnancy.

## Transvaginal Ultrasonography

Evaluating a patient with suspected ectopic pregnancy properly with TVUS requires an understanding of the findings typical of normal and abnormal pregnancies. The earliest ultrasonographic finding of a normal IUP is the gestational sac surrounded by a thick echogenic ring, located eccentrically within the endometrial cavity. On

average, the gestational sac is seen on TVUS 5 weeks after the first day of the last menstrual period. The gestational sac grows and follows an approximate developmental timeline, which is represented by the following findings on TVUS: a yolk sac seen within the gestational sac at 5.5 weeks of gestation, an embryonic (fetal) pole at 6 weeks gestation, and cardiac activity at 6.5 weeks gestation.

A definitive IUP can be diagnosed by TVUS when a gestational sac with a yolk sac or embryo with or without cardiac activity is seen. A normal-appearing gestational sac should not solely be used to diagnose an IUP because it can be simulated by a pseudo-gestational sac and intrauterine fluid collection, which occurs in 8% to 29% of patients with ectopic pregnancy. The pseudogestational sac likely represents bleeding into the endometrial cavity by the decidual cast. The presence of an adnexal gestational sac with a fetal pole and cardiac activity is the most specific but least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases. Adnexal rings (fluid sacs with thick echogenic rings) that have a yolk sac or nonliving embryo are accepted as specific signs of ectopic pregnancy and are visualized in ectopic pregnancies 33% to 50% of the time.

A critical concept in the evaluation of early pregnancy by TVUS is that of the hCG discriminatory zone, or the level at or above which an examiner should see a normal intrauterine gestation, if present. In the setting of an hCG level above the discriminatory zone and no intrauterine pregnancy on ultrasound, an ectopic pregnancy or an abnormal intrauterine pregnancy is highly likely. The exact hCG discriminatory value varies somewhat based on the institution, ultrasound machine, ultrasonographer's experience, and hCG assay used. The value used should be conservatively high—at least 3000 mIU/mL and up to 3500 mIU/mL—to minimize the risk of misdiagnosing a desired IUP as an ectopic pregnancy and treating it as such.

## Hormonal Assays

Many patients with suspected ectopic pregnancy will present with a hCG below the discriminatory zone and have an ultrasound that does not provide a definitive diagnosis of an intrauterine or extrauterine gestation (7%–20%). This is a pregnancy of unknown location (PUL), and serial monitoring is needed to establish a definitive diagnosis. Repeat hCG measurements are indicated at least every 48 hours to evaluate the appropriateness of hormonal trends along with serial TVUS studies. Comparing serial measurements of hCG from an individual patient to accepted patterns of hCG trends in early pregnancy helps distinguish an ectopic pregnancy from a viable IUP or a spontaneous EPL.

When evaluating serial hCG levels and predicting an expected minimal rise between values for a viable IUP, current evidence demonstrates there is not a universal trend that applies to all pregnancies at all gestations. Rather, it depends on the initial hCG level. Previous data showed that approximately 99% of viable intrauterine pregnancies are associated with a  $\geq 53\%$  increase in  $\beta$ -hCG values every 2 days. For pregnancies with an initial hCG value below 1500 mIU/mL, this calculation could apply. However, for pregnancies with higher initial hCG values, a laxer calculation should be used. One study suggests the following for an expected minimal rise for different initial hCG levels: 49% for levels <1500 mIU/mL, 40% for levels 1500 to 3000 mIU/mL, and 33% for levels >3000 mIU/mL. This represents a more conservative approach to incorporating invasive diagnostic procedures when following hCG values to prevent the interruption of normal pregnancies.

Patients with symptomatic first-trimester pregnancies, nondiagnostic ultrasound, and a hCG level that is declining (when the initial value is below the discriminatory zone) should also be followed with serial hCG levels until resolution to distinguish a resolving EPL from an ectopic pregnancy. Fifty percent of patients with ectopic pregnancies will present with declining hCG levels. Research describing the expected elimination of hCG in spontaneous EPL indicate that the minimum rate of decline ranges from 12% to 35% at 2 days to 34% to 84% at 7 days. Faster rates of decline occur with higher initial hCG levels. When the serial decline in hCG is in the range associated with spontaneous EPL, continued follow-up surveillance is indicated. If the hCG decline is slower than expected for an EPL, an ectopic pregnancy must be highly suspected.

## Uterine Aspiration

The patient presenting with either (1) initial hCG below the discriminatory zone followed by an abnormal rise or decline or (2) initial hCG value at or above the discriminatory zone with no detectable intrauterine pregnancy has an abnormal pregnancy. The only exception to the rule for the second scenario would be if a multiple gestation had been conceived. The challenge for the clinician is then to determine whether the pregnancy is an abnormal IUP or an ectopic pregnancy. Office uterine vacuum aspiration or dilation and curettage in the operating room can help confirm the diagnosis of early pregnancy loss or ectopic pregnancy based on the presence or absence of chorionic villi. However, before this is considered, a progressing IUP must be reasonably excluded through serial monitoring with TVUS and hCG levels.

Uterine aspiration may spare some patients from receiving methotrexate<sup>1</sup>. If chorionic villi are present in the uterine aspiration specimen, then a failed IUP is confirmed. No further treatment is indicated. If chorionic villi are absent, hCG levels need to be monitored starting at 12 to 24 hours after the procedure to determine whether they increase, plateau, or decrease appropriately. The hCG trend after uterine aspiration determines whether medical management of ectopic pregnancy with methotrexate should be implemented. The patient's preference, development of symptoms, and level of clinical suspicion for ectopic pregnancy also play an important role in whether methotrexate is given.

There is debate in the literature on whether uterine aspiration is needed before methotrexate is given to treat ectopic pregnancy. Empiric treatment of suspected ectopic pregnancy without the performance of uterine vacuum aspiration or dilation and curettage could result in inappropriate treatment of up to 40% of patients. Performing uterine aspiration could delay treatment of an ectopic pregnancy; however, the risk of tubal rupture for these patients is low (1.7%).

## Treatment and Therapeutic Monitoring

Surgery has long been the mainstay of treatment for ectopic pregnancy, but medical management is a widely used alternative. Both are safe and effective treatment options for patients who are clinically stable. The choice of any treatment depends on factors such as clinical presentation, the risks of either surgery or medical management to the patient, and future fertility plans.

## Surgical Management

Patients with hemodynamic instability caused by a ruptured ectopic pregnancy require laparotomy and salpingectomy of the involved fallopian tube owing to extensive tubal damage. Most patients with ectopic pregnancy who are stable can be safely treated with laparoscopy. For patients with an unruptured ectopic pregnancy, surgical options include tube-sparing salpingostomy or removal of the fallopian tube (salpingectomy).

The decision between salpingostomy and salpingectomy depends on the location of the ectopic pregnancy within the fallopian tube, the extent of the damage to the fallopian tube, and the patient's desire for future fertility. Ideal candidates for salpingostomy include patients who have an ectopic pregnancy in the ampulla or infundibulum of the fallopian tube. Salpingectomy is reserved for patients with isthmic ectopic pregnancies, tubal rupture, or an ipsilateral recurrent ectopic pregnancy. Patients who have completed childbearing might be better candidates for salpingectomy than salpingostomy.

With respect to future fertility, subsequent IUP, and repeat ectopic pregnancy, a systematic review and meta-analysis of two randomized controlled trials (RCT) and 16 cohort studies showed that for the RCTs, there was not a difference between salpingectomy and salpingostomy for the likelihood of a subsequent IUP and repeat ectopic pregnancy. For the cohort studies, salpingectomy was associated with a lower likelihood of subsequent IUP. The cohort studies also found a higher risk for repeat

ectopic pregnancy among pregnant people treated by salpingectomy with risk factors for future infertility (previous ectopic pregnancy, endometriosis, history of infertility, history of tubal surgery, pregnancy conceived with in-vitro fertilization, known hydrosalpinx or tubal occlusion, or intraoperative identification of contralateral tubal pathology).

## Medical Management

Methotrexate (MTX) is a folic acid antagonist that impairs DNA synthesis and cellular replication targeting rapidly proliferating cells such as trophoblasts. It can be used for medical management of ectopic pregnancy in patients who have a confirmed or high clinical suspicion of ectopic pregnancy, an unruptured mass, and no contraindication to the medication.<sup>1</sup>

Absolute contraindications to medical management of ectopic pregnancy are listed in [Table 1](#). Among the most important of these is the inability of the patient to comply with follow-up after initiation of therapy. Without the ability to monitor the response to MTX and provide additional doses if deemed appropriate, opportunities to prevent ectopic rupture could be missed. To ascertain whether a patient is eligible for MTX therapy, a comprehensive laboratory and medical evaluation should first be performed, including a complete blood count and renal and liver function tests. Treatment failure occurs when the hCG level decline is deemed inadequate and surgery is required. In some cases, medication failure presents as tubal rupture requiring emergent surgery.

Relative contraindications in [Table 1](#) pertain to patient characteristics that reduce the odds of successful treatment. The strongest predictor for the efficacy of MTX treatment is an initial hCG concentration >5000 mIU/mL, and it is associated with a failure rate of 14.3% or higher.

Three methotrexate treatment regimens exist: single-dose, two-dose, and multidose regimens ([Table 2](#)). These designations refer more to the number of intended doses in the protocol rather than the actual number or doses received by all patients. For any of the protocols, once hCG levels have declined by at least 15% between interval assessments, no additional doses of medication are required, but hCG must still be followed until complete resolution to ensure treatment efficacy. A systematic review and meta-analysis of six RCTs demonstrated that the single-dose and multiple-dose regimens have similar success rates, and the difference between the single-dose and double-dose regimens was not statistically significant. More side effects occurred with the multiple-dose regimen compared with single-dose and double-dose. The definition of successful treatment with MTX is resolution of the ectopic pregnancy without surgery, and the success rate ranges from 70% to 95% depending on the initial hCG level and treatment protocol.

The biggest risk of medical management with MTX is ectopic pregnancy rupture. There is also the risk of fetal death or teratogenic effects if an IUP occurs shortly after treatment, and patients should be counseled to wait one ovulatory cycle after hCG levels are undetectable before attempting pregnancy again.

Side effects of MTX therapy occur in up to 30% of patients; however, most of these resolve rapidly and are generally of minor consequence. Abdominal pain is common early in treatment and is of concern as a possible indicator of tubal rupture. A potential cause of this pain in nonacute patients can be tubal miscarriage. Additional potential side effects include nausea, vomiting, diarrhea, gastritis, stomatitis, and liver transaminitis. Serious side effects such as alopecia and neutropenia can occur but are extremely rare.

Reproductive success after successful MTX therapy appears similar to that after salpingostomy. The most critical predictors of fertility after ectopic pregnancy treated by any conservative means are the condition of the contralateral fallopian tube and the presence of additional ectopic risk factors.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Contraindications to Medical Management of Ectopic Pregnancy With Methotrexate

	ACOG*	ASRM†
Absolute contraindications	Intrauterine pregnancy; breastfeeding; laboratory evidence of immunodeficiency; preexisting blood dyscrasias (bone marrow hypoplasia, leukopenia, thrombocytopenia, or clinically significant anemia); known sensitivity to methotrexate; active pulmonary disease; peptic ulcer disease; clinically significant hepatic, renal, or hematologic dysfunction; hemodynamically unstable patient; inability to participate in follow-up	Breast-feeding; evidence of immunodeficiency; moderate-to-severe anemia, leukopenia, or thrombocytopenia; sensitivity to methotrexate; active pulmonary or peptic ulcer disease; clinically important hepatic or renal dysfunction; intrauterine pregnancy
Relative contraindications	Ectopic mass >4 cm by TVUS; embryonic cardiac activity by TVUS; high initial hCG concentration (>5,000 mIU/mL)	Ectopic mass >4 cm detected by TVUS; embryonic cardiac activity detected by TVUS; patient declines blood transfusion; patient is not able to participate in follow-up; high initial hCG level (>5000 mIU/mL)

TVUS, transvaginal ultrasound; hCG,  $\beta$ -human chorionic gonadotropin.

\*Data are from the American College of Obstetricians and Gynecologists (ACOG).

†Data are from the American Society for Reproductive Medicine (ASRM).

**TABLE 2** Methotrexate<sup>1</sup> Protocols for Treatment of Ectopic Pregnancy

	SINGLE DOSE	TWO DOSE	MULTIDOSE
Day 1	Check hCG value. Administer first dose of MTX 50 mg/m <sup>2</sup> IM.	Check hCG value. Administer first dose of MTX 50 mg/m <sup>2</sup> IM.	Check hCG value. Administer first dose of MTX 1 mg/kg IM followed by leucovorin <sup>1</sup> 0.1 mg/kg IM on day 2. Check hCG on day 2.
Day 4	Check hCG value.	Check hCG value. Administer second dose of MTX 50 mg/m <sup>2</sup> IM.	Administer second dose of MTX (day 3) and leucovorin (day 4). Check hCG on day 4.
Day 7	Check hCG value looking for 15% decrease between days 4 and 7. If >15% fall, check hCG weekly until not detectable in serum. If <15% fall, administer second dose of MTX 50 mg/m <sup>2</sup> IM.	Check hCG value for 15% decrease between days 4 and 7. If >15% fall, check $\beta$ -hCG weekly until not detectable in serum. If <15% fall, administer third dose of MTX 50 mg/m <sup>2</sup> IM.	Continue administering doses of MTX and leucovorin (i.e., course 3 days 5 and 6 and course 4 days 7 and 8) until hCG values have declined by 15%. Do not exceed 4 courses. If >15% decline, check hCG weekly until not detectable in serum.
Day 11		Check hCG value for 15% decrease between days 7 and 11. If >15% decline, check hCG weekly until not detectable in serum. If <15%, administer fourth dose of MTX 50 mg/m <sup>2</sup> IM.	
Weekly surveillance	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.	If follow-up hCG value plateau or rise, consider surgical intervention or repeat dose of MTX as additional therapy.

hCG,  $\beta$ -human chorionic gonadotropin; IM, intramuscular; MTX, methotrexate.

<sup>1</sup>Not FDA approved for this indication.

## Expectant Management

Because numerous ectopic pregnancies resolve spontaneously, there has been great interest in considering expectant management in selected patients. Expectant management includes close monitoring of symptoms, determination of hCG levels every 48 hours, and serial TVUS. The likelihood of successful ectopic resolution is highest in the presence of a nondiagnostic ultrasound and hCG values below the discriminatory zone.

## HYPERTENSION IN PREGNANCY

Method of

Leah G. Peterson, MD

### CURRENT DIAGNOSIS

- Hypertensive disorders of pregnancy are a major cause of morbidity and mortality for women and infants.
- Hypertensive disorders of pregnancy are divided into four categories:
  - Chronic hypertension
  - Gestational hypertension
  - Chronic hypertension with superimposed preeclampsia
  - Preeclampsia (with and without severe features)
- Preeclampsia can be diagnosed by the presence of hypertension and end-organ damage, even in the absence of proteinuria.

### CURRENT THERAPY

- To prevent preeclampsia in at-risk patients, daily low-dose aspirin<sup>1</sup> should be initiated between 12 weeks and 28 weeks of gestation (optimally before 16 weeks) and continued daily until delivery.
- Blood pressure (BP) readings  $\geq 160/105$  require pharmacologic treatment.
- Nifedipine, labetalol, and methyldopa are approved for treatment of hypertensive disorders in pregnancy.
- Patients with gestational hypertension and preeclampsia should be monitored with regular laboratory tests, ultrasoundography, and antenatal testing.
- Delivery is the definitive treatment for preeclampsia.
- Hypertensive disorders in pregnancy are an indication for early delivery. Delivery time is based on the severity of maternal symptoms and fetal estimated gestational age (EGA).
- Magnesium sulfate ( $\text{MgSO}_4$ ) injection is indicated for prevention of eclampsia in patients with preeclampsia with severe features. It is also the preferred agent for treatment of eclampsia.
- Hypertensive disorders of pregnancy can present in the postpartum period.
- Preeclampsia is associated with increased risk for cardiovascular disease later in life.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Hypertensive disorders complicate nearly 10% of pregnancies (ACOG, 2013), and their incidence is increasing. Preeclampsia causes 50,000 to 60,000 deaths per year worldwide in addition to causing significant maternal and fetal morbidity in hundreds of thousands of others. Some of these outcomes can be prevented or improved upon through implementation of updated recommendations in clinical practice.

### Pathophysiology

The precise mechanism for the development of preeclampsia is unknown. A major component in the development of preeclampsia is the excessive placental production of antagonists to both vascular epithelial growth factor (VEGF) and transforming growth factor beta (TGF- $\beta$ ). These antagonists to VEGF and TGF- $\beta$  disrupt endothelial and renal glomerular function, resulting in

edema, hypertension, and proteinuria. In addition, there appears to be a heritable component, and oxidative stress and abnormal placental implantation can further increase the risk of developing the disease.

### Prevention

In select clinical situations, low-dose aspirin<sup>1</sup> is recommended during pregnancy to prevent or delay the onset of preeclampsia. Table 1 outlines high-risk and moderate-risk categories for preeclampsia. In individuals at high risk for preeclampsia and those with more than one moderate-risk factor, 81 mg of aspirin should be initiated between 12 weeks and 28 weeks of gestation (optimally before 16 weeks) and continued daily until delivery (ACOG, 2018). Low-dose aspirin is not associated with increased bleeding or placental abruption. High-risk category risk factors are consistently associated with the greatest risk for preeclampsia, conferring at least an 8% risk for developing preeclampsia (ACOG, 2018).<sup>1</sup>

The U.S. Preventive Services Task Force (USPSTF) includes Black race and lower income as examples of environmental, social, structural, and historical inequities that result in risk for development of preeclampsia. These factors influence health-risk exposure, access to health care, and unequal distribution of resources. Black race is not included because of biologic propensities, but as a proxy for underlying racism (Davidson et al, 2021).

Supplementation with vitamin C<sup>1</sup> or vitamin E<sup>1</sup> is not recommended for the prevention of preeclampsia. Supplementation of calcium<sup>1</sup> in women with preeclampsia is only indicated in those who are calcium deficient. Bed rest and salt restriction are not recommended for prevention of preeclampsia (ACOG, 2013).

### Diagnosis

Isolated hypertensive disease diagnosed before 20 weeks of gestation is classified as *chronic hypertension*. *Gestational hypertension* is defined as the onset of hypertension ( $\geq 140/90$  on two occasions at least 4 hours apart) after 20 weeks of gestation in a woman who has a previously normal BP and no other diagnostic criteria for preeclampsia.

*Preeclampsia* is a hypertensive disorder that is multisystemic in nature and is specific to pregnancy. It presents after the 20th week of gestation, typically near term. The diagnosis of preeclampsia has been traditionally based on new-onset hypertension and the presence of proteinuria. However, this is problematic because some patients present with hypertension and signs of systemic disease in the absence of proteinuria. Thus diagnostic criteria have shifted. The presence of end-organ damage (Table 2) (ACOG, 2018) combined with onset of hypertension after 20 weeks of gestation is sufficient for a diagnosis of preeclampsia, even in the absence of proteinuria.

Clinically significant proteinuria is defined as  $\geq 300$  mg on a 24-hour urine collection or a spot microalbumin/creatinine ratio  $\geq 0.3$ . The use of dipstick quantification of proteinuria is discouraged unless no other method of quantification is available (ACOG, 2013). Urinary protein levels are not correlated with outcome severity and are not themselves considered a severe feature (ACOG, 2018).

The presence of any one of the signs of end-organ damage may signal an impending eclamptic seizure (ACOG, 2018). In addition to seizure and maternal end-organ damage, complications from preeclampsia include intrauterine growth restriction, placental abruption, and fetal demise.

Women with gestational hypertension with severe-range BPs (systolic BP  $\geq 160$  mm Hg or diastolic BP  $\geq 110$  mm Hg) should be diagnosed with preeclampsia with severe features. These severe ranges of BP or any of the severe features listed in Table 3 can increase the risk of morbidity and mortality (ACOG, 2020).

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Risk Factors for Preeclampsia**High Risk**

- History of preeclampsia, especially with adverse outcome
- Multifetal gestation
- Chronic hypertension
- Pregestational type 1 or 2 diabetes
- Kidney disease
- Autoimmune disease (systemic lupus erythematosus, antiphospholipid syndrome)
- Combinations of multiple moderate-risk factors

**Moderate Risk**

- Nulliparity
- Obesity (BMI >30)
- Family history of preeclampsia
- Black race
- Lower income
- Age 35 years or older
- Personal history factors (low birth weight or small for gestational age, previous adverse pregnancy outcome, >10-year pregnancy interval)
- In vitro fertilization

Adapted from ACOG Committee Opinion No. 743. Low-dose aspirin use during pregnancy, *Obstet Gynecol* 132(1):e44–e52, 2018.

**Management****Chronic Hypertension**

Chronic hypertension is associated with intrauterine growth restriction, placental abruption, and progression to preeclampsia (ACOG, 2018). Treatment of chronic hypertension is indicated if the BP is consistently >160/105 (ACOG, 2013). Approved treatment agents include methyldopa, nifedipine, and labetalol. It is essential to avoid overtreatment to prevent adverse fetal outcomes from decreased placental perfusion. Therefore, the goal is to keep BP >120/80 with treatment. Angiotensin-converting-enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and atenolol (Tenormin) should not be used in pregnancy because of fetal risk. Women with chronic hypertension should be monitored with serial ultrasound testing after fetal viability is reached.

**Gestational Hypertension**

Gestational hypertension is managed with expectant monitoring and delivery at 37/0 weeks. BP should be measured twice weekly, and the patient should have weekly assessment of liver function tests (LFTs) and platelet count to assess for development of preeclampsia (ACOG, 2018). Antihypertensive therapy should be initiated for BP  $\geq$ 160/105. Additionally, the patient should have regular antepartum testing. Data to support when to start testing, the frequency of testing, and which test to use are scarce. The author recommends antenatal testing starting at 32 weeks (or time of diagnosis of hypertensive disorder in pregnancy), consisting of either twice-weekly non-stress tests or weekly biophysical profiles. Gestational hypertension and preeclampsia are known risk factors for fetal death, and antenatal testing is indicated. However, limited to no data exist regarding when to start testing, the frequency of testing, and which test to use (ACOG, 2020). Inpatient management for 72 hours postpartum is recommended for patients with gestational hypertension; persistently elevated BP and severe elevations may require initiation of antihypertensive therapy.

**Preeclampsia and Preeclampsia with Severe Features**

Preeclampsia should be managed similarly to gestational hypertension, with the addition of regular ultrasound examinations for fetal growth, and twice weekly fetal nonstress testing. Delivery should occur at 37/0 weeks and at 34/0 weeks if the patient develops severe features.

**TABLE 2** Diagnostic Criteria for Preeclampsia

## Blood pressure

- Systolic BP of 140 mm Hg or more or diastolic BP of 90 mm Hg or more on two occasions at least 4 hours apart after 20 weeks of gestation in a woman with a previously normal BP
- Systolic BP of 160 mm Hg or more or diastolic BP of 110 mm Hg or more. (Severe hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy).

and

## Proteinuria

- 300 mg or more per 24-hour urine collection (or this amount extrapolated from a timed collection)
- or
- Protein-to-creatinine ratio of 0.3 or more
- or
- Dipstick reading of 2+ (used only if other quantitative methods not available)

Or in the absence of proteinuria, new-onset hypertension with the new onset of any of the following:

- Thrombocytopenia: platelet count less than  $100 \times 10^9/L$
- Renal insufficiency: serum Cr concentrations greater than 1.1 mg/dL or a doubling of serum Cr concentration in the absence of other renal disease
- Impaired liver function: Elevated blood concentrations of liver transaminases to twice-normal concentration
- Pulmonary edema
- New-onset headache unresponsive to medication and not accounted for by alternative diagnoses or visual symptoms

**TABLE 3** Preeclampsia with Severe Features

- Systolic BP of 160 mm Hg or more, or diastolic BP of 110 mm Hg or more on two occasions at least 4 hours apart (unless antihypertensive therapy is initiated before this time)
- Thrombocytopenia (platelet count less than  $100 \times 10^9/L$ )
- Impaired liver function not accounted for by alternative diagnoses, as indicated by
  - Elevated transaminases to twice normal concentration
 or
  - Severe persistent right upper quadrant or epigastric pain unresponsive to medications
- Renal insufficiency (serum creatinine concentration more than 1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease)
- Pulmonary edema
- New-onset headache unresponsive to medication and not accounted for by alternative diagnoses
- Visual disturbances

In the event that the patient develops preeclampsia with severe features before 34 weeks, immediate delivery should be considered. Steroids (12 mg betamethasone [Celestone]<sup>1</sup> IM q24h  $\times$  2 doses, or 6 mg dexamethasone [Decadron]<sup>1</sup> q12h  $\times$  4 doses) can be administered, and delivery can be postponed for 48 hours unless maternal or fetal instability develops. Contraindications to expectant management in this scenario include uncontrollable severe

**TABLE 4** Signs and Symptoms of Magnesium Toxicity

MANIFESTATIONS	LEVEL (mg/dL)
Loss of patellar reflex	8–12
Double vision	8–12
Feeling of warmth, flushing	9–12
Somnolence	10–12
Slurred speech	10–12
Muscular paralysis	15–17
Respiratory arrest	15–17
Cardiac arrest	30–35

hypertension, eclampsia, pulmonary edema, disseminated intravascular coagulation, placental abruption, nonreassuring fetal heart tones, and intrapartum fetal demise. If severe features are noted before fetal viability, delivery should occur immediately; expectant management is not recommended because of maternal risk.

In addition, MgSO<sub>4</sub> is indicated in preeclampsia with severe features. Administration of MgSO<sub>4</sub> has been shown to prevent eclamptic seizures and placental abruption in these patients (Leeman et al, 2016). Patients with preeclampsia without severe features should be monitored closely, and MgSO<sub>4</sub> should be started if severe features develop (ACOG, 2013). MgSO<sub>4</sub> is given as a 4- to 6-g intravenous loading dose, followed by a maintenance infusion of 1 to 2 g per hour. Women with normal renal function do not require serum magnesium testing, but all women receiving MgSO<sub>4</sub> should be monitored closely for signs of magnesium toxicity by serial evaluations of reflexes, respiratory rate, and urinary output (Duley et al, 2010). Signs and symptoms of magnesium toxicity are as noted in Table 4 (Duley et al, 2010).

Inpatient management for 72 hours postpartum is recommended for women with preeclampsia. BP levels decrease in most women, but if the BP remains >150/100 on two occasions 4 hours apart, an antihypertensive regimen should be started. If the level is >160/100, the BP should be rechecked 15 minutes later, and antihypertensive treatment should be started within 60 minutes. Oral nifedipine or labetalol, and intravenous labetalol or hydralazine are commonly used agents (ACOG, 2018). Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided in patients with hypertension that persists past 24 hours postpartum as they may worsen BP.

Preeclampsia may begin in the postpartum period, so all patients should be counseled about signs and symptoms before discharge. In addition, preeclampsia is a risk factor for future cardiovascular disease. In women who delivered before 37 weeks or have a history of recurrent preeclampsia, yearly assessment of BP, lipids, fasting glucose, and BMI is suggested (ACOG, 2013).

### Complications

HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelet count*) occurs in 20% of pregnancies complicated by preeclampsia with severe features (Leeman et al, 2016).<sup>5</sup> In HELLP syndrome, the main presenting symptoms are right upper quadrant pain and generalized malaise in up to 90% of cases and nausea and vomiting in 50% of cases (Sibai, 2004). HELLP syndrome is diagnosed by the presence of LFTs >2× normal, hemolysis (LDH >600 U/L, damaged erythrocytes noted on peripheral smear, or bilirubin >1.2 mg/dL), and platelet count <100,000/μL. The diagnosis of HELLP syndrome can be difficult, as 12% to 18% of patients with the disorder are normotensive, and 13% do not have proteinuria (Sibai, 2004). Evaluation for HELLP syndrome includes a CBC and LFTs. A DIC panel should also be considered if the platelet count is <50,000.

Patients with HELLP syndrome should receive MgSO<sub>4</sub> from admission until 24 to 48 hours postpartum. Platelet transfusion

is indicated if counts are <20,000/μL before vaginal delivery or <50,000/μL before cesarean delivery or in women with abnormal bleeding (ACOG, 2018). Corticosteroids have been shown to increase platelet counts in women with HELLP syndrome, but they have not been shown to improve maternal or fetal outcomes, except for the benefit of improving fetal lung function before 34 weeks gestational age (ACOG, 2013). Because the condition is often progressive and associated with sudden deterioration of both maternal and fetal condition, prompt delivery is indicated if the syndrome presents later than 34 weeks (ACOG, 2013).

Eclampsia is a life-threatening complication of preeclampsia, defined as new-onset grand mal seizures in a woman with preeclampsia (ACOG, 2013). Seizures typically last 60 to 90 seconds and may be followed by a postictal state (Leeman et al, 2016). During an eclamptic seizure, the fetus often becomes hypoxic and bradycardic. Eclampsia can occur antepartum, intrapartum, or postpartum. It can be preceded by a wide range of symptoms including persistent headache, visual changes, altered mental status, and upper abdominal pain, and it can occur in the absence of proteinuria or hypertension.

MgSO<sub>4</sub> is the drug of choice in treating eclampsia, both for the initial convulsion and for prevention of subsequent ones. The dosing regimen is 6 g loading dose given over 15 to 20 minutes, followed by a maintenance infusion of 2 g/h for at least 24 hours after the convulsion (Duley et al, 2010). No other anticonvulsants should be given in an attempt to shorten or abolish the initial convulsion. Care should be taken to protect the airway, reduce risk of aspiration, and prevent maternal injury. Ten percent of eclamptic women will have a second convulsion after receiving magnesium. If this occurs, an additional 2 g dose of MgSO<sub>4</sub> should be given intravenously over 3 to 5 minutes.

## POSTPARTUM CARE

Tara J. Neil, MD

### CURRENT DIAGNOSIS

- The postpartum period consists of the period from delivery of the infant until 6 to 8 weeks postpartum.
- Postpartum hemorrhage is a medical emergency and is usually caused by uterine atony.
- Fever during the postpartum period is typically caused by endometritis or mastitis.

## CURRENT THERAPY

- Continue to monitor and check for resolution of any complications or medical conditions that arise during pregnancy.
- Uterine atony responds to massage and medications. Providers should be familiar with the medications and their dosages.
- Postpartum contraception counseling should be started immediately and all forms can be used by 6 weeks postpartum.
- Breastfeeding is the preferred nutrition for newborns and success is dependent on provider counseling and encouragement.

### BOX 1 Causes of Postpartum Hemorrhage

- Uterine atony
- Vaginal or cervical laceration
- Coagulation disorder
- Uterine inversion
- Retained placenta/products

Postpartum care encompasses the period after delivery of infant and placenta until 6 to 8 weeks after delivery. The hormonal and physiologic systems that underwent changes during pregnancy return to normal during this time. During the initial 24 to 48 hours, most patients are monitored in the hospital for possible complications after delivery.

### Postpartum Hemorrhage

Postpartum hemorrhage is defined as blood loss greater than 500 mL after vaginal delivery or greater than 1000 mL after cesarean section. It is the major cause of maternal morbidity and mortality worldwide. Practitioners should be prepared to diagnose and treat the cause.

Some common causes of hemorrhage are identified in [Box 1](#), including the most common cause: uterine atony. Once abnormal bleeding is identified, resuscitation measures should be started, including intravenous (IV) access, nursing assistance, starting fluid resuscitation with crystalloids or blood products, and anesthesia if needed. In addition, administration of tranexamic acid (Cyklokapron)<sup>1</sup> 1000 mg IV has been shown to decrease mortality regardless of the cause of bleeding. The uterus should be examined using a bimanual examination and vigorous massage. If the uterus is boggy, the medications listed in [Table 1](#) can be used to improve uterine tone and decrease bleeding. If the bladder is full, a catheter should be placed. Careful inspection of the cervix, vaginal walls, and perineum should be performed to identify other sources of hemorrhage. If bleeding is not slowed or the cause of hemorrhage not identified, manual exploration of the uterus can be performed with proper anesthesia to check for retained products. Surgical treatment with dilation and curettage and hysterectomy can also be used if manual exploration and medical management do not control bleeding. If the patient is hemodynamically stable and the resources are available, embolization of the uterine arteries can also control bleeding.

<sup>1</sup>Available as dietary supplement.

### Postpartum Care After Hospital Dismissal

Clinical care in the postpartum period should be focused on continued care of the mom and baby and not as a single visit. To better facilitate this, the patient should have clinical contact by phone or at appointment with the provider or clinical team in the first 3 weeks. Ongoing care should be provided on an as-needed basis. Ultimately, the postpartum period ends with a comprehensive visit and exam occurring by 12 weeks. This visit should include full physical and psychosocial assessment as well as discussion of interpregnancy spacing and management of any chronic health conditions.

### Fever and Infection

Fever greater than 38°C (100.4°F) should be evaluated and a source identified. [Box 2](#) lists the most common causes of postpartum fever. Evaluation should include a physical examination to include the uterus and breasts, with attention to any lacerations or incisions. Laboratory testing should include urinalysis, complete blood count (CBC), and blood cultures if appropriate.

Endometritis, a polymicrobial infection of the endometrium of the uterus, typically causes fever in the first 1 to 2 weeks postpartum. Diagnostic criteria include fever and uterine pain with palpation. Endometritis is treated with IV broad-spectrum antibiotics until fever and uterine pain resolve. If there is no clinical improvement after several days of treatment, imaging with computed tomography (CT) or ultrasound of the pelvis can be used to look for complications, including pelvic abscess and septic pelvic thrombophlebitis.

Mastitis causes fever in breastfeeding mothers. It is caused by the introduction of skin flora through cracks in the nipple and skin and infects milk ducts and surrounding soft tissues in areas of stasis. Treatment includes frequent feeding or pumping to alleviate the stasis. There is inadequate evidence to support antibiotic use, but if symptoms persist after effectively emptying breasts, most practitioners treat with a 10- to 14-day course of oral narrow-spectrum antibiotics. Complications can include breast abscesses, which are usually diagnosed by ultrasound.

### Immunization

Immunizations should be updated during the postpartum period. Rubella status is routinely checked during the prenatal period and immunization should be given if indicated. Tdap (tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine [Adacel, Boostrix]) should be given to the patient and offered to other members of the family if they have not received a pertussis booster to help protect the infant from contracting pertussis. Influenza vaccine should be given if it was not given during pregnancy. Rh(D)-negative mothers should receive anti-D immune globulin if their infants are Rh(D) positive.

### Breastfeeding

Breast milk is universally recognized as the best nutrition for newborns. Infants who are breastfed have fewer ear, lower respiratory, and gastrointestinal infections. They are also less likely to develop asthma, diabetes, and obesity. Contraindications to breastfeeding include human immunodeficiency virus (HIV), active herpetic lesions on breasts, maternal drug abuse, and certain medications. Any medications prescribed during breastfeeding should be checked for safety. It is currently recommended, when possible, for infants to be exclusively breastfed until 6 months and supplemented with foods between the ages of 6 months and 1 year. Clinicians play a crucial role in educating mothers about the importance of breastfeeding and supporting them during breastfeeding.

### Contraception

Discussing contraception after delivery is important for healthy birth spacing. Ovulation can occur as early as 3 weeks after delivery. Breastfeeding mothers can use lactational amenorrhea during this period if they are exclusively breastfeeding. They can also

**TABLE 1** Medications Used to Treat Uterine Atony

MEDICATION	ADMINISTRATION	FREQUENCY	SPECIAL CONSIDERATIONS
Oxytocin (Pitocin)	10 units IM 10–40 units in 1000 mL of IV solution	Once Continuous to maintain uterine tone	Should not be given directly in IV
Methylergonovine maleate (Methergine)	0.2 mg IM/IV 0.2 mg PO	Repeat every 2–4 h as needed 3–4 times daily for maximum of 7 days	Contraindicated in hypertension
Carboprost tromethamine (Hemabate)	0.25 mg IM	Repeat every 15–90 min. Maximum dose 2 mg	Contraindicated in active cardiac, renal, pulmonary, and liver disease. Use cautiously in asthmatics.
Misoprostol (Cytotec) <sup>1</sup>	800–1000 µg rectally <sup>3</sup>	One-time dose	

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

**BOX 2** Causes of Postpartum Fever

- Mastitis
- Endometritis
- Urinary tract infection
- Wound infection (perineal or abdominal)
- Septic thrombophlebitis
- Deep vein thrombosis

use progesterone-only contraception (Micronor, Depo-Provera, Nexplanon) or intrauterine device starting 6 weeks postpartum. Combined estrogen-progesterone formulations can be started as early as 3 weeks postpartum in nonbreastfeeding mothers. Starting estrogen-containing formulations before this can increase the risk for thromboembolism. Intrauterine devices and diaphragms are typically placed at 6 weeks after the uterus has returned to its normal size. Medroxyprogesterone intramuscular (IM) injection (Depo-Provera) and etonogestrel subcutaneous (SC) implant (Nexplanon) may be given in the first 5 days postpartum if a patient is not breastfeeding.

**Other Considerations**

Close evaluation and continued management of medical conditions that develop during pregnancy, including thyroid disease, gestational diabetes, and preeclampsia, should be continued.

The postpartum period is an important time for new mothers. Open communication with their providers during this time helps support them and helps them to recognize conditions that are important for their health and the health of their newborn.

**POSTPARTUM DEPRESSION**

Method of

Daniel S. Oram, MD; and Lydia U. Lee, MD

**CURRENT DIAGNOSIS**

- All pregnant and postpartum women should be screened for postpartum depression with a validated tool, such as the Edinburgh Postpartum Depression Scale
- Care should be taken to exclude bipolar disorder

**CURRENT THERAPY**

- Cognitive behavioral therapy and interpersonal therapy are the most well-studied interventions
- Selective serotonin reuptake inhibitors are modestly effective for postpartum depression and are generally safe, with most data for sertraline (Zoloft)
- A newly approved neuroactive steroid, brexanolone (Zulresso), may prove to be useful in rapidly inducing remission, although use will likely be limited to the inpatient setting

**Introduction**

Postpartum depression is a common mood disorder that carries the potential for substantial morbidity. There is no universally agreed-upon definition. Increasingly, postpartum- and antepartum-onset depression are being considered together as peripartum depression; the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) uses the specifier “with peripartum onset” to refer to an episode of major depression which occurs during pregnancy or within 4 weeks of delivery. Clinically, however, postpartum depression is often identified if onset is within 1 year of delivery. There are considerations in management of mood disorders that are unique to the postpartum period. Therefore this chapter will focus on depressive episodes with postpartum onset, in line with much of the primary literature on this topic.

**Epidemiology**

In developed countries, postpartum depression has an incidence of about 15% (including both major and minor depression) in the first 3 months of the postpartum period. Worldwide prevalence varies widely by country; estimates using most rigorous methods

vary from 0.1% to 26%, with culture influencing both maternal mood and how mood symptoms are communicated.

**Risk Factors**

The most consistently identified risk factors for depression with postpartum onset include history of mental illness prior to or during the pregnancy (especially prior postpartum depression, recurrent major depression, and bipolar disorder), stressful life events, poor social support, poor partner relationships, and infant medical illness. Abuse is also frequently reported as a risk factor, and includes current or lifetime history of physical, psychological, or sexual abuse by intimate partners or family members. A wide range of other risk factors that have been less consistently cited include infant temperament, negative attitude toward pregnancy, low socioeconomic status, young maternal age, unplanned pregnancy, and obstetric complications. Among women who are identified as having postpartum depression, a recent prospective cohort study predicted risk factors for a severe depressive episode with high accuracy. They found that at-risk women had higher Edinburgh Postpartum Depression Scale (EPDS) scores obtained, higher parity, lower education, and lower Global Assessment of Functioning scores, though this approach will need further validation.

**Pathophysiology**

While the etiology of postpartum depression has not been fully elucidated, it is best understood through a biopsychosocial model. Sex hormones fall rapidly after delivery and likely precipitate depressive symptoms. In particular, experimental evidence in postpartum women supports the role of low postpartum levels of estrogen and the progesterone metabolite allopregnanolone (which affects GABA signaling) in contributing to the depressed mood. Genetic variants in hormonal and serotonergic pathways likely place some women at increased risk. This genetic risk is likely potentiated by social stressors. Finally, cultural factors affect both norms of social support provided to new mothers, and the language mothers use to express their symptoms.

**Prevention**

Care teams should identify women at high risk early in pregnancy; this process should include routine use of a mood inventory such as the EPDS. At-risk women should receive multifaceted support throughout pregnancy and the postpartum period. Components can include a longitudinal patient-provider relationship, which may benefit from more frequent visits, social needs assessment, referral to community maternal-infant health resources, and early initiation of therapy. Interpersonal therapy is the best-supported modality for the prevention of postpartum depression. Postpartum home visits and telephone follow-up have been found helpful in decreasing depression incidence. Starting an antidepressant prophylactically has not been effective experimentally in preventing postpartum depression. However, discontinuing antidepressants prescribed prior to pregnancy increases the risk of depression relapse, even in women whose depression is in remission prior to pregnancy.

**Clinical Manifestations**

In general, postpartum depression is similar to other forms of depression. However, the stresses of feeding and caring for a new infant, changes in partner relationship dynamics, and the sometimes traumatic experiences of childbirth add unique themes to the experience of postpartum depression. Depressive symptoms may arise in part from unmet expectations about childbirth or mothering; a sense of loss is common among women with postpartum depression. Compared to other episodes of depression, postpartum depression episodes are less correlated with sleep or appetite disruption, perhaps because these are common experiences among new mothers. Thoughts of harming the infant are

extremely common, though of varying severity. Effects of depression may be visible in a dysfunctional parenting style. Conversely, new moms may experience recurrent worries and intrusive thoughts about harm befalling their newborn, sometimes accompanied by a need to repetitively check the infant, which can be reminiscent of obsessive compulsive disorder.

**Diagnosis**

Screening should be performed during pregnancy and the postpartum period. The EPDS is the most well-studied inventory, and has been validated for use in the identification of patients with postpartum depression. It has a sensitivity of about 80% and a specificity of about 90%. Scores of 13 or higher are generally interpreted as a positive screen. Alternatively, it is reasonable to employ a lower score of 10 as a threshold for pursuing further investigation to improve sensitivity for detecting potential cases of postpartum depression. A clinical interview supportive of an episode of major depression then confirms the diagnosis (Table 1).

**Differential Diagnosis**

“Baby blues” is the most common mood disruption of the postpartum period. Though it lacks formal diagnostic criteria, it is considered to be a mild, self-limited condition characterized by frequent mood swings that does not extend beyond 2 weeks postpartum. Depending on how it is defined, it is present in 20% to 80% of postpartum women. Bipolar disorder should be considered any time postpartum depression is diagnosed. It is associated with increased morbidity, and antidepressants may trigger manic episodes in affected women. Further, up to 25% of women who screen positive on the EPDS meet criteria for bipolar disorder in some studies. Clinicians should consider routine screening for bipolar disorder with a validated questionnaire such as the Mood Disorder Questionnaire at the time of identification of a depressive episode. Finally, review of systems should include evaluation for hallucinations, delusions, or disorganized behaviors that would suggest psychosis.

**Therapy**

Postpartum depression can often be effectively managed in the primary care setting, and should begin with establishing a supportive clinician-patient relationship through frequent visits. Therapy is the cornerstone of treatment. Cognitive-behavioral therapy and interpersonal therapy are the most well-studied interventions. Interpersonal therapy, which focuses on troubleshooting relationships and maximizing social support, may be particularly well-suited to the relational transitions of the postpartum period. However, a wide variety of modalities and

**TABLE 1** Abbreviated Diagnostic Criteria for Major Depressive Disorder

Five or more during a 2-week period; must include either depressed mood or anhedonia.

SYMPTOM	ASSESSED IN EPDS?
Depressed mood	Yes
Anhedonia	Yes
Insomnia/hypersomnia	Yes
Weight or appetite decrease or increase	No
Psychomotor agitation or retardation	No
Fatigue or loss of energy	No
Worthlessness or guilt	Yes
Decreased concentration or indecisiveness	No
Thoughts of death, or suicidal plan/attempt	Yes

EPDS, Edinburgh Postpartum Depression Scale.

**TABLE 2** Selected Antidepressant Characteristics for Postpartum Depression

CLASS	MEDICATION	RCT SUPPORTING USE?	PREGNANCY CONSIDERATIONS	BREAST-MILK LEVELS	POSSIBLE INFANT ADVERSE EFFECTS?	CLINICAL COMMENTS
SSRIs	Sertraline (Zoloft) <sup>1</sup>	Yes	Preferred SSRI	Very low	None known	Most studied; preferred SSRI during breastfeeding
	Paroxetine (Paxil) <sup>1</sup>	Yes	Possibly higher risk of neonatal symptoms, cardiac malformations	Very low	None known	Well-studied in breastfeeding. Avoid in pregnancy. High risk for maternal withdrawal symptoms
	Fluoxetine (Prozac) <sup>1</sup>	Yes	Delayed infant clearance (long half-life)	Low-medium	Possible: poor weight gain. Case reports: colic, sleep disturbance, GI disturbance.	Metabolite with long half-life may dose-accumulate in infant
	Citalopram (Celexa) <sup>1</sup> /escitalopram (Lexapro) <sup>1</sup>	No*	Preferred SSRI	Low	Case reports: sleep disturbance, irritability.	Escitalopram is less well-studied than citalopram in breastfeeding, although clinical experience supports a similar safety profile
SNRIs	Venlafaxine (Effexor) <sup>1</sup>	No	Less well-studied than SSRIs	Low	None known	Case reports of higher infant levels of active metabolite. High risk for maternal withdrawal symptoms
	Duloxetine (Cymbalta) <sup>1</sup>	No	Minimal data	Low	None known	Less-studied in breastfeeding. Case reports of galactorrhea
Tricyclics	Nortriptyline (Pamelor) <sup>1</sup>	Yes	Less well-studied than SSRIs	Low	None known	Well-studied in breastfeeding
	Amitriptyline (Elavil) <sup>1</sup>	No		Low	Case report: Oversedation.	
Other	Bupropion (Wellbutrin) <sup>1</sup>	No	Minimal data	Low	Case report: seizure	Case report of galactorrhea
	Mirtazapine (Remeron) <sup>1</sup>	No	Minimal data	Low	None known	Less-studied in breastfeeding. Case reports of galactorrhea

GI, Gastrointestinal; RCT, randomized controlled trial; SNRIs, serotonin/norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors.

<sup>1</sup>Not FDA approved for this indication.

\*Citalopram (Celexa) and escitalopram (Lexapro) were among medications used in a naturalistic open-label RCT.

settings have been found to be effective. In light of this, brief office interventions can enhance patient's early access to care. For instance, clinicians can use motivational interviewing to support behavioral activation. Similarly, problem-solving interventions can assist patients in working through relationship difficulties, and discussion of mindfulness practices can promote more adaptive responses to stress.

In contrast to other forms of depression, the evidence base for pharmacotherapy is fairly small, and effect sizes are modest. Selective serotonin reuptake inhibitors (SSRIs) are the best-studied drug class, followed by tricyclic antidepressants (Table 2). Limited experimental evidence has not supported concurrent therapy and antidepressant use. However, this remains a clinically reasonable approach. In severe postpartum depression, therapy and medication may be started concurrently, as medication efficacy may be delayed several weeks.

Antidepressant safety is a frequent concern. A detailed discussion of use during pregnancy is outside the scope of this article. The most common class-related adverse effect is neonatal withdrawal, a syndrome of irritability and poor feeding, which affect a minority of infants and is usually self-limited. Inconsistent evidence suggests SSRIs may be associated with a small risk of

congenital cardiac lesions (possibly higher risk with paroxetine [Paxil]) or persistent pulmonary hypertension. Antidepressants are generally excreted in low levels in breastmilk, and evidence of infant toxicity is limited to case reports. There is limited evidence that antidepressants may transiently decrease breastmilk supply. While sertraline (Zoloft), paroxetine (Paxil), and nortriptyline (Pamelor) are the preferred agents in the postpartum period, in general, breastfeeding is not contraindicated with antidepressants. Consideration should be given to risk for future pregnancy; for instance, paroxetine is generally avoided in pregnancy due to potentially higher risk for cardiac anomalies.

An allopregnanolone analogue, brexanolone (Zulresso), was recently approved for the treatment of postpartum depression. It requires a 60-hour monitored infusion, gradually titrated to a target dose of 90 mcg/kg/h, which, in addition to cost, will likely limit its use to psychiatric hospitalizations. However, administration rapidly induced remission in women with moderate and severe depression, with a number needed to treat for remission at the end of infusion of about 3 to 4 in industry-funded stage 3 clinical trials. Differences from placebo were less pronounced at 30 days. Other allopregnanolone analogues are also undergoing clinical trials.

Among complementary modalities for treating postpartum depression, exercise has most consistently been shown to be beneficial. Yoga may also facilitate recovery. Limited evidence supports light therapy. The use of supplements is generally not evidence-based. For instance, omega-3 fatty acids<sup>7</sup> are the most-studied supplement and have not been clearly shown to alleviate postpartum depression.

### Monitoring

Clinicians should monitor for return to function in self-care, child care, and other interpersonal relationships. Re-administering depression inventories, such as the EPDS, can provide further objective evidence of disease course. An EPDS score of less than 10 is often used as evidence of remission. If antidepressants are being used, they should be continued for a minimum of 6 months beyond entrance into remission.

The maternal-infant pair should be assessed in the office for signs of dysfunctional attachment. Women with depression may display decreased responsiveness to infant needs, or conversely an anxiety-driven over-responsiveness. Breastfeeding difficulties may be a sign of impaired attachment. Clinicians should offer nonjudgmental support to women regardless of their preference to continue or discontinue breastfeeding, as this can be a significant source of stress for some mothers while providing therapeutic benefit to others.

Risk for suicide and infanticide should be assessed routinely. Suicide is a leading cause of death in the postpartum period, and postpartum women may be more likely than their peers to attempt suicide with high-lethality methods such as use of a weapon. Similarly, thoughts of infanticide are very common, although rarely acted upon. Risk-increasing factors include the presence of psychosis, mania, or severe cognitive distortions.

### Management of Complications

Hospitalization is indicated if a woman demonstrates signs of mania, psychosis, or high-risk thoughts of suicide or infanticide. Expert consultation should be considered if depression is refractory to therapy or medication. Electroconvulsive therapy has been shown to be effective for treatment of refractory postpartum depression.

<sup>7</sup>Available as dietary supplement.

## VAGINAL BLEEDING IN PREGNANCY

Method of

Zachary J. Baeseman, MD, MPH

### CURRENT DIAGNOSIS

- There are several diagnoses in the differential of dangerous late pregnancy bleeding and management varies based on the etiology.
- Avoid digital vaginal examination in a patient with late pregnancy bleeding until placenta previa has been excluded by ultrasound.
- Uterine tenderness with vaginal bleeding is consistent with a clinical diagnosis of placental abruption.
- Vaginal bleeding with a rupture of membranes should prompt consideration of vasa previa.
- Early pregnancy bleeding in a hemodynamically stable patient is worked up with a complete history and physical, complete blood count, human chorionic gonadotropin, and a transvaginal ultrasound.

### CURRENT THERAPY

- Placenta previa requires cesarean delivery; however, with a placental edge of more than 2 cm from the cervical os, a vaginal delivery may be attempted in a stable patient.
- Antenatal diagnosis of vasa previa by ultrasound, appropriate administration of antenatal steroids, and a planned cesarean delivery between 34 and 36 weeks gestation is associated with significantly reduced perinatal morbidity and mortality.
- Definitive management of a patient with late-pregnancy bleeding who is hemodynamically unstable should not be delayed in order to obtain an ultrasound or other diagnostic testing.
- In early and late pregnancy bleeding, attention must be directed to the Rh status of the pregnant woman.

## Vaginal Bleeding in Late Pregnancy

### Epidemiology

Bleeding in the second half of pregnancy complicates 2% to 5% of pregnancies. Placental previa, placental insertion into the

lower uterine segment covering all or part of the internal cervical os, causes 30% of late-pregnancy bleeds and occurs in 0.5% of all pregnancies. Placental abruption, premature separation of the placenta from the uterine wall, causes 20% of antepartum hemorrhages and occurs in 1% of all pregnancies. The diagnosis of placental abruption is typically clinical; ultrasound can be useful to rule in the diagnosis, but notably, it can miss >50% of diagnoses. Other serious causes include uterine rupture (occurs in approximately 0.7% of women with a history of previous low-transverse cesarean section) and vasa previa (0.5% of late-pregnancy bleeding and approximately 0.0002% to 0.0008% of all pregnancies). Vasa previa occurs when fetal blood vessels are present in the membranes, traversing the cervix beneath the fetal presenting part.

### Risk Factors

Higher parity and maternal age, smoking or cocaine use, a prior history of placenta previa or placental abruption, and multifetal gestation are risk factors for both placenta previa and abruption. Risk factors for placenta previa also include uterine abnormalities, assisted reproductive technology (ART), and history of uterine surgery, including cesarean section. Additional risk factors for abruption include blunt abdominal trauma, polyhydramnios, hypertensive disorders in pregnancy, and external cephalic version. The greatest risk factor for uterine rupture is a trial of labor after cesarean section (TOLAC), particularly with induction and the use of prostaglandins, which are contraindicated in TOLAC. A uterine scar increases risk; spontaneous uterine rupture is rare on an unscarred uterus. Other risk factors include uterine abnormalities, maternal connective tissue disease, abnormal placentation, and uterine hyperstimulation during labor. Shortened interpregnancy interval (less than 18 to 24 months between pregnancies) can also increase risk. Risk factors for vasa previa include artificial reproductive techniques, bilobed or succenturiate lobed placenta (odds ratio [OR] = 22.11), placenta previa (OR = 22.86), certain fetal anomalies, and a velamentous cord insertion.

### Pathophysiology

The cause of placenta previa is unknown but may be related to impaired placental attachment in a uterus with a previous scar. Placental abruption, defined as premature separation of the placenta from the uterus, is caused by hemorrhage where the placenta and decidua meet. Abruption is often preceded by vasospasm (such as that induced by cocaine), thrombosis, or shearing forces. Some cases are acute, but many cases could present a chronic process in which abruption is the end result. Uterine rupture most often occurs in a uterus with a previous scar and is a dehiscence of that scar; often the presenting sign is an abnormal fetal heart rate or a regression of fetal station in labor. The pathophysiology of vasa previa is unknown, although it is theorized to be caused by abnormal development or growth of the umbilical cord secondary to a velamentous insertion or reduced intrauterine space.

### Prevention

Previous cesarean section is a risk factor for both placenta previa and uterine rupture, therefore reducing unnecessary cesarean sections can prevent these conditions. Patients who have had a cesarean section should be advised to space out their next pregnancy by 18 to 24 months to mitigate the risk of uterine rupture. Uterine rupture may also be prevented by limiting or avoiding certain agents to induce or augment labor. In women undergoing TOLAC, spontaneous labor is preferred due to the lower risk of uterine rupture. Although vasa previa cannot be prevented, fetal morbidity and mortality are significantly reduced by early diagnosis and delivery. Placental abruption is associated with smoking and cocaine use; counseling directed to cessation theoretically reduces risk. Seat belts are recommended for all pregnant women; trauma sustained during a motor vehicle accident is a potential cause of abruption due to shearing forces. Control of hypertension and treatment of thrombophilia have not been

proved to prevent abruption, although both interventions are recommended. Magnesium sulfate given intrapartum to women with preeclampsia can reduce the risk of placental abruption.

### Clinical Manifestations

Placenta previa classically manifests with painless vaginal bleeding, whereas placental abruption and uterine rupture are typically associated with pain and bleeding. Because these conditions are not mutually exclusive, it is important to consider the possibility of more than one serious cause of antepartum hemorrhage. Bleeding secondary to placenta previa may be heavy or light, can recur, and is not associated with the degree of previa or prognosis. Thirty percent of women with placental abruption may not present with vaginal bleeding and have a retroplacental clot concealing an abruption. Approximately one half of women with placental abruption present in labor, and 30% of cases are complicated by fetal death. Monitoring can reveal uterine irritability or hypertonicity. Uterine rupture can manifest with abnormal fetal heart tracing, loss of fetal station, or palpable uterine defect. Pain and bleeding might not occur until after uterine rupture, when both maternal and fetal status are compromised. Vasa previa is detectable on ultrasound and color Doppler imaging, but it most commonly presents as vaginal bleeding with rupture of membranes. Placental abruption, uterine rupture, and vasa previa can manifest with concerning fetal heart tracings.

### Diagnosis

Ultrasound can reliably detect placenta previa and vasa previa. Transvaginal ultrasonography (TVU) is recommended to establish placental location because transabdominal ultrasonography has a false-positive rate for placenta previa up to 25%. TVU has a sensitivity of 87.5% and a specificity of 98.8% for placenta previa and is safe in the presence of vaginal bleeding. Vasa previa can be diagnosed using TVU and color Doppler. High-risk women may be screened in order to plan for cesarean delivery at 34 to 36 weeks of gestation. Vasa previa may also be detected on magnetic resonance imaging (MRI; rarely used), amnioscopy, palpitation of vessels during regional examination, or identifying fetal blood cells in vaginal blood, although tests to detect fetal hemoglobin cannot be performed quickly enough to be clinically useful. Placental abruption is primarily a clinical diagnosis; it can be ruled in by ultrasound, but notably >50% of cases of placental abruption are missed on ultrasound. The diagnosis is made clinically in a patient with bleeding and a hard or tender uterus, uterine irritability, and often a nonreassuring fetal heart tracing; bleeding may be absent in 20% to 30% of presentations.

### Differential Diagnosis

In addition to placenta previa, placental abruption, uterine rupture, and vasa previa, diagnostic considerations include bloody show, cervical trauma, cervical polyp, cervical cancer, or infection.

### Therapy

Women with placenta previa and active bleeding are managed expectantly in the hospital, although outpatient management may be a reasonable approach in women who are not bleeding, have adequate support at home, and are able to get to the hospital quickly. Women with any degree of placental overlap with the cervical os should be delivered by cesarean section.

Treatment of women with placental abruption depends on multiple factors including severity of clinical presentation, gestational age, fetal status, and maternal status. In the most severe cases in which there has been fetal death, vaginal delivery is acceptable if the maternal status is reassuring. Because of risk for disseminated intravascular coagulopathy (DIC) and blood loss, women should be carefully monitored, proceeding to cesarean section for worsening maternal status or failed vaginal delivery. In mild cases of placental abruption before term, steroids should be administered between 24 and up to 36 6/7 weeks of gestation; preterm birth is the leading reason for perinatal death. With a

stable abruption in a preterm patient with reassuring fetal and maternal status, outpatient management may be reasonable after a period of inpatient observation. Antenatal magnesium sulfate in women <32 weeks gestation can reliably decrease cerebral palsy and neonatal gross motor dysfunction, however, tocolysis is not routinely recommended in placental abruption. Labor may progress toward a goal of vaginal delivery if both maternal and fetal status are reassuring, although cesarean section should be performed expeditiously for any fetal or maternal compromise. Longer decision-to-incision intervals are associated with worse perinatal outcomes. When placental abruption is known or suspected in a term patient, delivery should proceed.

Vasa previa is managed with immediate cesarean section if diagnosed during labor and with a planned cesarean section if diagnosed antenatally. Administration of steroids is recommended at 28 to 34 weeks of gestation depending on the timing of planned delivery, and hospitalization should be considered at around 30 to 32 weeks of gestation because approximately 10% of women have premature rupture of membranes and could need an urgent cesarean section. Certain patients are appropriate candidates for outpatient management. Optimal time for planned cesarean section is not definitely established and has been recommended between 34 and 36 weeks gestation. Neonatal resuscitation, including fluid resuscitation or transfusion, may be required and should be anticipated.

Uterine rupture is associated with high perinatal morbidity and mortality. When rupture is clinically recognized or suspected, cesarean delivery should proceed rapidly. Occasionally a uterine window can be seen antenatally within the previous uterine scar on ultrasound. Scheduled cesarean delivery at 37 weeks is recommended for these patients and labor is contraindicated due to the risk of uterine rupture during labor.

### Monitoring

In placenta previa, the distance between the placental edge and cervical os is monitored during pregnancy by ultrasound because the placental location can change with advancing pregnancy. After 35 weeks' gestation, women with a placental edge more than 20 mm from the internal cervical os may be offered a trial of labor because they are likely to achieve vaginal delivery. When the placental edge is greater than 0 mm but less than 20 mm from the internal cervical os, vaginal delivery might still be possible, although the likelihood of cesarean section and intrapartum complications are much higher. Women at increased risk of vasa previa should be screened with TVU and color Doppler. When vasa previa is identified, serial ultrasound is indicated because abnormal vessels regress in up to 15% of women. If a woman has an Rh negative blood type and experiences bleeding in pregnancy, she should receive a standard dose of 300 µg Rho(D) human immune globulin to prevent maternal Rh alloimmunization. For massive maternal-fetal hemorrhage a Kleihauer-Betke test should be performed in Rh negative mothers to assist in confirming maternal-fetal hemorrhage and Rho(D) human immune globulin dosing.

### Complications

Maternal risks associated with placenta previa include need for cesarean section, postpartum hemorrhage, and blood transfusion. Women who have history of cesarean section and who have placenta previa are at increased risk for placenta accreta. Fetal risks are primarily associated with prematurity. Placental abruption can cause hypovolemic shock, postpartum hemorrhage, and DIC. Perinatal complications include prematurity, intrauterine growth restriction, anemia, coagulopathy, and death. Uterine rupture can be catastrophic for both mother and baby. Maternal risks include surgical risk associated with cesarean section, hypovolemic shock and hemorrhage, and hysterectomy. Perinatal morbidity can include hypoxic-ischemic encephalopathy. Stillbirth and neonatal death are possible as well. When undiagnosed prior to labor vasa previa carries a fetal mortality rate of greater than 60%. Antenatal diagnosis with planned cesarean section decreases fetal mortality to 2% to 3% and reduces the need for transfusion from

60% to 3%. Because the hemorrhage is fetal blood, maternal risk from vasa previa is primarily associated with complications related to cesarean section.

## Vaginal Bleeding in Early Pregnancy

### Epidemiology

Vaginal bleeding in early pregnancy is common and has been reported in 20% to 40% of pregnant women. A viable intrauterine pregnancy is the most common diagnosis. The two most common complicating diagnoses of early pregnancy bleeding are threatened abortion and ectopic pregnancy. Threatened abortion, an intrauterine pregnancy with bleeding and pain before 20 weeks gestation that has cardiac activity and a closed cervix, is the cause of 12% to 57% of early pregnancy bleeding. The incidence of ectopic pregnancy is 19.7 cases per 1000 pregnancies and is increasing worldwide. Ectopic pregnancy is the leading cause of morbidity and maternal mortality in the first trimester of pregnancy.

It has been suggested that the rate of miscarriage can be as high as 30% to 50% of all fertilized eggs and often goes undetected. The incidence of miscarriage in an intrauterine pregnancy with confirmed fetal cardiac activity is 2.1% in women under 35 years of age and 16.1% in women greater than 35 years of age. Other common causes of early pregnancy bleeding include intercourse, cervicitis, pelvic inflammatory disease, functional placenta hormonal changes, fertilized egg implantation into the uterine wall, and gestational trophoblastic disease.

### Pathophysiology

The most common diagnosis of bleeding in early pregnancy is a normal and viable intrauterine pregnancy. Vaginal spotting can commonly occur after implantation of a fertilized egg into the intrauterine wall, usually occurring a few days prior to the expected onset of menstruation (8 to 9 days after ovulation and fertilization). Early pregnancy bleeding may also be caused by the commencement of a hormonally functional placenta, usually at 6 to 7 weeks of gestation. Concerning causes of early pregnancy bleeding are maternal hormonal deficiency, placental dysfunction, subchorionic hemorrhage, extrauterine implantation of the embryo, and nonviability of the pregnancy. The amount of hemorrhage in early pregnancy may be associated with the risk of pregnancy loss.

### Management

Early pregnancy bleeding is worked up with a complete set of vital signs, a complete history and physical examination including visualization of the cervix with a speculum, a complete blood count, β-hCG (human chorionic gonadotropin), and a transvaginal ultrasound (TVU) to determine fetal viability and exclude an ectopic pregnancy. Concern for ectopic or early pregnancy loss should be raised if the β-hCG level is greater than the discriminatory level (1500 to 3000 mIU/mL) without intrauterine contents seen on TVU. If the patient is hemodynamically unstable, urgent surgical consultation is paramount as it is possible to have intra-abdominal exsanguination from a ruptured ectopic pregnancy. If the patient is hemodynamically stable and the pregnancy is viable, bleeding is most often managed expectantly, provided the fetus has not reached extrauterine viability of 23 to 24 weeks gestation.

If the patient is hemodynamically stable, a miscarriage can be managed expectantly, inducing medical expulsion of the nonviable fetal tissue with a combination of mifepristone and misoprostol, or surgical management with dilation and suction curettage depending on the risk of infection, maternal hemorrhage and anemia, maternal preference, and medical necessity. Medical management has been proven to increase the effectiveness and decrease the time of complete expulsion compared to expectant management. Due to the risk of alloimmunization, it is recommended that women who are Rh negative blood type have surgical management and receive prophylactic Rho(D) human immune globulin to reduce the risk of alloimmunization. Alloimmunization is a devastating complication where an Rh negative mother

can develop antibodies to Rh positive fetal blood, placing future pregnancies at risk.

If a woman has an Rh negative blood type and experiences bleeding in pregnancy, she should receive Rho(D) human immune globulin to prevent maternal Rh alloimmunization. Failure to receive Rho(D) human immune globulin can complicate all subsequent pregnancies and ultimately lead to future severe fetal anemia and hydrops fetalis (severe and life-threatening fetal edema secondary to profound fetal anemia). For early pregnancy bleeding in an Rh negative mother of less than 12 weeks of gestation, 150 µg of Rho(D) is sufficient; greater than 12 weeks of gestation, a standard dose of 300 µg should be given. These dosages provide maternal protection from up to 30 mL of fetal whole blood. For massive maternal-fetal hemorrhage a Kleihauer-Betke test should be performed in Rh negative mothers to assist in confirming maternal-fetal hemorrhage and Rho(D) human immune globulin dosing.

If there is recurrent pregnancy loss, defined as greater than 3 total pregnancy losses, two consecutive pregnancy losses, or a pregnancy loss greater than 20 weeks of gestation, secondary causes should be sought including a workup for antiphospholipid antibody disorder, clotting disorders, and maternal or fetal chromosomal testing. The products of conceptions resulting from gestational trophoblastic disease should undergo chromosomal analysis.

## ACUTE LEUKEMIA IN CHILDREN

Method of

Stacy Cooper, MD; and Rachel E. Rau, MD

Leukemias are characterized by a marked proliferation of abnormal blood cells in the bone marrow and blood that may be associated with widespread infiltration in extramedullary sites including the central nervous system (CNS), testes, thymus, liver, spleen, and lymph nodes.

### Classification

The first level of classification of leukemia is *acute* versus *chronic*. Acute leukemia is characterized by the predominance of very immature white blood cell precursors, or blasts, and is an aggressive, rapidly fatal disease if left untreated. Conversely, chronic leukemia is characterized by proliferation of relatively mature white blood cells and is typically a more indolent disease. Chronic leukemias are uncommon in pediatrics.

The second level of classification is *lymphoid* versus *myeloid*, depending on whether the leukemic cells display characteristics of lymphocyte precursors or myelocyte (granulocyte, erythrocyte, monocyte, or megakaryocyte) precursors. Acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) account for the overwhelming majority of pediatric leukemias.

ALL and AML are further subclassified by morphology and expression of cell surface antigens using flow cytometry. For ALL, classification is largely based on cell surface and cytoplasmic marker expression (Table 1). AML cases are classified by characteristic chromosomal abnormalities (if present) or by light microscopic morphology in cases where these specific chromosomal changes are absent (Box 1).

### Epidemiology

Leukemia accounts for approximately 30% of childhood cancers, making it the most common form of childhood cancer. The distribution of the major forms of leukemia is vastly different in children than in adults (Figure 1). In general, children are far

more likely to have acute leukemia, and ALL is much more common than AML. In adults, most cases of leukemia are chronic, and AML is more common than ALL. Specifically, there are approximately 3100 children and adolescents diagnosed with ALL in the United States each year and approximately 700 children and adolescents diagnosed with AML in the United States each year.

The incidence of the various forms of leukemia varies by age in both children and adults (Figure 2). This is especially true for childhood ALL, for which there is a marked incidence peak in the 2- to 4-year-old age group. This ALL age peak is primarily found in children living in industrialized nations, leading to speculation that a common environmental exposure, coupled with age-related immunologic susceptibility, is at least partially responsible for many cases of ALL. Except for a small peak in infants, the incidence of AML is fairly constant in childhood but rises quickly in later adulthood.

### Prognosis

One of the most dramatic success stories in modern medicine is the improvement in survival of children with ALL over the past four decades. Leukemia was once a uniformly fatal diagnosis, with less than a 5% to 10% cure rate until the mid- to late 1960s. Today, approximately 90% of children with ALL are cured. The improved prognosis has been built on pioneering observations on the efficacy of multiagent systemic therapy and the importance of CNS treatment in the late 1960s and early 1970s. Further successive, incremental improvements in outcome have been achieved due to clinical trials conducted by large single centers and national and international cooperative groups that have successfully enrolled a high percentage of eligible children.

Similar approaches have unfortunately not been quite so successful in improving the prognosis of children with AML. Although approximately one half of children with AML are cured today, this has been accomplished by intensifying therapy to the point that the toxic death rate in the early phases of therapy is about 10%. Current research in AML is therefore focusing on developing novel molecularly targeted agents that hold the promise of improving efficacy and limiting toxicity.

**TABLE 1** Classification of Childhood Acute Lymphoblastic Leukemia

ALL SUBTYPE	PHENOTYPIC MARKER				%	COMMENT
	CD19	CD10	CLG	SLG		
Pre-pre B	+	-	-	-	5	Mostly infants, poor prognosis, frequent <i>KMT2A</i> 11q23 rearrangements
Early pre-B	+	+	-	-	63	Common ALL, young children, good prognosis
Pre-B	+	+	+	-	16	Older children, good prognosis with intense therapy
B-cell	+	+	+	+	4	Burkitt leukemia, <i>MYC/Ig</i> fusion genes, good prognosis with lymphoma-type therapy
T-cell	-	-	-	-	12	Adolescents, anterior mediastinal mass, CNS involvement, good prognosis with intense therapy

ALL, Acute myeloid leukemia; *clg*, cytoplasmic immunoglobulin; CNS, central nervous system; *slg*, surface immunoglobulin.

**BOX 1**

**Classification of Childhood Acute Myeloid Leukemia (World Health Organization Criteria)**

**Acute Myeloid Leukemia With Recurrent Genetic Abnormalities**

- Acute myeloid leukemia with t(8;21)(q22;q22), (*RUNX1/RUNX1T1*)
- Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13q22) or t(16;16)(p13;q22), (*CBFβ/MYH11*)
- Acute promyelocytic leukemia with t(15;17)(q22;q12), (*PML/RARA*), and variants
- Acute myeloid leukemia with 11q23 (*KMT2A*) abnormalities

**Acute Myeloid Leukemia, Not Otherwise Categorized**

- Acute myeloid leukemia, minimally differentiated (FAB M0)
- Acute myeloid leukemia without maturation (FAB M1)
- Acute myeloid leukemia with maturation (FAB M2)
- Acute myelomonocytic leukemia (FAB M4)
- Acute monoblastic/acute monocytic leukemia (FAB M5)
- Acute erythroid leukemia (FAB M6)
- Acute megakaryoblastic leukemia (FAB M7)

FAB, French–American–British classification.

**Etiology**

The question “What is the cause of leukemia?” can be considered on a few different levels. First, what is wrong with *this child* that caused the child to develop leukemia? Second, what is wrong with *the leukemia cell* that causes it to behave so badly? Third, what is wrong with *the leukemia cell’s genes* that cause the cell to behave that way?

**Predispositions**

The answer to the first question is unknown in the vast majority of cases. Attempts to correlate various genetic features or environmental or infectious exposures with risk of childhood leukemia have been largely uninformative. It is presumed that children are particularly susceptible to ALL because of the marked expansion and genetic rearrangement of lymphocytes that occurs during early childhood as the result of exposure to a multitude of immunogenic antigens for the first time. The proliferation required to meet the constant demand for granulocytes, erythrocytes, and platelets is likely a setup for the development of AML in children.

Although a number of constitutional and single-gene disorders confer an increased risk of childhood leukemia (Table 2), in total, these are known to be involved in only a minority of cases. However, with a growing list of recognized genetic disorders predisposing to myeloid malignancies in particular, a careful

**Figure 1** Relative incidence of four major leukemia subtypes in children and adults. ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphoblastic leukemia; CML, chronic myeloid leukemia.

**Figure 2** Age-specific incidence of acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) in children and in adults (inset).

**TABLE 2** Summary of Known Constitutional and Heritable Childhood Leukemia Predispositions

DISORDER	INHERITANCE	MALIGNANCY TYPE	COMMENTS
Ataxia-telangiectasia	AR	ALL, NHL	<i>ATM</i> gene mutations lead to defective DNA repair
Bloom's syndrome	AR	AML, ALL	Chromosomal instability, sister chromatid exchanges
Down syndrome	Sporadic	AML, ALL	See text
Li-Fraumeni syndrome	AD	AML, ALL, many others	<i>p53</i> mutations; leukemias less common than solid tumors
Fanconi's anemia	AR	AML	Chromosomal instability, increased sensitivity to DNA damage
Kostmann's syndrome	AR	AML	G-CSF receptor mutations lead to agranulocytosis
Neurofibromatosis type 1	AD	AML, JMML, MPNST	<i>NF1</i> gene mutations lead to enhanced RAS signaling
Familial platelet disorder with associated myeloid malignancy	AD	MDS, AML, ALL	Loss of function mutations of the myeloid transcription factor RUNX1 lead to abnormal myeloid development Individuals have platelet defects and ~35% risk of myeloid malignancy development
Germline CEBPA mutations	AD	AML	Estimated penetrance of AML development ~90% in affected individuals. Approximately 10% of patients with biallelic <i>CEBPA</i> mutant AML have a germline <i>CEBPA</i> mutation. AML in those with germline <i>CEBPA</i> mutations are chemosensitive, but individuals have high rates of second primary AMLs.
MonoMAC syndrome; germline <i>GATA2</i> mutations	AD	MDS, AML	MonoMAC is an immunodeficiency with risk for mycobacterial, fungal, and human papilloma virus infections with monocytopenia and risk for MDS/AML, often with monosomy of chromosome 7
MIRAGE syndrome, ATXPC/MLSM7 syndrome; Germline mutation of <i>SAMD9</i> and <i>SAMD9L</i>	Mostly de novo		MIRAGE syndrome (myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, enteropathy); ATXPC, ataxia-pancytopenia syndrome and MLSM7, myelodysplasia and leukemia syndrome with monosomy 7 caused by gain of function mutation of <i>SAMD9</i> or <i>SAMD9L</i>
CBL syndrome	AD	JMML	Impaired growth, developmental delay, cryptorchidism, deafness, and predisposition to JMML caused by loss of function mutation of tumor suppressor gene <i>CBL</i> . JMML that develops can be self-resolving. Vasculitis risk later in life after JMML resolution.

AD, Autosomal dominant; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; AR, autosomal recessive; G-CSF, granulocyte colony-stimulating factor; JMML, juvenile myelomonocytic leukemia; MPNST, malignant peripheral nerve sheath tumor; NHL, non-Hodgkin lymphoma.

past medical history, family history, and examination for dysmorphisms and low threshold for genetic referral is warranted for any child with a myeloid malignancy. The most common of these is Down syndrome. Children with Down syndrome have a 10- to 20-fold increased risk of leukemia, with an approximately equal incidence of ALL and AML. The peak age at onset of leukemia for children with Down syndrome is earlier than for other children. In the newborn period, patients with Down syndrome can present with transient myeloproliferative disease (also known as transient abnormal myelopoiesis), which can manifest with hepatomegaly and peripheral blasts, that appears indistinguishable from congenital AML but usually resolves spontaneously within 3 to 6 months. These children have an increased risk of megakaryoblastic leukemia (AMKL, FAB classification M7) within the first 4 years of life. Children with Down syndrome tend to present with leukemia that is particularly susceptible to chemotherapy agents (e.g., cytarabine [Cytosar], methotrexate), but they also suffer increased toxicity from therapy. On balance, the prognosis of leukemia in Down syndrome patients with ALL is inferior to those without Down syndrome, whereas in AML, children with

Down syndrome have favorable outcomes compared with children without Down syndrome.

The only environmental exposures that are known to predispose to leukemia are ionizing radiation (such as was seen with atomic bomb survivors) and prior exposure to certain chemotherapy drugs (e.g., cyclophosphamide [Cytosan], etoposide [Toposar, VePesid]). There is also evidence that in utero exposure to maternal diagnostic radiation also increases the risk of childhood cancer (including leukemia), particularly if the exposure is in the first trimester. Other environmental or infectious exposures remain unproven as risk factors for childhood leukemia, including electromagnetic fields from power lines.

#### Cellular Pathogenesis

Three major characteristics of leukemia cells distinguish them from normal hematopoietic cells. They proliferate rapidly, they do not differentiate, and they have defects in apoptosis. This results in a growth advantage for leukemia cells, leading to progressive replacement of the normal bone marrow with a massive clonal population of poorly differentiated leukemic blasts.

**TABLE 3** Summary of Common Leukemogenic Genetic Events

ACUTE LYMPHOBLASTIC LEUKEMIA	ACUTE MYELOID LEUKEMIA

<i>CDKN2A</i> deletion	<i>NPM1</i> mutation
<i>IKZF1</i> mutation	<i>WT1</i> mutation
<i>TP53</i> mutation	<i>CEBPA</i> mutation

Another characteristic of leukemia cells is their tendency to spread throughout the body and infiltrate organs other than the bone marrow. This is discussed in more detail in the section on clinical presentation.

**Molecular Pathogenesis**

As is true of most human cancers, development of leukemia is a multihit process. The initiating mutation (first hit) in childhood ALL often occurs in utero or early infancy, which is the peak of lymphocyte expansion and recombinase activity for the normal immune system.

The initiating events are typically chromosomal rearrangements that activate expression of cellular proto-oncogenes by fusing them to transcriptionally active immunoglobulin or T-cell receptor genes or alternatively by joining two genes from different chromosomes to create a new fusion gene that encodes a chimeric protein with unique functional properties. The most common of these sentinel chromosomal rearrangements are translocations (exchanges of genetic material between chromosomes), which can serve as a unique marker of the malignant clone. Retrospective studies of blood obtained at birth and preserved on filter paper used for diagnosis of genetic disorders (Guthrie cards) of children who developed leukemia in early childhood have shown that leukemia-associated fusion genes were present at birth in a large percentage of children, including some who did not develop leukemia for one or more years.

In ALL, the promotional mutation (second hit) likely occurs during the proliferative stress generated by immune responses to exogenous antigens. Because these are maximal in the 2- to 4-year-old age group, this is thought to explain the age peak of childhood ALL during these years. The lack of such a peak in AML suggests that the promotional mutations can occur at any time or are not necessarily triggered by immune stimulation. Examples of specific genetic hits known to be associated with the development of childhood leukemia are summarized in Table 3.

**Clinical Presentation**

Most symptoms and signs of childhood leukemia are the result of the propensity of leukemia cells to replace the bone marrow and infiltrate multiple other organs throughout the body. It is estimated that approximately 10<sup>9</sup> (1 trillion) leukemia cells are present in the child's body at diagnosis.

**BOX 2** Summary of Clinical Manifestations of Childhood Leukemia\*

**Bone Marrow**

Pancytopenia, bone pain

**Reticuloendothelial System**

Lymphadenopathy  
Hepatosplenomegaly

**Thymus**

Anterior mediastinal mass (T-cell leukemia)

**Bones**

Bone pain is common  
Fractures and chloromas are rare

**Gums**

Gingival hypertrophy (M4 and M5 AML)

**Skin**

Leukemia cutis and chloromas (M2, M4, and M5 AML, infant ALL)

**Central Nervous System**

Meningitis  
Cranial nerve palsies  
Rarely intracranial epidural or orbital chloromas (M4 and M5 AML, T-cell ALL)

**Kidneys**

Often infiltrated or enlarged  
Rarely acute renal failure (except in tumor lysis syndrome)

**Genitourinary**

Testicular enlargement (T-cell ALL)

\*See Box 1 for descriptions of classifications.

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; TBSA, total body surface area.

The replacement of normal bone marrow is responsible for the characteristic abnormal blood counts, which in most cases include the triad of neutropenia, anemia, and thrombocytopenia. Depending on the number of circulating leukemic blasts in the peripheral blood, the total white blood cell (WBC) count may be low, normal, or high. The neutropenia is often profound (absolute neutrophil count <500/μL) and is associated with an increased risk of serious infection. Blood cultures and broad-spectrum intravenous antibiotic coverage are indicated in any patient with newly diagnosed leukemia and fever. Anemia is often manifested by fatigue, lethargy, headache, pallor, and, in extreme cases, congestive heart failure that may be precipitated by vigorous transfusion or intravenous hydration. Thrombocytopenia often leads to bruising and petechiae; however, clinically significant hemorrhage is uncommon in industrialized countries. Platelet transfusion is indicated for bleeding or for very low platelet counts (<10,000–20,000/μL).

Infiltration of organs other than the bone marrow with leukemia cells is responsible for additional presenting clinical features. Box 2 summarizes the organ systems most often involved in leukemia and the typical clinical manifestations.

**Medical Emergencies in Childhood Leukemia**

A child with newly diagnosed leukemia needs to be promptly evaluated for several medical emergencies. There are several potentially life-threatening complications that may be present at diagnosis or can develop within a short time after diagnosis, in addition to the need to diagnose and treat potential infection in patients who are febrile and neutropenic, which was discussed earlier.

Tumor lysis syndrome (TLS) is a complication resulting from the rapid breakdown of large numbers of tumor cells, releasing

intracellular contents. Although TLS is seen most often after initial treatment with chemotherapy, it can also be present before therapy is initiated due to spontaneous lysis. Risk factors include high WBC count, lymphadenopathy, hepatosplenomegaly, high mitotic index, and specific diagnoses of ALL (especially Burkitt leukemia or lymphoma and T-cell ALL). TLS is characterized by the triad of hyperuricemia (from breakdown of purines by xanthine oxidase), hyperkalemia, and hyperphosphatemia (with secondary hypocalcemia). Renal insufficiency can develop due to the nephrotoxic effects of precipitated urate crystals in the renal tubules; in severe cases, dialysis may be necessary.

Management consists of aggressive hydration to reduce tubular uric acid concentration. The xanthine oxidase inhibitor allopurinol (Zyloprim) is routinely used to decrease uric acid production. Rasburicase (Elitek) (recombinant urate oxidase) is a new agent used in severe cases of TLS to almost instantaneously convert uric acid to the more soluble allantoin. Frequent electrolyte monitoring with standard management of abnormal levels is essential.

Hyperleukocytosis becomes a potential clinical problem and is usually seen with WBC counts above 100,000/ $\mu$ L. Markedly elevated WBCs lead to increased blood viscosity that can produce sludging of blood in the brain, lungs, kidneys, and other organs, causing clinical features such as depressed level of consciousness, stroke, intracranial hemorrhage, respiratory distress, hypoxia, diffuse pulmonary infiltrates, and renal insufficiency. The risk of hyperviscosity is higher with AML than ALL because myeloblasts are generally larger and “stickier” than lymphoblasts (likely due to increased expression of integrins and other mediators of cell-cell adherence on the surface of myeloblasts). Management consists of treating the leukemia as soon as possible. It is also possible to perform exchange transfusion or leukopheresis in cases where symptoms are severe, although this is only a temporizing measure at best.

Life-threatening bleeding is another potential complication of leukemia. Although all patients with thrombocytopenia are at risk, patients with concomitant coagulopathy due to disseminated intravascular coagulation (DIC) are at particularly high risk. The leukemia subtype most commonly complicated by DIC and serious bleeding is acute promyelocytic leukemia (APL). This association results from the release of thromboplastin from the cytoplasmic granules in these promyelocytic blasts. Aggressive blood product support through transfusions and early treatment with the differentiation-inducing agent all-*trans* retinoic acid (ATRA, tretinoin) has been shown to decrease the risk of bleeding in APL. Despite these measures, up to 10% of patients die of bleeding complications during the initial weeks of therapy, and additional patients suffer lasting morbidity from retinal hemorrhages and nonfatal CNS hemorrhages.

Tracheal compression and superior vena cava syndrome can result from large anterior mediastinal masses, which are commonly present in T-cell ALL but are also rarely seen in other forms of leukemia as well. Patients can present with respiratory distress, cough, orthopnea, headaches, syncope, dizziness, facial swelling, or plethora. A chest x-ray should be performed to assess the mediastinum in any patient suspected to have leukemia. If the mediastinum is enlarged, a neck computed tomography (CT) is indicated to assess airway patency. This evaluation must precede any attempts at sedation for diagnostic procedures because even light sedation can precipitate acute airway collapse. Diagnostic material should be obtained by the least invasive method possible before treatment. If necessary, emergent airway compromise can be treated with radiation or steroids, or both, although recognize that the use of steroids prior to diagnostic procedures can impair staging (e.g., CSF involvement at diagnosis, presenting peripheral WBC count).

### Differential Diagnosis

Although leukemia should be considered in cases of isolated neutropenia, anemia, or thrombocytopenia, the vast majority of

leukemia patients present with decreases in more than one cell line. In suspected cases of immune thrombocytopenic purpura (ITP), for example, a careful review of the peripheral blood smear should be performed to rule out the presence of circulating leukemic blasts or other morphologic abnormalities. Routine bone marrow aspiration is not necessary for children with ITP, but it should be performed in patients with atypical features, such as concomitant anemia or neutropenia, hepatosplenomegaly, bone pain, or significant weight loss. Treatment of ITP with corticosteroids should be instituted only after evaluation by an experienced hematologist.

Pancytopenia can be caused by diseases other than leukemia. Some viral infections have a propensity to suppress bone marrow function and cause low peripheral blood cell counts, including Epstein-Barr virus (EBV), herpes simplex virus (HSV), influenza, hepatitis viruses, and HIV. Infectious mononucleosis from EBV infection can be particularly difficult to differentiate from leukemia because patients often have hepatosplenomegaly and circulating atypical lymphocytes (which can appear very similar to leukemic blasts). Pancytopenia on the basis of bone marrow failure (from acquired aplastic anemia or rare inherited bone marrow failure syndromes) can be distinguished from leukemia by bone marrow biopsy for assessment of overall marrow cellularity. Certain solid tumors have a tendency to metastasize to the bone marrow and cause cytopenias, including neuroblastoma and rhabdomyosarcoma, but it is rare for pancytopenia to be the sole primary presenting feature in these cases.

Joint pain, fever, hepatosplenomegaly, and pallor are common presenting features in both systemic-onset juvenile idiopathic arthritis (JIA) and leukemia. An elevated platelet count should be seen in JIA and can be helpful to distinguish the two, as a low or even normal platelet count is rare in JIA given the inflammation that should cause elevations in acute phase reactants. A bone marrow aspirate should be performed to rule out leukemia before treatment with steroids in suspected cases of systemic-onset JIA.

### Risk Stratification

In the last several years, treatment decisions for children with newly diagnosed acute leukemia have been based on the concept of risk stratification. Using factors identified during clinical trials to predict a high or low risk of relapse, patients are separated into risk groups before the start of treatment, at the end of the first month of induction therapy, and at postinduction therapy timepoints for select patients. Based on these features, the treatment plan is tailored to the degree of risk. The desired result is that patients with relatively low-risk disease can be treated with less toxic therapy without compromising cure rates, and patients with high-risk disease receive more-intensive, potentially toxic therapy and/or warrant consideration of experimental options. The risk groups are currently defined based on several criteria and differ for ALL and AML. Different centers and cooperative groups typically employ different risk-stratification strategies.

In ALL, risk assignment is based on a combination of leukemia phenotype (B- versus T-lineage), clinical and genetic features, and early response to therapy. The initial risk assessment for B-ALL is based on two simple clinical parameters that are available immediately at the time of diagnosis (the National Cancer Institute [NCI] or Rome criteria): WBC count ( $>50,000/\mu$ L is high risk), and age ( $<1$  year or  $>9$  years is high risk). Presence or absence of leukemia outside of the bone marrow (extramedullary) including presence and level of disease in the CNS and leukemic involvement of the testes increases the risk of relapse.

For B-ALL, low-risk cytogenetic features include hyperdiploidy ( $\geq 50$  chromosomes in the leukemia cells) or trisomies of specific chromosomes or the presence of a  $t(12;21)$  that results in *TEL/AML1* fusion. High-risk cytogenetic features include hypodiploidy ( $<44$  chromosomes in the leukemia cells), the presence of either an  $11q23$  (*KMT2A*, formerly *MLL*, gene) rearrangement,

**TABLE 4** Summary of Treatment for Childhood Leukemia

CHARACTERISTICS	ACUTE LYMPHOBLASTIC LEUKEMIA	ACUTE MYELOID LEUKEMIA
<b>Remission Induction</b>		
Chemotherapy	4 weeks with prednisone or dexamethasone, vincristine, PEG asparaginase, daunorubicin (not all cases)	Two courses (6–8 weeks) with cytarabine (Ara-C), doxorubicin, others (e.g., etoposide, <sup>1</sup> thioguanine)
Toxic death rate	Low (<3%)	High (>10%)
Remission rate	>98%	75%–85%
<b>CNS Preventive Therapy</b>		
Intrathecal Chemotherapy	Methotrexate	Cytarabine
Cranial irradiation	For high risk only (excessive disease in CSF at diagnosis)	None
<b>Consolidation</b>		
Chemotherapy	Combinations of various drugs (not cross-resistant) Intensity/duration based on risk stratification	Based on cytogenetic/molecular risk group and minimal residual disease (MRD) Low risk: 2–3 additional courses Intermediate risk: If MRD-negative, treat as low risk; if MRD positive, treat as high risk High risk: BMT for patients with best available donor
<b>Maintenance</b>		
Chemotherapy	Low-dose oral (6-mercaptopurine) <sup>1</sup> and methotrexate Total duration of therapy 2–3 years	No maintenance therapy (does not improve survival)

BMT, Bone marrow transplant; CNS, central nervous system; CSF, cerebrospinal fluid; HLA, human leukocyte antigen; WBC, white blood cell.

<sup>1</sup>Not FDA approved for this indication.

the presence of intrachromosomal amplification of chromosome 21 at the locus containing the gene, *RUNX1* (iAMP21), or a t(9;22), or Philadelphia chromosome, that creates a *BCR/ABL* fusion gene. For T-ALL, cytogenetic features have not been routinely incorporated into risk stratification.

Early response has historically been measured by the response to a prednisone prophase that includes a single dose of intrathecal methotrexate and 7 days of prednisone, or by the percentage of blast cells remaining in the bone marrow after 7 to 14 days of multiagent therapy. Over the past 15 to 20 years, measures of tumor burden remaining in the marrow at the end of induction therapy (minimal residual disease [MRD]) have been shown to be highly predictive of outcome and have been integrated into risk-stratification schemata of all the major leukemia cooperative groups.

In AML, risk stratification is based largely on cytogenetics. Low-risk features include t(8;21), which results in the *RUNX1-RUNX1T1* (formerly *AML1/ETO*) fusion and either inv(16) or a t(16;16), both of which create the *CBFβ/MYH11* fusion. High-risk features include monosomy 7 and abnormalities in the long arm of chromosome 5. More recently, data suggest other cytogenetic features may portend a poor prognosis, such as certain *KMT2A* fusions, t(3;21)(q26.2;q22) resulting in the *RUNX1-MECOM* fusion, and 11p15 rearrangements involving the gene *NUP98*, among others. Most other cytogenetic abnormalities, as well as normal cytogenetics (which are seen in approximately 60% of cases), are considered intermediate risk by most pediatric leukemia consortia. In addition to cytogenetic features, specific molecular lesions are also prognostically relevant in AML. Mutations of the genes *NPM1* and *CEBPA* are associated with a more favorable outcome. Mutations of the receptor tyrosine kinase, *FLT3*, most commonly as internal tandem duplications (ITD) of the juxtamembrane domain, have been historically associated with a poor prognosis, but this risk appears to be dependent on the constellation of co-occurring mutations, as those with both *FLT3*-ITD mutations and either mutation of *NPM1* or *CEBPA* appear to have favorable outcomes. Thus how such mutations are

incorporated into risk stratification schemas varies among pediatric cancer consortia.

Response to therapy has also been incorporated into the risk stratification of AML. Failure to achieve remission with induction chemotherapy is another high-risk feature in AML. Measurement of MRD at the end of induction is now also routinely used for risk stratification of AML.

### Treatment

There are significant differences in the specific treatments for ALL and AML, so they will be discussed separately. Table 4 summarizes the most salient features of the treatment for each.

### Acute Lymphoblastic Leukemia

Treatment for ALL generally occurs in three phases: remission induction, consolidation, and maintenance with CNS preventive therapy administered throughout each of these phases. Remission induction in ALL typically lasts 4 to 6 weeks and includes three to five systemic agents. Common to almost all regimens are a corticosteroid (either prednisone [Deltasone] or dexamethasone [Decadron]), vincristine (Vincasar), and PEG asparaginase (pegasparase [Oncaspar]), which compose the three-drug induction. An anthracycline, typically daunorubicin (Cerubidine), is also included in many regimens (four-drug induction), with other agents such as cyclophosphamide (Cytoxan) or etoposide (Toposar, VePesid)<sup>1</sup> used in a small minority of centers. More than 98% of children enter morphologic remission (defined as <5% blasts in the bone marrow) by the end of 4 weeks of induction therapy, and the mortality rate from toxicity during induction therapy is generally less than 2% to 3% in industrialized countries.

The concept that the CNS could be a sanctuary site for leukemia emerged in the mid-1960s when the introduction of multiagent systemic chemotherapy led to high remission rates,

<sup>1</sup>Not FDA approved for this indication.

but a majority of patients relapsed within 6 to 12 months, with many of these recurrences being limited to the CNS. Routine introduction of presymptomatic CNS radiation in the late 1960s and early 1970s led to substantial increases in cure rates to approximately 50%. Modern CNS preventive therapy includes periodic administration of intrathecal chemotherapy (usually methotrexate) starting at the time of the first diagnostic lumbar puncture. Systemic agents with improved CNS penetration (dexamethasone rather than prednisone, higher doses of intravenous methotrexate) might also play an important role in CNS control. Cranial irradiation is currently reserved for patients at the highest risk for CNS relapse (e.g., those with high diagnostic WBC count or leukemic blasts in CSF at diagnosis). Over time, CNS radiation has been given to fewer and fewer ALL patients; some groups believe that it can be eliminated for all patients. With these modern strategies, the risk of isolated CNS relapse is less than 5%.

Following the induction of remission, patients receive additional chemotherapy designed to consolidate the remission. The intensity and duration of the consolidation phase are risk based, and alternating cycles of non-cross-resistant chemotherapy drugs are typically used. These consolidation or intensification phases typically last about 6 months and often include a reinduction phase similar to the first month of treatment.

It has been clearly demonstrated that the risk of relapse in ALL can be reduced with an extended phase of continuous low-dose chemotherapy (maintenance) that lasts until 2 to 3 years from the time of diagnosis. Oral 6-mercaptopurine (Purixan, Purinethol) and methotrexate are used universally, with variable administration of intrathecal chemotherapy. Some centers or groups also employ periodic doses of vincristine and 5- to 7-day pulses of prednisone or dexamethasone. The optimal frequency of intrathecal chemotherapy treatments and vincristine and steroid pulses is uncertain and might depend on the intensity of therapy delivered during the induction and consolidation phases.

### Acute Myeloid Leukemia

Remission induction in AML typically consists of two courses of very intensive chemotherapy with cytarabine (Cytosar, Tarabine) and doxorubicin (Adriamycin), often combined with thioguanine (Tabloid) or etoposide.<sup>1</sup> Remission rates are 75% to 85%, with about one half of the failures due to resistant leukemia and the others to mortality from toxicity (usually infection).

Similar to ALL, CNS preventive therapy in AML begins at diagnosis with intrathecal chemotherapy (usually cytarabine) and continues with additional periodic intrathecal treatments during consolidation. High-dose cytarabine, which is a key component of most AML treatment regimens, also contributes to CNS treatment. Cranial radiation is not typically administered by most groups to children with AML, except for treatment of chloromas (solid masses of leukemia cells) that do not resolve with chemotherapy.

Consolidation in AML is risk dependent. High-risk patients can be identified who have less than a 20% to 25% chance of cure with intensive chemotherapy. Most groups consider these patients to be candidates for bone marrow transplant (BMT). If a matched sibling is unavailable, then alternative donor sources (e.g., matched unrelated bone marrow, umbilical cord blood, or haplo-identical transplant from a parent) are usually offered. For low-risk patients, for whom the cure rate with chemotherapy alone approaches 70%, BMT is usually not offered in first remission, even for patients with a matched sibling donor. In addition, relapses in low-risk patients, unlike relapses in intermediate-risk or high-risk patients, can often be successfully treated with BMT in second remission, justifying reservation of BMT for use as a salvage therapy for low-risk patients. Consolidation in these cases consists of two to three additional

chemotherapy courses that are slightly less intense and usually consist of cytarabine combined with drugs not used in induction, such as mitoxantrone (Novantrone) and L-asparaginase (Elspar).<sup>1</sup> For intermediate-risk patients, MRD testing at the end of induction is increasingly being used to determine whether to consolidate with chemotherapy or BMT. Unlike ALL, most groups have found no benefit to extended maintenance therapy in children with AML.

### Relapse

The most common site of relapsed leukemia is the bone marrow (with or without concomitant CNS involvement). Less common are isolated extramedullary relapses (CNS or testicular relapse in ALL, chloromas in AML). For both ALL and AML, a critical determinant of outcome following relapse is the time from diagnosis to relapse.

ALL patients who relapse within 18 months of initial diagnosis have a dismal outcome, with only about one half able to attain a second remission and less than 10% overall cure rate; the outcome is marginally better for those who relapse between 18 and 36 months after diagnosis. ALL patients with such early relapses are typically treated with 3 to 4 months of intensive therapy to achieve a second remission and attain further cytoreduction, followed by BMT using a matched sibling or unrelated donor. In contrast, children with ALL who relapse more than 3 years after initial diagnosis have an approximately 95% chance of entering a second remission, and 40% to 70% can be cured with intensive chemotherapy without BMT. Notably, with successful introduction of immunotherapeutic agents such as blinatumomab (Blinicyto), the CD19-targeting bispecific T-cell engager and CD19-directed chimeric antigen receptor T-cell (CART) tisagenlecleucel (Kymriah), the therapeutic approach for relapsed B-ALL is evolving. Recent data suggest blinatumomab compared with standard chemotherapy is better tolerated and more likely to achieve an MRD-negative remission prior to hematopoietic stem cell transplant (HSCT) in high-risk relapsed B-ALL. Additionally, emerging evidence suggest CD19 CART can achieve durable remissions in some relapsed B-ALL patients without BMT. Thus the approach for the treatment of relapsed ALL is largely shifting away from intensive standard chemotherapy and BMT to a hybrid of chemotherapy and immunotherapy with or without BMT.

Overall, relapsed AML has a dismal outcome (long-term survival approximately 20%), and the approach is to attempt to reinduce remission and then proceed to BMT or investigational treatments. Even in this setting, there is clearly an improved outcome for patients who relapse after a prolonged initial remission (>12 months from the end of remission-induction therapy) compared with patients who have refractory disease or who relapse after a shorter period of remission.

New treatment strategies are urgently needed for patients with relapsed ALL and AML because the current regimens produce poor results and are associated with a great deal of toxicity. The major clinical trial groups are testing novel and targeted therapies in these patient populations.

### Late Effects

Approximately 70% of children with leukemia are cured of their disease. As the numbers of long-term survivors of childhood leukemia have grown, there has been increasing interest in assessing the late effects of leukemic therapy. In childhood ALL, with cure rates of 90%, a major effort is being made in ongoing clinical trials to reduce the intensity of therapy for lower-risk patients, with the hope of reducing late effects of therapy without compromising high cure rates. The most common late effects of leukemia therapy, with the known treatment-related risk factors and recommended diagnostic approach for each, are summarized in [Table 5](#). Many pediatric

**TABLE 5** Summary of Late Effects of Leukemia Treatment

LATE EFFECT	TREATMENT-RELATED RISK FACTORS	DIAGNOSTIC APPROACH
Bone	Avascular necrosis, osteonecrosis	X-ray and/or MRI of major joints for persistent pain
Cardiac dysfunction	Anthracyclines: cardiomyopathy (risk related to cumulative dose, higher risk in AML)	ECG or echocardiogram every 3–5 years (cardiomyopathy can occur decades after treatment)
Cataracts	CNS RT	Yearly eye examination
CNS and psychosocial	CNS RT, IT chemotherapy: learning problems, neurocognitive dysfunction	Yearly educational assessment, neurocognitive testing
Dental abnormalities	CNS RT	Yearly dental examinations
Endocrine and reproductive	CNS RT: pituitary dysfunction Alkylators: primary gonadal failure	Yearly growth curves, TSH, LH, FSH LH, FSH, estradiol or testosterone, semen analysis
Hepatic dysfunction	Methotrexate, 6-mercaptopurine, 6-thioguanine: late hepatic fibrosis	Yearly LFTs
Secondary neoplasms	CNS RT: brain tumors Alkylators or epipodophyllotoxins: secondary AML	MRI for symptoms CBC in symptomatic patients

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; FSH, follicle-stimulating hormone; IT, intrathecal; LFT, liver function test; LH, luteinizing hormone; MRI, magnetic resonance imaging; RT, radiation therapy; TSH, thyroid-stimulating hormone.

oncology centers have developed late-effects programs to conduct surveillance for the development of these problems and provide follow-up care to patients who develop late complications of therapy.

### CURRENT DIAGNOSIS

- In addition to general medical care, it is important to identify psychosocial health concerns at all adolescent visits.
- The key components of a psychosocial history are addressed in the HEADS private and confidential interview.
- Conducting a Home/Education/Employment/Activities/Accident Prevention/Diet/Disordered Eating/Drugs/Depression/Suicide/Self-harm/Sex/Sleep/Social Media (HEADS) interview is standard practice for adolescent care: it should be part of all adolescent well-checks and used, as time permits, in acute visits for teens who have high-risk behaviors or have no regular health care.
- High-acuity areas identified from the HEADS interview include substance use, disordered eating, sexual activity, and mental health.
- Depression screening should be part of well visits for all patients between 12 and 21 years of age.
- Anxiety screening is recommended for girls 13 years and older. Clinical discretion should guide screening frequency.
- Substance use screening should be included in all adolescent well visits.
- HIV universal screening should be completed initially between 15 and 18 years of age and the need for rescreening reassessed annually.
- Immunization status should be assessed at every visit, with routine and catch-up vaccines provided.

### CURRENT THERAPY

- Long-acting reversible contraception (LARC) provides safe and effective contraception for teenagers.
- Emergency contraception should be offered within 5 days of unprotected sexual activity.
- Treatment for teens is often multidisciplinary, involving subspecialists, mental health providers, medical or psychiatric inpatient units, and county welfare or health departments.

### Setting the Stage for the Adolescent Visit

Comprehensive care for adolescents includes screening for high-risk behaviors in addition to routine medical care. To facilitate open communication, providers should be clear about consent and confidentiality policies in their practices. This can be achieved by discussing policies with patients and parents/caretakers during young adolescent visits (11 to 14 years) and by providing materials documenting the policies and practices, such as a standard letter to parents. Policies can also be displayed in the office, provided in practice newsletters and materials, and made available through patient access portals.

Adolescent visits differ from early childhood visits in several important respects. At the beginning of the visit, time should be spent with both the teen and parent or caregiver clarifying medical history and current concerns. The adolescent should then be offered time without the parent or caregiver present to discuss sensitive issues, including reproductive and mental health. At the end of the visit, the parent/caregiver should be provided with a summary of the visit, limited to the nonconfidential portion, and including recommendations and arrangements for follow-up appointments.

### Consent and Confidentiality Laws—Consent Does Not Equal Confidential

Consent and confidentiality laws vary by state. Most states allow minors to consent for reproductive health care, including testing and treatment for sexually transmitted infections (STIs). Most states also allow providers to prescribe contraceptives to minors. Many states have a “mature minor” statute that allows physicians to provide care if they deem the adolescent patient mature and capable of understanding the medical care. These laws give teens autonomy to consent to their own health care and they also enable care to be provided when a parent is unable to attend the appointment.

While consent and confidentiality laws are related, they are separate entities. Many states allow minors to consent for specific health services but do not prohibit a provider from informing the teen’s parent/caretaker about that service. Even if allowed by law, expert consensus holds that such disclosures should only be made when in the best interest of the minor patient. The disclosure should not compromise future health care. Many teens will not seek reproductive health care if they have to involve a parent, making confidentiality necessary for comprehensive adolescent health care.

Confidentiality is limited when a minor patient is in direct harm, such as intimate partner violence, sexual coercion or rape, certain pregnancy, suicidality, or self-harm. In such instances, a parent/caretaker should become involved, unless he/she is the perpetrator or some other extraordinary circumstances exist. Local authorities or social welfare agencies may also need to be contacted. These necessary breaches in confidentiality to protect safety must be explained beforehand to the patient and be included in written policies. Any breach of confidentiality must be carried out in a professional manner, explained sensitively to the patient and others, and be well documented. Every attempt must be made not to compromise future care.

Information on consent and confidentiality laws for each state is available at the Guttmacher Institute website ([guttmacher.org](http://guttmacher.org)).

### The HEADS Interview

The HEADS acronym provides a structured psychosocial history-taking tool that also screens for high-risk behaviors (Table 1). Although several variations of HEADS have been described, they all cover the most common risk categories for adolescents. Progressing from the least invasive topics to the most sensitive issues, HEADS covers all essential categories (see Table 1).

When using the HEADS interview tool, it is important to build rapport with the patient. The teen deserves explanation of why they are being asked personal questions and every attempt should be made to increase patient comfort and trust. The interview begins with questions regarding hobbies, school, and home life. Once rapport is established, questions proceed to more sensitive issues. Questioning should be open-ended, nonassuming, and nonjudgmental. This allows for honest answers and does not discriminate among patients.

### Home/Education/Employment/Activities/Accident Prevention

These topics begin the confidential interview with the least risky activities for adolescents. Although grouped together in this text, each category deserves its own time and questions (see Table 1). All adolescents should have a trusted adult with whom they can discuss concerns. Safety at home and school safety, including any bullying or coercion regardless of site or circumstances, should be discussed and addressed. Current school performance, concerns, grades and post graduation goals should be discussed. After-school employment has benefits but can also negatively impact academic performance, mood, or family dynamics. These should be screened for and addressed if present. Healthy after-school activities should be encouraged. Predictably, adolescent illegal activity, drug use, and sexual activity peak during after-school

**TABLE 1** HEADS Acronym with Sample Questions

H	Home	Who lives with you at home? Tell me about your relationships at home. Are you safe at home? Do you have a trusted adult to confide in at home? Do you have your own space at home? Have there been any changes at home?
E	Education	What grade are you in and what school? Do you feel like you have enough food at home? Are you ever worried you might not get three meals a day because there is not enough food? Is your school safe? Tell me about your friends. Does anyone bother you at school? How are your grades? Do you have any problems with school? How many days of school have you missed this year and why? Do you plan to graduate? What do you want to do after graduation?
	Employment	Are you working? Do you like your job? How do you spend the money you earn from working? Do you feel stressed because of work? Is your family stressed by your work? How many hours a week do you work?
A	Activities	What do you do for fun? Who do you hang out with? Tell me what you do after school. Are you in any organized after-school or summer activities? Tell me about your hobbies. Do you have a religious preference?
	Accident prevention	Tell me about your activities. Do you wear a seatbelt? Do you wear a helmet while biking or using an all-terrain vehicle? Have you ever ridden with someone while they were under the influence of drugs or alcohol, or have you ever driven under the influence? Where is your cell phone while you are driving?
D	Diet/disordered eating	Tell me about your diet. Do you feel like you have enough food at home? Are you ever worried you might not get three meals a day because there is not enough food? Do you eat breakfast daily? How many fruits and vegetables do you eat? How do you feel about your weight? Do you like the way you look? Have you ever not eaten to try to lose weight? Do you ever feel guilty about what you have eaten? Have you ever skipped meals, thrown up on purpose, or exercised excessively after you have eaten?
	Drugs	Have you seen drugs at your school? Do any of your friends smoke, vape, drink alcohol, or use other drugs? Have you ever tried drugs? Have you ever been in trouble because of drug use?
	Depression	Do you ever feel sad, down, or depressed? Have you ever felt like you had nothing to look forward to? Do you still like to do the things you used to do? Do others say you are more irritable than normal?
S	Suicide/self-harm	Have you ever been so upset you have wanted to hurt yourself? Have you ever cut yourself? Have you ever thought about killing yourself or someone else? Who would you talk with if you did have thoughts like this?
	Sex	Are you in a relationship? When is the last time you had sex? Did you use a condom? Are you using anything to prevent pregnancy? Have you ever been tested for STIs? How many partners have you had? Tell me about your partner (age, gender, etc.). Do you feel safe with your partner? Have you ever been forced to have sex or do something you were not comfortable with?
	Sleep	What time do you go to bed? Where is your cell phone when you go to sleep? When do you wake up in the morning?
	Social media	What social media sites do you have profiles on? Are you friends with people you do not know in real life? How much time do you spend on social media? Does this affect your grades? Tell me about your privacy settings. Do you have any trusted adults that can access your social media sites?

Adapted from Klein DA, Goldenring JM: HEEDSSS 3.0: The psychosocial interview for adolescents updated for a new century fueled by media. *Contemporary Pediatrics*. 2014. Available at <http://contemporarypediatrics.modernmedicine.com/contemporary-pediatrics/news/probing-scars-how-ask-essential-questions?page=full> (Accessed October 13, 2014).

hours. Participation in organized, supervised, extracurricular activities has been shown to decrease these risky behaviors and confer positive health and emotional benefits. Accidents remain the leading cause of death for this age group and prevention should be emphasized. Safety should be assessed at this time, as well as throughout the course of the interview as it applies to each topic.

#### Diet/Disordered Eating

Nutritional health problems are of concern with adolescents. Many lifestyle habits, especially regarding nutrition, are formed during this period. Asking the teen to describe his/her typical diet provides insight on potential areas for improvement. Limiting portion sizes, avoiding excessive or late night snacking, and replacing sugary drinks with water is common advice for teens. This portion of the interview provides

opportunity to screen for body image distortion or disordered eating. The growth chart should be reviewed and any significant weight changes discussed.

#### Drugs (Substance Use)

When asking about riskier behaviors, it is important to have rapport and trust. The subject of substance use can be broached by asking if peers use substances. Because alcohol, marijuana, electronic vaping, and tobacco use is so prevalent among high school students, this initial question can make a teen more comfortable moving on to talk about personal use. The CRAFFT acronym is a brief and effective screening tool designed specifically for use with adolescents and helps the provider determine if further conversation or evaluation regarding substance use is warranted. The questions are broken into part A and B. If a patient answers "yes" to any questions in A, then part B questions are asked. If the patient

**TABLE 2** CRAFFT+N Substance Use Disorder Screening Tool for Adolescents (to be verbally administered by a clinician in a private setting with the teen)

Part A.

During the past 12 months did you:

1. Drink more than a few sips of beer, wine, or any drink containing alcohol? Say “0” if none.
2. Smoked any marijuana (weed, oil, or hash by smoking, vaping, or in food) or “synthetic marijuana” (like “K2”, “Spice”)? Say “0” if none.
3. Used anything else to get high (like other illegal, prescription, or over-the-counter medications, and things that you sniff, huff, or vape)? Say “0” if none.
4. Use any tobacco or nicotine products (for example, cigarettes, e-cigarettes, hookahs, smokeless tobacco)? Say “0” if none.

If all answers in part A are 0, then ask only “CAR” Part B, then stop. If any answer to part A is >0, then ask all 6 questions of Part B.

Part B.

- |   |   |
|---|---|
| C | 1. Have you ever ridden in a <b>CAR</b> driven by someone (including yourself) who was high or had been using alcohol or other drugs? |
| R |   |
| A | 2. Do you ever use alcohol or other drugs to <b>RELAX</b> , feel better about yourself, or fit in?                                    |
| F |   |
| F | 3. Do you ever use alcohol or other drugs while you are by yourself, <b>ALONE</b> ?   |
| T |   |
|   | 4. Do you ever <b>FORGET</b> things you did while using alcohol or drugs?   |
|   | 5. Do your <b>FAMILY</b> or <b>FRIENDS</b> ever tell you that you should cut down on your drinking or drug use?                       |
|   | 6. Have you ever gotten into <b>TROUBLE</b> while you were using alcohol or other drugs?  |

\*Two or more YES answers suggest a serious problem and need for further assessment. See <http://crafft.org/get-the-crafft/> for further instructions.

The CRAFFT+N 2.1. John R. Knight, MD: The Center for Adolescent Substance Abuse Research (CeASAR); Boston Children’s Hospital; Harvard Medical School Teaching Hospital. 2018. Available at: <http://crafft.org> (Accessed October 4, 2019).

answers “yes” to two or more questions of part B, the screen is positive and further evaluation is recommended (Table 2). If necessary, referral should be made to a qualified mental health provider for treatment. Substance use is a leading cause of morbidity and mortality for teens in the United States, and teens who use substances at an early age are more likely to become addicted. Substance use should not be ignored or minimized by providers. Counseling on prevention should contain a clear message of nonuse.

### Depression/Anxiety/Suicide/Self-Harm

Depression screening is recommended at all well visits beginning at age 12. Several screening tools are available. Questions covering loss of interest in normal activities and feeling depressed, down, or hopeless open the door to more specific questions regarding signs and symptoms of depression. In addition to depressive feelings, teens should be explicitly screened for suicidal intention, past attempts, plans, self-harm, and safety. If a teen discloses an unsafe environment, law enforcement should be included in an immediate plan of care. If a teen is actively suicidal, then immediate inpatient treatment is warranted. Anxiety is common in adolescent females, and those 13 and older should be screened. Screening can occur concomitantly with depression screening. History should assess social function, somatic symptoms, and coping strategies. Outpatient treatment for mental health disorders in teens includes cognitive behavioral therapy with or without medication. For most teens, parental involvement is necessary when treating mental

health disorders. If the provider feels the teen is unsafe due to their own actions or those of others, then the confidential interview is no longer appropriate and the caretaker must be included in the next stage of management.

### Sex

Nearly half of high school students have had sex. Of those, only about a quarter used reliable contraception at their last intercourse. Adolescents and young adults account for the majority of gonorrhea and chlamydia cases each year. Risk factors for morbidity related to sexual activity include early sexual initiation, increasing number of partners, substance use prior to sex, and unprotected sexual acts. Teenagers and men who have sex with men are the population groups at highest risk for STIs. STI screening should be discussed for those at risk. Recommendations are outlined in Table 3.

When discussing the sensitive issue of sex with teens, it is important to use neutral terms and remain nonjudgmental. It is also important to include gender identity in the history. Sexual history should include age of first sexual encounter, age of partner(s), gender of partner, number of partners, type of sexual activities, date of last sexual activity, and contraceptive and barrier use. Quality of relationships should also be assessed, as 7% of high school students report that they have experienced sexual dating violence including sexual coercion and rape. As with substance use, providers should relay a clear message of abstinence as the safest method to prevent morbidity.

Teens should be counseled on contraceptive options, emphasizing that LARC (intrauterine contraception and implants) is safe and the most reliable contraception available for teens. Quick-start contraception (prescribing or providing contraception at the current appointment) should be strongly considered to improve adherence in sexually active teens. The possibility of pregnancy should be reasonably ruled out prior to providing contraception by taking a careful sexual history, including last menstrual period, date of last sex, and method of contraception; lab work may also be considered (see the US Selected Practice Recommendations for Contraceptive Use for guidance on how to reasonably rule out pregnancy, [https://www.cdc.gov/reproductivehealth/contraception/contraception\\_guidance.htm](https://www.cdc.gov/reproductivehealth/contraception/contraception_guidance.htm)). If a patient has been recently sexually active, most non-intrauterine contraceptives have not been shown to harm an existing pregnancy. Nevertheless, counseling regarding this risk is important prior to initiating contraception, and pregnancy testing should be performed 2 to 4 weeks following contraception initiation. For patients who have had unprotected sex in the past 5 days, emergency contraception should be discussed and offered at the time of quick start contraception. Concurrent barrier contraception should be stressed. Aside from abstinence, male condoms are the most effective way of preventing STIs.

### Sleep/Social Media

The conclusion of this format of the HEADS interview concerns less sensitive topics and allows for a comfortable close to the interview. Sleep is problematic for many teens and can usually be improved with better sleep hygiene. Encourage all teens to have a consistent sleep and wake time and 8 to 10 hours of sleep daily. Caffeinated beverages should be limited. Daily exercise should be recommended. The teen’s bedroom should be free from distractions, including screened electronic devices.

Social media and cell phones are now integral to popular culture. While these offer benefits to teens, use should be limited. Both social media and cell phones contribute to unintentional injuries, especially with distracted driving. In addition, personal information being shared on the internet through electronic media opens the teen up to vulnerability. Lastly, both can act as significant distractions from academic work, family

**TABLE 3** Laboratory Screening and Procedure Recommendations

SCREENING	AGE	TEST/PROCEDURE	COMMENTS
Dyslipidemia	9–11 17–21	Nonfasting lipid profile	Once between 9 and 11 years and again between 17 and 21 years with annual risk assessment (NHLBI, AAP) Insufficient evidence for screening (USPSTF)
Hemoglobin/hematocrit	11–21	Verbally screen for risk	No routine testing recommended
Human immunodeficiency virus (HIV)	15–18	HIV 1–2 immunoassay	At least once if >15 years with more frequent screening if high-risk (CDC, USPSTF, AAP) Screen MSM at least annually (CDC)
Chlamydia	Females <25	NAAT at site of potential infection	Screen all sexually active women <25 years at risk (USPSTF) or annually and MSM at least annually (CDC)
Gonorrhea	Females <25	NAAT at site of potential infection	Screen all sexually active women <25 years at risk (USPSTF) and MSM at least annually (CDC)
Syphilis*	Adolescents at increased risk	Serology with confirmatory testing if positive	Screen persons at increased risk (USPSTF). Screen MSM at least annually (CDC)
Cervical dysplasia screening	21 years	Pap smear	Other indications for pelvic exam still apply but routine Pap testing <21 years is not recommended (USPSTF, AAP)
Immunizations	All ages	Routine vaccinations per CDC guidelines	Immunization status should be assessed and routine and catch-up vaccines provided at all adolescent visits

AAP, American Academy of Pediatrics; CDC, Center for Disease Control and Prevention; MSM, Men who have sex with men; NAAT, nucleic acid amplification testing; NHLBI, National Heart, Lung, and Blood Institute; *Pap smear*, Papanicolaou smear; USPSTF, US Preventive Services Task Force.

\*Also consider screening high-risk adolescents for hepatitis B infection with HbsAg (USPSTF).

time, and sleep. Discuss safe and appropriate use of electronic devices with patients and summarize to parents.

### Pandemic/Post-pandemic Screening

Adolescents have been significantly affected by the COVID-19 pandemic. It is important to acknowledge this and screen for negative effects and for resiliency. Asking teens about safety at home and access to a trusted adult is important. As many families are experiencing extreme financial stress, the questions outlined regarding adolescent employment and food security are also important. Likewise, many families have lost loved ones to the pandemic. These experiences affect the mental health of adolescents; therefore, screening for bereavement, major depression, anxiety, and disordered eating should be included in all visits for the foreseeable future. Traditional schooling has also been altered during this time; therefore, talking with teens about their learning environment, use of multiple digital devices, and academic performance can shed light on areas to target for behavioral counseling. Last, physicians and clinicians should talk with teens about resiliency and encourage good self-care during adolescent health visits.

### Summary

In addition to providing routine health care to teens, providers should focus on the psychosocial history. The HEADS acronym provides a tool for providers to approach these sensitive topics systematically. This interview should take place privately, respecting the teen's ability to consent for certain care, and when able, keeping care confidential. Providers should be familiar with the laws regarding consent and confidentiality of minors in their state. Although teens should be allowed access to confidential health care, providers must be aware that often the best care includes a trusted adult. Parents should be involved in their teen's care when appropriate. Once teens have been assessed for high-risk behaviors, problematic behaviors should be addressed and low-risk behaviors should be commended and encouraged.

## ASTHMA IN CHILDREN

Method of

Susan M. Pollart, MD, MS; Katharine C. DeGeorge, MD, MS; and Amanda Kolb, MD

### CURRENT DIAGNOSIS

- Recurrent wheeze, cough, and shortness of breath are typical asthma symptoms.
- A personal or family history of atopy is associated with an increased risk of developing asthma.
- Atopy, allergic rhinitis, eczema, or nasal polyps are common comorbidities in patients with asthma.
- Specifically ask about symptom triggers such as allergens, irritants, exercise, stress, cold, or infection.
- At initial diagnosis, outline symptom frequency, intensity, and timing to classify severity.
- Physical examination of asthmatic children is often normal, but mucosal edema of nasal turbinates, eczematous skin rashes, tachypnea, tachycardia, expiratory wheezes, and lung hyperexpansion may be observed.
- In children older than 5 years, spirometry revealing an obstructive pattern at least partially reversible with bronchodilators confirms the diagnosis. In children younger than 5 years, diagnosis is based on history, physical examination, and a trial of antiasthma medications.
- Chest x-ray, complete blood count (CBC), and IgE levels are not routinely recommended but may be useful in certain situations.

### CURRENT THERAPY

- The goal of asthma management is to reduce impairment of activities and decrease risk of exacerbations.
- Initial assessment of asthmatics should focus on symptom frequency, timing, and effect on activities.
- The four central components of management are frequent assessment and monitoring, patient education, controlling environmental triggers, and appropriate use of medication.
- Short-acting inhaled  $\beta_2$ -adrenergic receptor agonists such as albuterol are the mainstay of acute therapy in an episode of bronchoconstriction. Additionally, anticholinergics such as ipratropium bromide<sup>1</sup> and systemic steroids are important components of managing an acute exacerbation. Magnesium sulfate<sup>1</sup>, epinephrine<sup>1</sup>, and terbutaline<sup>1</sup> are reserved for refractory cases, and terbutaline is only approved for children 12 years and older.
- Inhaled corticosteroids are the most effective daily controller medications for children. Long-acting  $\beta_2$ -agonists, leukotriene-receptor antagonists, and mast cell stabilizers are commonly used adjunctive therapies.
- Visits should be scheduled frequently in the outpatient setting to reassess symptom severity, adjust medications accordingly, and emphasize patient education.
- Consider increasing medication therapy only after assessing the patient's adherence and technique with medications. Consider a step-down in therapy only after 3 months of adequate control of symptoms.
- Involve both children and their caregivers in designing a written asthma action plan to empower patients in recognizing and managing escalating symptoms.
- Refer to a pulmonologist or allergist if there is any question regarding diagnosis or if symptoms are not adequately controlled with standard treatment. Consultation by a pulmonologist is recommended for children aged 5 years or older at  $\geq$ step 4 of therapy (or  $\geq$ step 3 in children younger than 5 years).

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Asthma prevalence in the United States has been on the rise since the 1990s. It is currently estimated that 9.6% of children younger than 18 years (7.1 million children) carry the diagnosis of asthma. Male sex, African American or Puerto Rican ethnicity, and lower socioeconomic status are associated with an increased risk of developing asthma. Prevalence estimates for these groups are as high as 11% to 16%.

Although no significant difference in asthma prevalence between urban areas and suburban or rural areas has been found, there do seem to be broader geographic trends with higher prevalence in the Northeast and Midwest. Mortality rates remain low, but preventable deaths attributable to asthma exacerbations persist.

### Risk Factors

No clear precipitating factors have been associated with the onset of asthma in children, but multiple risk factors for the development of this disease have been identified. Perhaps the strongest link is that between a family history of atopy, atopic dermatitis in infancy, or elevated serum immunoglobulin (Ig)E levels and subsequent sensitization to aeroallergens at 5 years of age. Recent observational data support an association with both prenatal exposure to acid-suppressive drugs and the use of antibiotics or acid-suppressive drugs in the first 6 months of life. Other identified associations include sensitization to dust mites, preterm birth, exposure to tobacco smoke, and certain respiratory infections such as respiratory syncytial virus (RSV).

### Pathophysiology

Asthma is a chronic disease with recurrent episodes of reversible airway obstruction. It is thought to consist of three major pathophysiologic components: bronchoconstriction, airway inflammation, and bronchial hyperresponsiveness. Bronchoconstriction results from bronchial smooth muscle contraction in response to exposure to allergens, irritants, stress, infection, exercise, or certain medications such as aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Inflammation occurs via the T helper 2-(T<sub>H</sub>2) and IgE-mediated pathways. Examination of the airways of asthmatics reveals inflammatory infiltrates consisting of neutrophils, eosinophils, lymphocytes, and activated mast cells. These mast cells release histamine along with other inflammatory mediators, causing airway edema, mucous hypersecretion, and airway hyperresponsiveness to environmental stimuli. Over time, remodeling can occur with airway thickening and smooth muscle hyperplasia, with a resulting decline in lung function and reduced response to therapeutic interventions.

Long-term observational studies have suggested that declining lung function is most commonly seen in children with symptom onset before 3 years of age. It still remains unclear whether older children or adults experience the same reductions in lung function.

### Prevention

Primary prevention of asthma is a much-studied topic, yet few studies have successfully identified effective strategies for preventing asthma. The effect of breast-feeding on asthma prevalence has been a focus of extensive research. Much of the literature regarding breast-feeding as primary prevention for asthma suggests a protective effect of breast-feeding, but this has not been borne out consistently. A Cochrane review of 5 trials (952 pregnant or lactating mothers) found no evidence that avoidance of antigens (milk, eggs, nuts) by breast-feeding mothers during pregnancy or lactation decreased asthma or eczema in children through the study period of 18 months.

There is conflicting evidence regarding allergen avoidance to prevent the onset of asthma, although reducing exposure to inhaled allergens such as mites and pet dander can improve symptoms in patients with diagnosed asthma.

Based on the best available evidence, breast-feeding should be encouraged for its many known health benefits and potential protective effect on developing asthma. Avoidance of household dust mite aeroallergen or specific single food allergen exposure during pregnancy, breast-feeding, or first years of life is not routinely

**BOX 1** Asthma Triggers.**Allergens**

- Animal dander
- Pollen
- Dust mites
- Mold

**Chemical irritants**

- Tobacco smoke
- Wood stove smoke
- Air pollution
- Cleaning chemicals
- Gases

**Medications**

- Aspirin
- Nonsteroidal antiinflammatory drugs
- $\beta$ -Blockers

**Other**

- Gastroesophageal reflux
- Exercise
- Respiratory infection
- Extremes of emotion
- Stress
- Changes in weather
- Cold air

recommended for primary prevention of asthma. The topic of primary prevention of asthma warrants further study to clearly establish feasible preventive measures.

**Clinical Manifestations**

Asthma is characterized by recurrent episodes of wheezing, chest tightness, and shortness of breath. Asthma can also manifest as a chronic dry cough, especially if occurring at night. Young children commonly present with chronic cough alone, a form of asthma called cough-variant asthma. Wheezing that recurs in the setting of specific, predictable triggers is also a manifestation of asthma.

**Diagnosis**

A focused history revealing recurrent episodes of wheezing, shortness of breath, or cough suggests asthma and merits further investigation. In infants, the symptoms of asthma can involve difficulty feeding. Parents might also report intermittent grunting or loud breathing.

When taking the history, it is important to ask about symptom triggers, time course, and frequency of symptoms to assess severity. It is also important to discuss any family history of atopy, asthma, eczema, or nasal polyps. Triggers such as exposure to inhalant allergens (mold, dust, pollen, pet dander), irritants (chemicals, cigarette smoke), weather changes, intense emotion, physical activity, and viral illnesses should be elicited specifically (Box 1).

Begin the physical examination with measurements of height and weight and inspection of the growth chart. Most children do not have a significant growth or height reduction as a result of asthma. If a child's growth chart demonstrates a marked decrease in growth velocity, it is prudent to seriously consider alternative diagnoses.

Owing to the intermittent nature of asthma symptoms, children with asthma often have an entirely normal examination. Upper airway findings can include nasal polyps or mucosal edema of nasal turbinates. The skin examination might reveal signs of atopic dermatoses such as eczema or urticaria. Lung examination may be remarkable for wheezing, hyperexpanded barrel chest, increased respiratory rate, or tachycardia, depending on severity of symptoms. The American Academy of Allergy, Asthma, and Immunology recommends spirometry as a useful means of obtaining objective data on lung function and presence of obstructive disease for the diagnosis of asthma prior to trial of medications in patients over the age of 5 years, a recommendation that is part of the Choosing Wisely campaign.

**BOX 2** Differential Diagnosis.**Upper Airway**

Allergic rhinitis  
Sinusitis

**Large Airway Obstruction**

Vocal cord dysfunction  
Laryngotracheomalacia (infants)  
Tracheal stenosis (infants)  
Vascular rings  
Tracheal webs  
Inhaled foreign body  
Tumor or enlarged lymph nodes compressing airway

**Small Airway Obstruction**

Viral bronchiolitis  
Pneumonia  
Obliterative bronchiolitis  
Cystic fibrosis  
Bronchopulmonary dysplasia  
Heart failure

**Other**

Gastroesophageal reflux disease  
Swallowing mechanism dysfunction leading to aspiration

From National Heart, Lung, and Blood Institute, National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the diagnosis and management of asthma. Summary report 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>. Accessed March 13, 2018.

Spirometry before and after short-acting  $\beta$ -agonist inhalation should show reversibility of obstruction in a patient with asthma. A rise in forced expiratory volume in 1 second (FEV<sub>1</sub>) of 200 mL and 12% above baseline after bronchodilator is consistent with reversible obstruction. In children younger than 5 years, such studies might not be feasible. In these cases, diagnosis is based on history and physical. A trial of bronchodilator is helpful in establishing the diagnosis as well as ruling out other possible etiologies of symptoms.

A common presenting symptom of asthma in children is chronic cough. In cough-variant asthma, spirometry may be entirely normal. A trial of antiasthma medication that results in resolution of cough confirms the diagnosis.

Peak flow meters are useful in monitoring symptom severity but should not be used to make a diagnosis owing to wide variations in individual results and normal values.

Chest x-ray should be considered when ruling out alternative diagnoses but is not recommended in routine diagnostic testing for asthma. Allergy skin testing can identify potentially avoidable inhalant indoor allergens and, when appropriate, guide immunotherapy. Finally, checking a complete blood count with differential and serum IgE levels is not clearly indicated in making a diagnosis but may be useful in guiding treatment. Eosinophilia (greater than 4%) can indicate the need for controller medications, and patients with high levels of IgE have been shown to have a particularly good response to inhaled corticosteroids.

Finally, fractional exhalation of nitrous oxide (FeNO) may have an emerging role in diagnosing asthma and monitoring response to treatment. A 2016 Cochrane review of nine randomized controlled trials suggested that using FeNO levels to tailor treatment may decrease exacerbations overall, including severe exacerbations requiring oral corticosteroids.

**Differential Diagnosis**

The differential diagnosis of recurrent respiratory symptoms is broad and must be considered when initiating diagnostic work-up. When creating a list of other diagnoses, it can be useful to consider the airway from the top down, as is shown in Box 2. Also keep in mind that the age of the patient and the chronicity of symptoms can point to certain diagnoses in your differential.

**TABLE 1** Classification of Asthma Severity.

COMPONENTS OF SEVERITY	AGE (YEAR)	INTERMITTENT	PERSISTENT		
			MILD	MODERATE	SEVERE
<b>Impairment</b>					
Symptoms	All	≤2 days/week	>2 day/week but not daily	Daily	Throughout the day

## Treatment

To treat asthma in children appropriately, the severity of symptoms must first be assessed. This initial evaluation should be followed by an ongoing assessment that monitors response to therapy. The general tenets of asthma treatment are to reduce the functional limitations caused by asthma symptoms and decrease the risk of exacerbations, decline in lung function, and side effects of medications. The Expert Panel Report 3 of the National Asthma Education and Prevention Program describes a patient-oriented and clinically relevant approach to asthma management. Emphasis is placed on organized primary care visits and patient education. It is important to plan routine visits with a child's pediatrician or family physician until symptoms are adequately controlled.

Once the diagnosis of asthma is made in a child, symptom severity should be assessed. To determine severity, the frequency of daytime symptoms, nighttime symptoms, frequency of using short-acting β<sub>2</sub>-agonists, impairment of activities, frequency of exacerbations requiring oral steroids, and lung function must be considered (Table 1). Once severity has been classified, treatment can be started based on the stepwise approach outlined in Table 2. This stepwise approach is intended to be a guideline only. Clinical judgment is necessary when applying these guidelines to the individual patient. Children 12 years and older may be assessed and treated according to the guidelines described for adults.

Assessing adequacy of symptom control is essential to the management of asthma. At each follow-up visit, discussion should focus on how often the patient is having asthma symptoms and how much those symptoms are interfering with normal activities. Tools such as the Asthma Control Test (ACT) or the Childhood Asthma Control Test are helpful in measuring symptom control in a standardized fashion. Symptom assessment determines adequacy of control and guides changes in treatment, as shown in Tables 2 and 3. Frequency of primary care visits depends on severity of symptoms and can initially occur every 2 to 6 weeks. As control improves, visits may be decreased to every 1 to 6 months. At each visit, medications can be reviewed, doses adjusted, and education reiterated on recognizing symptoms and using medication and spacers.

Only after at least 3 months of adequate control should a decrease in therapy be considered. When stepping down, do so gradually, with frequent reassessment for reemerging symptoms. In the same way, therapy should be increased only after ensuring that the patient has been adherent with medications and is using the inhaler properly and that comorbid conditions have been addressed.

Referral to a pulmonologist or allergist is recommended if there is any question about the accuracy of diagnosis or if symptoms are difficult to control. The National Heart, Lung, and Blood Institute (NHLBI) recommends consultation if a child older than 5 years requires step 4 or higher level of therapy (step 3 or higher therapy in children younger than 5 years).

**TABLE 2** Levels of Asthma Control

COMPONENTS OF CONTROL	AGE (YEAR)	WELL CONTROLLED	NOT WELL CONTROLLED	VERY POORLY CONTROLLED
<b>Impairment</b>				
Symptoms	0–4	≤2 day/week but ≤1 times/day	>2 day/week or multiple times on ≤2 day/week	Throughout the day
	5–11			
	≥12	≤2 day/week	>2 day/week	
Nighttime awakenings	0–4	≤1 times/month	>1 times/month	>1 times/week
	5–11	≤1 times/month	≥2 times/month	≥2 times/week
	≥12	≤2 times/month	1–3 times/week	≥4 times/week
Interference with normal activity	All	None	Some limitation	Extremely limited
SABA for symptoms	All	≤2 day/week	>2 day/week	Several times/day
<b>Lung Function</b>				
FEV <sub>1</sub> (predicted) or PEF (personal best)	≥5	>80%	60%–80%	<60%
FEV <sub>1</sub> /FVC	5–11	<80%	75%–80%	<75%
<b>Validated Questionnaires</b>				
ATAQ	≥12	0	1–2	3–4
ACQ	≥12	≤0.75	≥1.5	N/A
ACT	≥12	≥20	16–19	≤15
<b>Risk</b>				
Exacerbations requiring oral corticosteroids	0–4	≤1 times/year	2–3 times/year	>3 times/year
	5–11	≤1 times/year	≤2 times/year	
	≥12	≤1 times/year	Consider severity and interval since last exacerbation	
Reduction in lung growth	5–11	Evaluation requires long-term follow-up care		
Loss of lung function	≥12	Evaluation requires long-term follow-up care		
Treatment-related adverse effects	All	Medication side effects can vary in intensity from none to very troublesome and worrisome		
<b>Recommended Treatment</b>				
Recommended treatment actions	All	Maintain current step Regular follow-up q1–6 months Consider stepping down if well controlled for ≥3 months	Step up 1 step  Before stepping up, review adherence to medication, inhaler technique, environmental control, comorbid conditions If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step Reevaluate the level of asthma control in 2–6 weeks and adjust therapy accordingly For side effects, consider alternative treatment options	Step up 1–2 steps and consider short course of oral corticosteroids

ACQ, Asthma control questionnaire; ACT, asthma control test; ATAQ, asthma therapy assessment questionnaire; FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroid; PEF, peak expiratory flow; SABA, short-acting  $\beta_2$ -adrenergic receptor agonist. From National Heart, Lung, and Blood Institute: National Asthma Education and Prevention Program Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. NIH Publication Number 08-5846. Washington, DC: National Heart, Lung, and Blood Institute; 2007.

Allergen avoidance is currently recommended in the management of all asthmatics, but there is limited evidence that these interventions are effective. Various studies have analyzed the effects of controlling dust mite exposure with specially designed mattress and pillow covers and the use of air filtration units to reduce the burden of airborne pet dander. None of these studies have demonstrated clear benefits in decreasing symptoms. One

nonblinded, randomized controlled trial, however, did suggest that removal of mold and improved ventilation in homes affected by mold can reduce symptoms of wheezing, rhinitis, and need for asthma medications.

Yearly inactivated influenza vaccination is recommended for all children with asthma to reduce the risk of complications due to influenza, although any clinically significant benefit for asthma symptoms

**TABLE 3** Stepwise Treatment of Asthma in Children Younger than 12 Years.

STEP	0–4 YEARS OLD	5–11 YEARS OLD
Step 1: Intermittent	SABA as needed	SABA as needed
Step 2: Mild persistent	Add low-dose daily ICS <i>or</i> cromolyn <i>or</i> montelukast (Singulair)	Add low-dose daily ICS <i>or</i> cromolyn, LTRA, nedocromil (Tilade)* <i>or</i> theophylline
Step 3: Moderate persistent	Increase ICS to medium dose	Increase ICS to medium dose <i>or</i> continue low-dose ICS <i>plus</i> either LTRA, LABA, <i>or</i> theophylline
Step 4: Severe persistent	Medium-dose ICS <i>plus</i> either LABA <i>or</i> montelukast	Medium-dose ICS <i>plus</i> LABA, <i>or</i> medium-dose ICS <i>plus</i> either LTRA <i>or</i> theophylline
Step 5: Severe persistent	High-dose ICS <i>plus</i> either LABA <i>or</i> montelukast	High-dose ICS <i>plus</i> LABA, <i>or</i> high-dose ICS <i>plus</i> LTRA <i>or</i> theophylline
Step 6: Severe persistent	Step 5 <i>plus</i> oral glucocorticoids	Step 5 <i>plus</i> oral glucocorticoids
Step-Down Therapy	Step-Up Therapy	
If control is adequate for 3 months, may consider gradual decrease in treatment Reassess every 1–3 months	SABA use >2 times /week can indicate inadequate control Check for triggers, medication adherence, medication technique, comorbid disease before increasing therapy	

Children  $\geq 12$  years: May be treated according to adult guidelines.

Children 5–11 years: Consider subcutaneous allergen immunotherapy if the child has allergic asthma in steps 2 to 6.

All children: Treat comorbid conditions to improve asthma control.

For exacerbations that occur at all levels:

SABA 2–4 puffs every 4–6 h for 24 h with physician consultation.

Consider 3- to 10-day course of oral glucocorticoids for moderate to severe exacerbation.

\*Not available in the United States.

ICS, Inhaled corticosteroid; LABA, long-acting  $\beta$ -agonist; LTRA, leukotriene receptor antagonist; SABA, short-acting  $\beta_2$ -adrenergic receptor agonist.

†Symptoms of obstruction not responsive to initial SABA use.

SABA, Short-acting  $\beta_2$ -adrenergic receptor agonist; *soln*, solution.

is questionable. The live attenuated influenza vaccine (LAIV, FluMist) is typically not offered to children with asthma due to limited safety data in this population, although one trial of 2229 children and adolescents with asthma demonstrated better prevention of influenza with LAIV than injectable vaccine and no differences in asthma symptoms or exacerbations. Pneumococcal vaccination is recommended for all children and, based on limited data, appears to reduce asthma exacerbations in those with asthma. Finally, management of comorbid conditions has been implicated in improving asthma control. Sinusitis, allergic rhinitis, gastroesophageal reflux disease (GERD), and obesity are thought to contribute to asthma symptoms. Research has shown, however, that treatment of GERD with lansoprazole (Prevacid) in children with poorly controlled asthma not only had no effect on asthma symptoms but also led to a significant increase in respiratory infections.

## Medications

Asthma management requires both fast-acting rescue medications and long-term controller medications. The goal of therapy is to find a daily controller medicine that reduces symptoms to such a degree that rescue medications are needed only rarely. Patients and their caretakers must be educated regarding the different

roles of these two classes of medication to ensure the best possible outcome and the patient's safety.

## Rescue Medications

Fast-acting bronchodilators are important in both the mildest and the most-severe forms of asthma. Short-acting  $\beta_2$ -adrenergic receptor agonists lead to smooth muscle relaxation and airway dilation. Racemic albuterol is a commonly used member of this group, but levalbuterol is an alternative. Initially levalbuterol was thought to have fewer side effects, but studies have shown similar tolerability between racemic albuterol and levalbuterol. There is no significant difference in efficacy between these medications. Short-acting  $\beta_2$ -adrenergic receptor agonists should be reserved for relief of acute symptoms. Frequent use is discouraged and can indicate inadequate control of symptoms. See [Table 4](#) for usual dosing of rescue medications.

## Controller Medications

Inhaled corticosteroids are the most effective long-term controller medications. Some commonly used inhaled corticosteroids are fluticasone, budesonide, beclomethasone, mometasone, and flunisolide. No single formulation of inhaled corticosteroid is superior to another. These medications reduce frequency of exacerbations

and hospitalizations and are superior to leukotriene receptor antagonists and mast cell stabilizers. They are available as both metered-dose inhalers and dry-powder inhalers. A significant concern related to their use in children, however, is their effect on bone density and growth. High- and medium-dose inhaled corticosteroids have been linked to reduced growth velocity, but several studies have shown that at low doses they do not consistently or significantly affect growth. A systematic review and meta-analysis of effects of asthma and ICS on final adult height concluded that ICS does not significantly affect final adult height. To minimize potential side effects, continuous monitoring, reevaluation, and consideration of step-down treatment is imperative.

Long-acting  $\beta$ -agonists include salmeterol and formoterol. They are an adjunctive therapy to inhaled corticosteroids and should be considered in step 3 of management of symptoms in children aged 5 to 11 years and in step 4 in children 0 to 4 years old. Long-acting  $\beta$ -agonists carry a risk of increased asthma-related deaths, intubations, and hospitalizations when used alone. This risk was most prominent in children 4 to 11 years of age. Long-acting  $\beta$ -agonists should never be used as monotherapy and are not recommended for use during exacerbations. In combination with inhaled corticosteroids, however, long-acting  $\beta$ -agonists have been shown to increase asthma control days and improve lung function, but safety data are unclear based on a systematic review in 2012. For children younger than 5 years, data are lacking.

Leukotriene-receptor antagonists, including montelukast (Singulair) and zafirlukast (Accolate), are another adjunctive therapy to inhaled corticosteroids. They reduce symptoms by blocking the inflammatory cascade initiated by mast cells. In the mildest forms of asthma, they may be used as an alternative to inhaled corticosteroids if the steroids are not well tolerated or there is difficulty with administration. They are also effective in decreasing symptoms of exercise-induced asthma.

Mast cell stabilizers such as cromolyn sodium (Intal) or nedocromil (Tilade)<sup>2</sup> have a role similar to that of the leukotriene-receptor antagonists. They reduce inflammation by preventing mast cells from initiating the inflammatory cascade. They are safe and well tolerated in children, but the efficacy of inhaled sodium cromoglycate (Intal) has been brought into question after a systematic review found insufficient evidence to demonstrate sodium cromoglycate's superiority over placebo. The nedocromil inhaler has been discontinued owing to difficulties with manufacturing inhaler propellant.

Immunotherapy consists of subcutaneous injections of extracts from allergens intended to desensitize a patient to specific allergic triggers. This should occur in consultation with an allergist and may be considered at steps 2 through 6 of asthma treatment in children ages 5 to 11 years if asthma symptoms are predominantly allergic.

Immunomodulators are reserved for the most refractory cases of asthma. Omalizumab (Xolair, an anti-IgE agent) functions by blocking the binding of IgE to mast cells and basophils. It is effective in children with allergic triggers for their asthma but carries a risk of anaphylaxis, and the FDA, as of 2014, has associated its use with an increase in cardiovascular and cerebrovascular events. In 2013, the National Institute for Health and Care Excellence (NICE) issued a recommendation that omalizumab be reserved for children age 6 and older who have frequent need for oral steroids (more than three courses in prior 12 months) and who have failed optimized therapy. Optimized therapy is defined as a full trial of inhaled high-dose corticosteroid, long-acting  $\beta_2$  agonist, leukotriene receptor antagonist, theophyllines, and oral steroids.

Early data from a randomized controlled trial suggests improved FEV<sub>1</sub> in children with severe symptomatic asthma with the addition of the anticholinergic drug tiotropium to an established regimen of medium- or high-dose inhaled steroids plus 1 or

2 other asthma control medications. More studies are needed to determine clinical benefit, however.

Theophylline was previously a mainstay of asthma management but is no longer a first-line medication. With the development of alternative treatments and because of theophylline's risk for toxicity, theophylline now has a lesser role in asthma management. Currently it is used as an alternative treatment in the chronic management of patients with symptoms refractory to or intolerant of standard therapies. Use of this medication requires frequent monitoring of drug serum levels. It can cause nausea, vomiting, or tachyarrhythmias if dosing is too high. See [Table 5](#) for usual dosing of controller medications.

### Acute Asthma Exacerbations

Exacerbations consist of worsening wheezing, cough, or shortness of breath. They can vary in severity from mild to life threatening. When deciding how to treat a patient in an exacerbation, use the history and physical examination to determine severity. As in all emergency situations, first assess airway, breathing, and circulation. In a life-threatening exacerbation, the patient can appear confused or obtunded, may be bradycardic, and can have minimal respiratory effort, indicating imminent respiratory arrest. A child in a severe exacerbation can appear short of breath even at rest, may be agitated, and might only be speaking one word at a time. The child is likely tachycardic and tachypneic, with obvious use of accessory muscles. In certain cases, lung examination might not reveal wheezing owing to severe impairment of aeration; only after treatment does the wheezing become audible as air movement improves. In mild to moderate exacerbations, the patient might only be short of breath with walking, might speak in short phrases or full sentences, and can appear anxious but not necessarily agitated. Lung examination can reveal wheezing.

The cornerstone of treatment of asthma exacerbations is rapid recognition of symptoms, correction of hypoxemia, and early initiation of short-acting  $\beta_2$ -adrenergic receptor agonists and corticosteroids. Oxygen administration should be employed to maintain oxygen saturation at greater than 94%. Short-acting  $\beta$ -agonists are essential to relieve bronchoconstriction and may be combined with ipratropium<sup>1</sup>, especially if the patient is not responsive to initial therapy with a short-acting  $\beta_2$ -adrenergic receptor agonist alone. Ipratropium should not be used as single agent, as it is less efficacious than  $\beta_2$  agonists alone as well as combined  $\beta_2$  agonist–ipratropium. Combined anticholinergics and short-acting  $\beta$ -agonists were shown to decrease the rate of hospitalization in children when used during initial treatment for an exacerbation with a NNT of 16; however, benefit did not persist with continuing use during hospitalization. In 2006, a systematic review showed that metered-dose inhalers with a spacer are as effective in administering  $\beta$ -agonists as nebulizers are in children older than 2 years. It was noted in the same study that length of stay in the emergency department was reduced in those using the spacers.

Corticosteroids given systemically are also considered rescue medications, although the onset of action is 1 to 2 hours and duration of action is 18 to 36 hours. They work primarily as antiinflammatories and are an important treatment in exacerbations. Early use of systemic steroids, either oral or intravenous, reduced rates of relapse and decreased admissions to the hospital. The greatest benefit of systemic steroids was seen in patients having a severe attack and those who were not already on a course of steroids. Studies have shown that oral steroids are as effective as intravenous or intramuscular preparations. Even a short course of oral steroids can reduce relapse and decrease the need for rescue inhalers. Systemic corticosteroids should be continued for 3 to 10 days after an exacerbation.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 5** Usual Dosing of Controller Medications

DRUG	FORMAT	DOSING
Fluticasone	HFA: 44, 110, 220 µg per puff DPI: 50, 100, 250 µg per inhalation	Low: 88–176 µg BID Medium: 176–440 µg BID High: > 440 µg BID
Fluticasone-salmeterol	DPI 100 µg/50 µg MDI 45 µg/25 µg	> 5 y: DPI 100 µg/50 µg BID MDI 90 µg/50 µg BID
Budesonide	DPI 90 or 180 µg/inhalation	Low: 90–180 µg BID Medium: 180–360 µg BID High: 540–720 µg TID–QID
Budesonide-formoterol	HFA MDI 80 µg/4.5 µg per inhalation	80 µg/4.5 µg–160 µg/9 µg BID
Beclomethasone HFA	40 or 80 µg per puff	Low: 80–160 µg BID Medium: 160–320 µg BID High: > 320 µg BID
Mometasone aerosol DPI	110, 220 µg per puff	110 µg daily is max per guidelines for 4–11 yR
Flunisolide HFA	80 µg per puff	5–11 y: 80–160 µg BID >12 y: 160–320 µg BID
Montelukast	4 mg or 5 mg chewable tablet 4 mg granule packets	< 5 y: 4 mg hs 6–14 y: 5 mg hs
Zafirlukast	10 mg tablet	Ages 5–11 y: 10 mg BID
Cromolyn sodium	Nebulized soln (20 mg/2 mL), MDI <sup>2</sup> 800 µg	> 2 y: nebulized soln: inhale 20 mg qid Age > 2: MDI: 2 puffs QID
Theophylline	Liquids, sustained-release tablets and capsules	Starting dose: 10 mg/kg/d < 1 y: max dose 0.2 × (age in weeks) + 5 = mg/kg/d ≥ 1 y: max dose 16 mg/kg/day

cap, Capsule; DPI, dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler; soln, solution.

<sup>2</sup>Not available in the United States.

Information from Lexicomp. <http://online.lexi.com>

A taper is not necessary if the course is less than 1 week or less than 10 days in a patient who is also using an inhaled corticosteroid (ICS). Prolonged use of systemic corticosteroids carries significant risk for side effects such as adrenal suppression, osteoporosis, reduced growth, and cataracts, and thus their use should be minimized. Despite some evidence that use of ICS in acute exacerbations can reduce hospital admission rates, mounting data do not support treatment with increased doses of ICS (2 to 5 times maintenance dose) in children with acute asthma exacerbations, as rates of oral corticosteroid use do not appear to be reduced, yet the magnitude of increased cumulative ICS dose with this practice raises concern for potential height restriction.

Use of intravenous magnesium sulfate<sup>1</sup> (a smooth muscle relaxer) should be reserved for severe exacerbations only. Its use has not been shown to reduce admission rates in milder exacerbations but can improve lung function in those with only a partial response to short-acting β-agonists. Similarly, subcutaneous epinephrine<sup>1</sup> and subcutaneous terbutaline<sup>1</sup> should be reserved for emergency department settings when patients are not responding to short-acting β<sub>2</sub>-adrenergic receptor agonists, anticholinergics, or corticosteroids, or when air entry is so diminished that inhaled medications are not effective.

Finally, not enough evidence exists to make a recommendation regarding routine use of antibiotics during an acute asthma exacerbation. In some circumstances, when there are findings consistent with bacterial infections (such as consolidation on chest x-ray), their use may be warranted. See [Table 6](#) for usual dosing of medications used in acute exacerbations.

### Monitoring

Asthma is a dynamic disease whose symptoms fluctuate based on a number of variables. Routine scheduled appointments with a pediatrician or family physician are essential to monitor symptoms and adjust therapy. Initial management can require visits

**TABLE 6** Usual Dosing of Medications Used in Exacerbations

DRUG	DOSING
<b>Chronic Management</b>	
Corticosteroids (methylprednisolone, prednisolone, prednisone)	0.25–2 mg/kg daily or every other day
<b>Acute Exacerbation</b>	
Ipratropium bromide <sup>1</sup>	Age 0–5 years: 250 µg nebulized × 2, then q4h prn Age 5–11: 500 µg nebulized × 2, then q4h prn
Corticosteroids (methylprednisolone, prednisolone, prednisone)	1–2 mg/kg/day (max 60 mg/day) in 2 divided doses × 3–10 days
<b>Severe Acute Exacerbation</b>	
<b>Not Responding to SABAs</b>	
Magnesium sulfate <sup>1</sup>	25–50 mg/kg IV up to 2 g over 10–20 min
Terbutaline <sup>1</sup>	0.01 mg/kg SC q20min for 3 doses, then every 2–6 hr prn
Epinephrine <sup>1</sup>	0.01 mg/kg up to 0.3–0.5 mg SC q20min for 3 doses
<b>Related to Allergic Reaction</b>	
Epinephrine	1:1000: 0.01 mL/kg SC (max 0.3 mL)

<sup>1</sup>Not FDA approved for this indication.

SABA = Short-acting β<sub>2</sub>-adrenergic receptor agonist.

every 2 to 6 weeks; as control of symptoms improves, the interval may be increased to every 3 to 6 months.

Patient education is essential to successfully controlling this disease. Education should be focused on the theory behind controller and rescue medications, the importance of medication compliance, and how to administer these medications properly. Newer trial data support improved inhaler adherence with the use of electronic reminders such as mobile phone alarms. The National Asthma Education and Prevention Program Expert Panel 3 emphasizes the importance of asthma action plans to empower patients in recognizing and treating escalating symptoms of asthma. Action plans also provide recommendations on reducing exposure to irritants, allergens, and triggers. Some plans are based on peak flow levels, but studies show that symptom-based written action plans are better at decreasing acute care visits. Examples of asthma action plans can be found on the National Heart, Lung, and Blood Institute website.

## Complications

The most worrisome complications of asthma include reduced lung function, pneumonia, pneumothorax, and death. More common complications include chronic cough, fatigue due to poor sleep, missed school days and worse academic performance, and limited ability to participate in sports.

## ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Method of

Sophie Robert, PharmD; Erin Hayes, MD; and Jennifer K. Poon, MD

### CURRENT DIAGNOSIS

- Attention-deficit/hyperactivity disorder (ADHD) is one of the most common childhood neurodevelopmental disorders affecting not only academic achievement but also well-being and social interactions.
- ADHD is a chronic condition that can continue to cause symptoms and dysfunction into adulthood.
- The primary care provider encountering any child or adolescent 4 years of age and older should evaluate for ADHD when there is a presenting academic or behavioral problem with symptoms of inattention, hyperactivity, or impulsivity.
- The diagnosis of ADHD is a clinical diagnosis that is based on criteria from the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*), documenting symptoms and dysfunction in more than one setting, including parent/patient concerns, as well as collateral information from individuals who have knowledge of how the patient functions in another setting.
- The use of ADHD-specific questionnaires and rating scales is important in data collection and to detect the presence of coexisting conditions.
- All ADHD evaluations should assess for coexisting behavioral conditions, such as oppositional defiant disorder, mood disorders, anxiety, depression, substance use, developmental conditions such as learning and language disorders, and physical conditions including tics and sleep apnea.

## CURRENT THERAPY

- The goal of treatment is symptomatic and functional improvement.
- Evidence-based, age-appropriate behavioral and educational interventions may be recommended as initial treatment, or in addition to pharmacotherapy, especially if there are coexisting conditions; psychoeducation is recommended along with pharmacotherapy.
- For preschool-age children, evidence-based parent training in behavior management and/or classroom behavior interventions are the first line of treatment, if available.
- For children 6 years of age and older, first-line treatment includes stimulant medications or nonstimulant alternative medications such as atomoxetine (Strattera) and viloxazine (Qelbree).
- Second-line treatment includes alpha2 agonists (e.g., clonidine [Kapvay], guanfacine [Intuniv]), bupropion (Wellbutrin),<sup>1</sup> and venlafaxine (Effexor).<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

## Pathophysiology

The cited prevalence of attention-deficit/hyperactivity disorder (ADHD) varies throughout the literature as a result of methodologic differences, the diagnostic criteria used, the population studied, and the sources used to make the diagnosis. There are no specific laboratory tests or imaging studies that diagnose ADHD. It is a clinical diagnosis. The prevalence has ranged from 4% to 12%, often higher in community samples, and higher among males. National studies cite that approximately 7% of children meet the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*) criteria for ADHD. Males are more commonly diagnosed because they present with externalizing symptoms such as overactivity and aggression, in contrast with females, who present with less noticeable internalizing symptoms such as daydreaming and poor school performance. ADHD is considered a chronic condition because data suggest that approximately 50% of cases will persist into adulthood. Follow-up studies indicate that functional impairment persists in approximately 10% to 60% of childhood-onset cases.

ADHD has no single causative factor, and common theories such as allergies to food coloring, poor parenting/discipline, and/or poor schooling have not been supported by research. Rather, the disorder has a complex, multifactorial etiology consisting of genetic and environmental factors. ADHD is familial, and a number of family epidemiologic studies of association of symptoms in twin, adoption, and segregation analyses have supported heritability at 65% to 90%. Neuroimaging studies have demonstrated differences in the basal ganglia, cerebellar vermis, and frontal lobes in individuals with ADHD versus controls. Biologic factors such as prenatal exposure to substances have been associated with ADHD symptomatology. Also, psychosocial problems such as parental psychopathology and poor family cohesion have been cited to be more common in families of children with ADHD than in children without the disorder.

## Clinical Manifestations

The life course of ADHD may be variable from person to person, depending on a number of psychosocial factors. However, parents may first notice difficulties in children as toddlers who may be overly active, sometimes posing behavioral issues at daycare, safety issues, or social difficulties. However, at the toddler age, it may be difficult to discern between normative behavior of an active child versus true ADHD before the preschool years. Hyperactivity may be noted more in preschool years if children are having challenges in a structured setting, such as school, or if safety issues emerge. The elementary school years are a common time when ADHD is brought to attention. During these years, inattention may be more prominent, particularly as academics evolve from rote memory

activities to second-order thinking. Often in adolescence and adulthood, the motor hyperactivity lessens, but there is persistent restlessness, impatience, inattention, and impulsivity.

As with any disorder, ADHD has functional consequences, not only affecting academics in school-age children, but occupational performance as well as interpersonal relationships for adults. There is a greater risk for development of conduct disorder in adolescence and antisocial personality disorder in individuals with ADHD. Furthermore, studies have found that individuals with ADHD have increased rates of substance use disorders (SUDs) and incarceration.

## Diagnosis

The American Academy of Pediatrics recommends an evaluation for ADHD in any child or adolescent 4 years of age or older presenting with inattention, hyperactivity, impulsivity, academic underachievement, and/or behavior problems. The diagnostic criteria for ADHD are found in the *DSM-5* within the neurodevelopmental disorders section. The practitioner specifies whether the patient meets criteria for the combined presentation, the predominantly inattentive presentation, or the predominantly hyperactive/impulsive presentation as well as whether symptoms are in partial remission and current severity of mild, moderate, or severe. ADHD is a clinical diagnosis.

To diagnose ADHD, several symptoms must be present before 12 years of age and affect the patient in two or more settings such as at home, at school, at work, with friends or relatives, or in other activities. The symptoms have a negative effect on the patient's level of social, academic, or occupational functioning. The symptoms are present to a degree that is inconsistent with the patient's developmental level. Symptoms must not occur exclusively during schizophrenia or another psychotic disorder or be part of another mental disorder. Symptoms must not be completely caused by oppositional behavior, being defiant, or failing to understand instructions and tasks.

Inattentive symptoms are designated in Criterion A1 of the *DSM-5*. To meet criteria for the predominantly inattentive presentation, a patient must have at least six of the following symptoms for the past 6 months: (1) failing to give attention to details or making careless mistakes, (2) having difficulty sustaining attention, (3) appearing to not listen when spoken to directly, (4) not following through on instructions or failing to complete schoolwork, chores, or workplace duties, (5) having difficulty organizing tasks and activities, (6) avoiding or lacking interest in tasks requiring sustained mental effort, (7) losing necessary objects to complete tasks or activities, (8) being distracted easily, and (9) being forgetful in completing daily activities. If older than 17 years of age, the patient must have at least five of the symptoms.

Hyperactive and impulsive symptoms are designated in Criterion A2 of the *DSM-5*. To meet criteria for the predominantly hyperactive/impulsive presentation, a patient must have at least six of the following symptoms for the past 6 months: (1) fidgeting or having trouble sitting still, (2) leaving a seat when it is expected to remain seated, (3) running or climbing in inappropriate situations, (4) having difficulty playing or doing leisure activities quietly, (5) being "on the go" or "driven by a motor," (6) talking excessively, (7) blurting out the answer before a question is completed, (8) having trouble waiting his or her turn, and (9) often interrupting and intruding on others. If older than 17 years of age, the patient must have at least five of the symptoms.

Patients with at least six symptoms in Criterion A1 and at least six symptoms in Criterion A2 are said to have the combined presentation.

To obtain an accurate picture of the effect these symptoms have in various settings, it is helpful to obtain collateral information from individuals who have knowledge of how the patient functions in a given setting. For this reason, it is common to obtain input from current and former teachers, coaches, religious leaders, other relatives, and so on. The use of ADHD-specific questionnaires and rating scales is important in data collection and detection of comorbid conditions. All ADHD evaluations should assess for coexisting conditions such as oppositional defiant disorder, mood disorders, anxiety disorders, trauma, and learning disabilities.

## Therapy

### Behavioral Interventions

For preschool-age children (48 to 59 months of age) with ADHD, the primary recommended first-line intervention is parent training behavior management, if available. Such training helps parents understand developmentally appropriate expectations, how to strengthen the parent-child relationship, and specific management of disruptive behaviors. The largest multisite study of methylphenidate used in preschool-age children with ADHD with moderate-to-severe dysfunction demonstrated that parent training behavior management alone resulted in symptom improvement. Such therapies may be group programs or dyadic therapy for the parent and child. Schools may also be able to provide behavioral support as well. **Box 1** lists patient and parent resources for the management of attention-deficit/hyperactivity disorder.

Parent training behavior management techniques and/or behavioral classroom interventions are also recommended along with medications approved by the U.S. Food and Drug Administration (FDA) for ADHD in children 6 to 12 years of age. Behavioral classroom interventions may include modifying school environment, class placement, instructional placement, and behavior supports. Such supports may include a rehabilitation plan (504 plan) or Individualized Education Program (IEP).

Similarly, adolescents 12 to 18 years of age should be prescribed FDA-approved medications for ADHD with their assent and should also have evidence-based training interventions and/or behavioral interventions if available, as outlined for school-age children. Furthermore, a transitional care plan is important as a part of a chronic care model for ADHD. This transition to adult care should be introduced at around 14 years of age to help identify resources before high school completion.

Behavioral therapy and training interventions have studies supporting their effectiveness for the treatment of ADHD; however, these should be differentiated from other psychological interventions, particularly ones that are designed to change emotional status or thought patterns (e.g., play therapy, talk therapy). The latter have not shown efficacy for the treatment of ADHD core symptoms and do not generalize to the home or classroom. Evidence-based behavior therapies involve training adults to shape the environment in order to improve behavior in a setting and to learn effective responses to symptoms such as interrupting, aggressive behaviors, and noncompliance with requests. Although studies indicate that stimulants have a greater immediate effect on the core symptoms of ADHD, there is greater parental satisfaction with behavior therapy, with the positive effects tending to last.

### Pharmacotherapy

Stimulants are considered first-line medications for the treatment of ADHD in patients 6 years of age and older. Nonstimulant alternatives include atomoxetine (Strattera), viloxazine (Qelbree), and  $\alpha_2$  agonists for school-age children and adolescents, with atomoxetine an option for adults as well. Additional options

with lesser evidence include bupropion (Wellbutrin),<sup>1</sup> venlafaxine (Effexor),<sup>1</sup> and tricyclic antidepressants (TCAs).<sup>1</sup>

For preschool-age children (4 to 6 years of age), pharmacotherapy with stimulants is generally reserved for patients with moderate to severe ADHD symptoms who have responded insufficiently to behavioral therapies. Although off-label in that age group, methylphenidate (Ritalin) is the preferred stimulant based on its evidence of efficacy and safety. Methylphenidate medications are listed in **Table 1**. Amphetamines are generally not recommended, despite FDA-approval of certain formulations, as evidence is insufficient. Other medications have not been studied in that age group.

### Stimulants

The benefits of short-term stimulant therapy on ADHD symptoms are well documented, with large effect sizes ranging from 0.9 to 1.0. Evidence suggests that amphetamines may be more efficacious, most notably in adults, yet may have poorer tolerability, particularly in children. Amphetamine medications are listed in **Table 2**. The subtype of ADHD does not appear to predict response to a specific class. Individual response to methylphenidate versus amphetamine is unpredictable, but 80 to 90% of patients will ultimately have a beneficial response with trials of various medications from both classes. Beyond symptomatic improvement, stimulant treatment is associated with improved academic outcomes, improved social functioning, and a protective effect on accidents and injuries.

Stimulants are Schedule II controlled drugs because of their potential for misuse and diversion. Overall, stimulant treatment of ADHD does not increase the risk of developing SUDs; on the contrary, effective treatment of ADHD (even with stimulants) at least delays, and may even reduce, the risk of developing SUDs. If concerns over misuse arise, extended-release formulations (or nonstimulants) should be favored given their slower increase in plasma concentrations resulting in less "likeability" and less potential for misuse. However, for patients with active SUDs, prescribing of stimulants should generally be reserved for mental health specialists. Additionally, diversion is a growing problem, particularly among adolescents and college-age students, thus nonstimulant alternatives can be considered if such concerns arise. Nonstimulant medications are listed in **Table 3**.

Stimulants are available as short-, intermediate-, and long-acting formulations, and they come in a variety of preparations. These include regular tablets, transdermal patches, liquid/suspension, chewable or orally disintegrating tablets, and capsules that can be opened with contents sprinkled on food. Although overall efficacy is similar, the pharmacokinetic characteristics of individual formulations affect the timeline and duration of action.

Short-acting formulations offer dosing flexibility, which may be especially beneficial for young children; disadvantages include multiple daily dosing and higher risk of abuse/misuse. Intermediate-acting formulations provide a longer duration of action (up to 8 hours) but often require twice daily dosing. Long-acting formulations allow for once daily dosing, which is associated with improved treatment adherence. Disadvantages include potential adverse effects on evening appetite and sleep along with higher cost, especially for branded formulations. Short- or intermediate-acting formulations can be used in combination with long-acting formulations early in the day (e.g., for faster onset in the morning) or later in the day (e.g., management of late afternoon "rebound"). Different formulations of the same stimulant may be tried to optimize response and tolerability. If maximum tolerated doses of a stimulant are inadequate, then another formulation within the same stimulant class or another stimulant class should be considered. When converting from one stimulant to another, the following dose equivalence can be utilized: amphetamines 10 mg = dextroamphetamine 10

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Methylphenidate Medications\*

MEDICATION (BRAND NAME EXAMPLES)	INITIAL DOSE	ONSET (MINUTES)	TMAX (HOURS)	DURATION (HOURS)	FDA MAXIMUM DAILY DOSE	FDA-APPROVED AGES	SPLIT/CRUSH/SPRINKLE	COMMENTS
<b>Short-Acting</b>								
Methylphenidate (Ritalin, Methylin)	5 mg BID–TID	20–30	1.9	3–4	60 mg	6–17, adults	Can split or crush tablet; oral solution (grape flavor); chewable tablet (grape flavor)	High-fat meal increases exposure by 25%, and decreases T <sub>max</sub> by 0.5 h for tabs but delays it by 1 h for solution and chewtabs
Dexmethylphenidate (Focalin)	2.5 mg BID	30	1–1.5	3–6	20 mg	6–17	Can split or crush	High-fat meal delays T <sub>max</sub> by 1.5 h; 2.5 mg = 5 mg methylphenidate
<b>Intermediate-Acting</b>								
Methylphenidate (Methylin ER)	20 mg AM	60–90	4.7	3–8	60 mg	6–17, adults	Do not crush, chew, or split	Preferable to take 30–45 min before meals
<b>Long-Acting</b>								
Methylphenidate (Ritalin LA)	10–20 mg AM	100	First: 1.5 Second: 6.6	7–9	60 mg	6–12	Can open and sprinkle on applesauce	Capsule is 50% IR and 50% DR beads; high-fat meal delays first T <sub>max</sub>
Methylphenidate (Metadate CD)	10–20 mg AM	90	First: 1.5 Second: 4.5	7–9	60 mg	6–15	Can open and sprinkle on applesauce	Capsule is 30% IR and 70% DR beads; high-fat meal delays first T <sub>max</sub> by 1 h
Methylphenidate (Quillivant XR)	10–20 mg AM	45	4	12	60 mg	6+	Oral suspension (banana flavor)	Suspension is 20% IR and 80% DR beads; high-fat meal reduces T <sub>max</sub> by 1 h; shake vigorously for at least 10 sec
Methylphenidate (QuilliChew ER)	10–20 mg AM	45	5	8	60 mg	6+	Chewable tablet (cherry flavor)	Tablet is 30% IR and 70% DR beads
Methylphenidate (Aptensio XR)	10 mg AM	60	First: 2 Second: 8	12	60 mg	6+	Can open and sprinkle on applesauce	Capsule is 40% IR and 60% DR beads; high-fat meal decreases second peak

*(Continued)*

**TABLE 1** Methylphenidate Medications\*—cont'd

MEDICATION (BRAND NAME EXAMPLES)	INITIAL DOSE	ONSET (MINUTES)	TMAX (HOURS)	DURATION (HOURS)	FDA MAXIMUM DAILY DOSE	FDA-APPROVED AGES	SPLIT/CRUSH/SPRINKLE	COMMENTS
Methylphenidate (Concerta)	Children: 18 mg AM Adults: 18–36 mg AM	30–60	First: 1 Second: 6–10	10–12	6–12 years: 54 mg ≥ 13 years: 72 mg	6–17, adults	No	Nonabsorbable tablet is 22% IR and 78% DR beads
Methylphenidate (Cotempla XR-ODT)	17.3 mg AM	Within 60 min	5	12	51.8 mg	6–17	Allow to dissolve, do not crush or chew	Tablet is 25% IR and 75% DR beads; 8.6 mg = 10 mg methylphenidate
Methylphenidate (Adhansia XR)	25 mg AM	30	First at 1.5 Second: ~12	16	85	6–17, adults	Can open and sprinkle on applesauce or yogurt	Capsule is 20% IR outer layer and 80% DR beads; more AEs at doses ≥70 mg in children or 85 mg in adults
Methylphenidate (Jornay PM)	20 mg PM	12–13 hours	14	10	100 mg	6+	Can open and sprinkle on applesauce	High-fat evening meal delays T <sub>max</sub> by 2.5 h
Methylphenidate transdermal (Daytrana)	10 mg AM	120–240	8–10	10–12	30 mg	6–17	Transdermal	Remove after 9 h; absorption may continue for several hours after removal; 15 mg approx. = 20 mg methylphenidate
Dexmethylphenidate (Focalin XR)	5 mg AM	30	First: 1.5 Second: 6.5	9–12	30 mg	6–17, adults	Can open and sprinkle on applesauce	Capsule is 50% IR and 50% DR beads; high-fat meal delays T <sub>max</sub>
Serdexmethylphenidate/ Dexmethylphenidate (Azstarys)	39.2/7.8 mg AM	30	2	13	52.3/10.4 mg	6+	Can open and sprinkle on applesauce or added to water	Capsule is 30% IR d-MPH and 70% XR prodrug of d-MPH (ser-d-MPH)

\*Pregnancy/lactation: risk of congenital anomalies does not appear to be increased based on animal studies and a limited number of human pregnancies.

DR, delayed release; ER, extended release; IR, immediate release; LA, long-acting; ODT, orally disintegrating tablet; SR, sustained release; T<sub>max</sub>, time to maximum concentration (peak); XR, extended release.

**TABLE 2** Amphetamine Medications

MEDICATION (BRAND NAME EXAMPLES)	INITIAL DOSE	ONSET (MIN)	TMAX (H)	DURATION (HOUR)	FDA MAXIMUM DAILY DOSE	FDA-APPROVED AGES	SPLIT/ CRUSH/SPRINKLE	COMMENTS
<b>Short-Acting</b>								
Dextroamphetamine (generic, ProCentra, Zenzedi)	3–5 years: 2.5 mg AM >6 years: 5 mg AM or BID	20–60	3	4–6	40 mg	3–16	Can split or crush tablet; oral solution (bubblegum flavor)	
Mixed amphetamine salts (Adderall)	3–5 years: 2.5 mg AM >6 years: 5 mg AM or BID	30	3	5–8	40 mg	3+	Can split or crush	
Amphetamine (Evekeo, Evekeo ODT)	3–5 years: 2.5 mg AM ≥6 years: 5 mg AM–BID	30	3	4–6	Rarely ≥ 40 mg	Evekeo: 3+ Evekeo ODT: 6–17	Tablet: can split or crush ODT: dissolves	1:1 d:l amphetamine ratio
<b>Intermediate-Acting</b>								
Dextroamphetamine (Dexedrine Spansules)	5 mg AM or BID	60–90	8	6–10	Rarely ≥40 mg	6–16	Can open and sprinkle on applesauce	
<b>Long-Acting</b>								
Mixed amphetamine salts (Adderall XR)	Children: 5–10 mg AM, Adults: 20 mg AM	30	7	10–12	30 mg/day (children 6–12 yrs Rarely ≥40 mg/day for adolescents and adults)	6–17, adults	Can open and sprinkle on applesauce	Capsule is 50% IR and 50% DR beads; food delays Tmax by 2–3 h
Mixed amphetamine salts (Mydayis)	>13 years: 12.5 mg AM Adults: 12.5–25 mg AM	30	7–10	12–16	25 mg	13–17, adults	Can open and sprinkle on applesauce	Capsule contains IR and two types of DR beads; high-fat meal delays peak by 5 h
Amphetamine (Dyanavel XR)	>6 years: 2.5–5 mg AM	60	4	10–13	20 mg	6+	Oral suspension (bubblegum flavor)	Ion exchange resin; high-fat meal delays peak by 1 h; 2.5 mg = 4 mg MAS
Amphetamine (Adzenys XR-ODT, Adzenys ER)	Children: 6.3 mg AM Adults: 12.6 mg AM	30	5	10–12	6–12 years: 18.8 ≥13 years: 12.5	6–17, adults	ODT: allow to dissolve, do not crush or chew (orange flavor) ER: suspension (orange flavor)	Tablet and suspension are 50% IR and 50% DR beads; 6.3 mg = 10 mg MAS

*(Continued)*

**TABLE 2** Amphetamine Medications—cont'd

MEDICATION (BRAND NAME EXAMPLES)	INITIAL DOSE	ONSET (MIN)	TMAX (H)	DURATION (HOUR)	FDA MAXIMUM DAILY DOSE	FDA-APPROVED AGES	SPLIT/ CRUSH/SPRINKLE	COMMENTS
Lisdexamfetamine (Vyvanse) (capsules)	30 mg AM	90–120	3.5	10–12	70 mg	6–17, adults	Can open and dissolve in water, yogurt or orange juice	High-fat meal delays peak by 1 h; lower abuse potential; 70 mg = 30 mg MAS
Lisdexamfetamine (Vyvanse) (chewable tabs)	30 mg AM	90–120	4.4	10–12	70 mg	6–17, adults	Chewable tablet (strawberry flavor)	High-fat meal delays peak by 1 h; lower abuse potential; 70 mg = 30 mg MAS

\*Pregnancy/lactation: limited human data suggest possible risk of premature delivery/low birth weight/neonatal withdrawal, but no impact on cognitive development at 3 years of age; not considered compatible with breast-feeding. DR, Delayed release; IR, immediate release; MAS, mixed amphetamine salts; ODT, orally disintegrating tablet; T<sub>max</sub>, time to maximum concentration (peak).

**TABLE 3** Nonstimulant ADHD Medications\*

MEDICATION* (BRAND NAME EXAMPLES)	INITIAL DOSE	ONSET (WEEKS)	TMAX	DURATION	MAXIMUM DAILY DOSE	FDAMAXIMUM DAILY DOSE	FDA-APPROVED AGES	SPLIT/ CRUSH/SPRINKLE	COMMENTS
Atomoxetine (Strattera)	<70 kg: 0.5 mg/kg/day (target 1.2 mg/ kg/day) >70 kg: 40 mg daily (target 80 mg daily)	2–4	1–2 h	24 h	100 mg	<70 kg: 1.4 mg/ kg/day; NTE: 100 mg >70 kg: 100 mg	6–17, adults	No	High-fat meal delays peak by 3 h; no abuse potential
Viloxazine Extended- Release (Qelbree)	Children: 100 mg Adolescents: 200 mg	1	5 h	24 h	600 mg	400 mg	6–17	Sprinkle	Can open and sprinkle on applesauce
Clonidine ER (Kapvay)	0.1 mg PM	2	6.5 h	12 h	0.4 mg	N/A	6–17	No	Do not stop abruptly; relative bioavailability 89% vs. clonidine
Guanfacine ER (Intuniv)	1 mg QD (target 0.05–0.12 mg/ kg/day)	2–3	6 h	8–14 h; up to 24 h in higher doses	6–12 years: 4 mg 13–17 years: 7 mg	6–12 years: 4 mg 13–17 years: 7 mg	6–17	No	Do not stop abruptly; high- fat meal increases exposure by 40%; relative bioavailability 58% vs. guanfacine
Bupropion <sup>1</sup> (Wellbutrin [IR], Wellbutrin SR or XL)	Children, adolescents: lesser of 3 mg/ kg/day or 150 mg daily Adults: 150–200 mg	2–4	IR: 2 h SR: 3 h XL: 5 h	XL: 24 h	Children, adolescents: lesser of 6 mg/kg or 300 mg Adults: 300–450 mg	N/A	Not for ADHD	IR: Split SR or XL: No	No abuse potential
Venlafaxine <sup>1</sup> (Effexor [IR], Effexor XR)	Children, adolescents: 12.5–25 mg Adults: 75 mg	2–4	IR: 2 h XR: 6 h	IR: 4–6 h XR: 24 h	Children, adolescents: <30 kg: 50 mg; ≥30 kg: 75 mg Adults: 150–225 mg	N/A	Not for ADHD	IR: split XR: No	No abuse potential; discontinuation syndrome

\*Pregnancy/lactation: Caution in pregnancy due to limited data; insufficient data for use during breast-feeding.

<sup>1</sup>Not FDA approved for this indication.

mg = lisdexamfetamine 30 mg = dexamethylphenidate 10 mg = methylphenidate 20 mg.

Stimulants are usually initiated at low doses and titrated gradually based on response and tolerability (see Table 2). Stimulant onset of effect is rapid; however, a 1-week trial or longer at an adequate therapeutic dose may allow for better assessment of full effect. Medication doses should be maximized as tolerated for an adequate period before changing treatment regimen due to insufficient symptomatic and functional improvement. Of note, effective dose is not closely correlated with age, weight, or symptom severity.

### Selective Norepinephrine Reuptake Inhibitors

Atomoxetine (Strattera) may be considered a first-line medication based on preferences or the presence of comorbidities such as anxiety, tics, or SUDs. Atomoxetine is an effective alternative for patients who experience severe side effects with stimulants. However, evidence suggests that atomoxetine is less efficacious than stimulants, with an effect size of 0.45 in adults and 0.6 in children/adolescents. Onset of action is slower over 1 to 2 weeks, and maximum benefits may not be reached for 4 to 6 weeks. Atomoxetine is best initiated at a low dose and titrated gradually to optimize tolerability (especially gastrointestinal). Although FDA labeling states that doses can be titrated after a minimum of 3 days, stepwise titrations at weekly intervals (e.g., 0.5 mg/kg/day, then 0.8 mg/kg/day, and then 1.2 mg/kg/day) may be better tolerated for patients weighing less than 70 kg.

Viloxazine (Qelbree), recently approved in the United States for the treatment of ADHD in children and adolescents, has a long history of use in Europe for the treatment of depression. Its efficacy is primarily ascribed to its norepinephrine reuptake activity, however serotonergic modulation observed in preclinical studies may also contribute. Evidence suggests that viloxazine is less efficacious than stimulants, with an effect size ranging from 0.5 to 0.6 in children and adolescents. Onset of action is 1 to 2 weeks, with full benefits reached after 4 weeks or longer. Dose titration may be considered at weekly intervals based on response and tolerability. Although viloxazine represents a new and interesting option for the management of ADHD, its cost as a brand-only product will likely be a significant barrier to widespread use. Additionally, viloxazine is a strong cytochrome P450 1A2 inhibitor, hence it may reduce the metabolism of several medications; its package label recommends avoiding concomitant use of several different medications such as duloxetine (Cymbalta) and melatonin<sup>7</sup> and cautious use with others such as clozapine (Clozaril) and olanzapine (Zyprexa).

### Alpha2 Agonists

Clonidine and guanfacine are available as immediate-release (IR) and extended-release formulations (ER). IR formulations have been used off-label for pediatric ADHD for many years, while ER formulations (clonidine ER [Kapvay], guanfacine ER [Intuniv]) were subsequently developed and FDA-approved as ADHD monotherapy or adjunctive therapy to stimulants for children and adolescents. Alpha2 agonists ( $\alpha_2$  agonists) are less efficacious than stimulants and closer in efficacy to other nonstimulant alternatives, with effect sizes of 0.6 to 0.7. For patients with coexisting tics or stimulant-exacerbated tics,  $\alpha_2$  agonists offer the best combined improvement in both tic and ADHD symptoms, either as monotherapy or as an adjunct to a stimulant. They may also be considered as alternatives to stimulants in the context of comorbid SUDs. These medications have not been studied in adult ADHD.

Generally,  $\alpha_2$  agonists are initiated at low doses and titrated gradually based on response and tolerability (see Table 3). Clinical trial data with guanfacine ER suggest increased efficacy with weight-based dosing; clinically meaningful ADHD symptom

improvement is seen with doses of 0.05 to 0.08 mg/kg/day, with further efficacy (but also increased incidence of side effects) at doses up to 0.12 mg/kg/day. Onset of effect on core ADHD symptoms is gradual over 2 to 4 weeks.

### Other Agents

Bupropion (Wellbutrin), venlafaxine (Effexor), and TCAs are occasionally used off-label for the treatment of ADHD. The evidence base for these medications is far weaker; effect sizes are smaller than stimulants and more similar to other nonstimulant alternatives. They may be considered in patients with coexisting depression, anxiety (namely venlafaxine), or nicotine use disorder who desire smoking cessation (bupropion).

### Side Effects

Both stimulant classes share a common set of side effects that can be transient (e.g., headache, dizziness, anxiety) and minimized with low-dose initiation, gradual titration, and possibly dose reductions. Contrary to popular belief, stimulant treatment of ADHD does not induce aggression but rather can provide strong benefits on associated aggression and antisocial behavior. Clinicians should distinguish between aggression/emotional lability that is present when the stimulant is active (which may indicate excessive dosage) and increased hyperactivity/impulsivity in the evening or at the end of a dosing interval when the medication is no longer effective (commonly referred to as *rebound*). The latter may be addressed by administering a small dose of short-acting stimulant in the late afternoon. Children who experience emotional lability, experience irritability (e.g., feeling too “wired”), or feel too serious, tired, dull, flat, or listless when the stimulants are active may benefit from a dose reduction or a switch to an alternate agent. Side effects that tend to persist in long-term treatment with all stimulants include insomnia, decreased appetite, and/or weight loss. Although controlled evidence does not show an increased risk of tics with stimulants, their use is occasionally associated with unmasking or worsening tics; if this side effect persists and is problematic, an alternative medication (particularly nonstimulant) may need to be considered.

Stimulants and selective norepinephrine reuptake inhibitors (sNRIs) should generally be avoided in patients with serious cardiac disease given concerns for increased cardiac events and possible sudden cardiac death; a detailed medical history and physical examination are recommended before initiation, with referral to a cardiologist if risk factors are detected. Both classes of medications are associated with small increases in heart rate and blood pressure overall; however, these may be clinically relevant in a subset of patients.

Growth impairments are linked to stimulant treatment and, to a lesser extent, atomoxetine treatment. Reduced growth velocity is most prominent in the first 1 to 3 years of stimulant treatment, with subsequent attenuation but a possible small negative impact on final adult height. Weight and body mass index (BMI) are also negatively affected by stimulant treatment; longer duration of treatment and higher doses have been linked to greater effects on height and weight suppression. Atomoxetine has also been associated with reduced growth velocity in the first 1 to 2 years of treatment, followed by normalization after 2 to 3 years of treatment.

sNRIs have less pronounced effects on sleep and appetite than stimulants but are associated with somnolence and more nausea and vomiting (atomoxetine more than viloxazine). Abdominal pain/discomfort may be improved by dividing the total daily dose of atomoxetine into twice-daily dosing (morning and early evening); however, this may further suppress appetite. Rare cases of hepatotoxicity, including liver failure, have been reported with the use of atomoxetine. Routine monitoring of hepatic function is not required during atomoxetine treatment; however, patients who develop jaundice, dark urine, or other symptoms of hepatic disease should discontinue

<sup>7</sup> Available as dietary supplement.

atomoxetine and seek medical evaluation including liver function test assessment. Atomoxetine and viloxazine carry a black box warning regarding increased suicidality risk in children and adolescents.

The  $\alpha_2$  agonists are associated with a high rate of drowsiness, headache, dizziness, hypotension, and bradycardia. Caution is recommended when discontinuing clonidine and guanfacine; the dose should be gradually decreased to avoid sudden increases in blood pressure.

### Monitoring

As mentioned earlier, small increases in blood pressure and heart rate and decelerations in growth can be observed with use of stimulant medication. It is recommended to monitor patient vital signs within 1 to 3 months of medication initiation and then every 6 to 12 months. Vital signs should be closely monitored with dosage titration or discontinuation because  $\alpha_2$  agonists may decrease blood pressure. In cases of poor weight gain secondary to stimulants, it may be beneficial to take a “drug holiday” from the medication over weekends or school breaks. At regular follow-up visits, providers will monitor for adverse drug reactions including insomnia and decreased appetite or weight loss with stimulant administration. If concerns exist for diversion or poor medication adherence, urine drug screens may be administered. To track the patient’s response to medication, rating scales from caregivers and teachers should be repeated throughout treatment. Clinicians should also regularly update family history, especially with regard to cardiac disease, and screen for cardiac symptoms.

### When to Refer

Patients who are younger than 6 years of age; have a comorbid substance use disorder, a conduct disorder, or bipolar disorder; or fail to respond to adequate trials of methylphenidate, amphetamine, or atomoxetine should be considered for referral to a mental health specialist.

## BRONCHIOLITIS

Method of

Tamara Wagner, MD

### CURRENT DIAGNOSIS

- Clinical diagnosis most commonly associated with respiratory distress in a child younger than 2 years of age.
- Symptoms include nasal congestion or rhinorrhea associated with findings of lower respiratory tract involvement, most notably elevated respiratory rate, wheezing, or crackles.
- Diagnostic testing in the form of chest x-ray or viral testing is not recommended.

### CURRENT THERAPY

- Standard treatment is supportive care, including clearance of nasal passages, oxygen for saturation less than 90%, fluids for dehydration, and early nutritional support.
- There is no indication for corticosteroids (inhaled or systemic), albuterol, racemic epinephrine, or decongestant drops.
- Nebulized hypertonic saline has recently become a treatment option, but clear benefit has not been established.
- Humidified high-flow nasal cannula (HHFNC) oxygen therapy, a new method of respiratory support, is used frequently in patients with increased work of breathing. Systemic reviews support HHFNC as safe and well tolerated, with a decreased association of intubation in intensive care unit (ICU) patients. Optimal use of HHFNC therapy for mild to moderate bronchiolitis remains unclear.

### Background

Clinical bronchiolitis remains one of the most significant diseases within the pediatric population. Bronchiolitis is caused by a viral infection, most often the respiratory syncytial virus (RSV). Bronchiolitis as a clinical disease has a long history of applied medical therapies, which initially showed some promise in small studies and then were abandoned later, when larger studies failed to demonstrate benefit. There remains a high variation in care for patients, which persists despite the development of standardized guidelines. Bronchiolitis is a self-limited disease with a favorable prognosis; recent care guidelines support elimination of therapies without proven benefit.

### Epidemiology and Virology

Bronchiolitis follows a seasonal epidemic most closely tied to the spread of the RSV virus. Within the United States, the incidence of RSV peaks between November and April with regional variation. Approximately 800,000 children in the United States require outpatient medical management during the first year of life as a result of bronchiolitis, and approximately 100,000 hospitalizations occur annually. RSV is the most commonly isolated viral pathogen in patients with bronchiolitis. RSV accounts for 50% to 80% of all hospitalizations for bronchiolitis. Other viruses associated with bronchiolitis include human rhinovirus, parainfluenza virus, human meta-pneumovirus, coronavirus, adenovirus, influenza virus, and enterovirus.

### Coronavirus Disease 2019

The emergence of the coronavirus disease 2019 (COVID-19) pandemic was associated with a clear epidemiologic shift in clinical bronchiolitis. Measures adopted in response to the pandemic such as masking, social distancing, social isolation, and stay-at-home orders dramatically interfered with the typical seasonal behavior

of viral respiratory infections. These measures were associated with disappearance of the typical winter season peak of bronchiolitis followed by an atypical summer peak in many countries coinciding with relaxation of social distancing measures. Previously, theories to explain seasonal bronchiolitis included outside ambient temperature, meteorologic factors, and increased transmission of viruses within indoor structures. The significant disruption of the established pattern of clinical bronchiolitis calls into question the importance of temperature and weather and brings into focus the importance of standard infection prevention measures in preventing RSV infections in young infants. COVID-19 as a pathogen can cause clinical bronchiolitis but does not seem to be associated with severe bronchiolitis symptoms. As an emerging pathogen, pediatric patients admitted with COVID-19 bronchiolitis should receive treatment according to current COVID-19 treatment guidelines, which may include steroids and anti-COVID-19 therapeutics.

### Risk Factors

The most significant risk factor for bronchiolitis is age. Up to 90% of children will become infected with RSV before 2 years of age, and nearly one-half of those children will experience bronchiolitis. Infants younger than 3 months of age and those with a history of prematurity have a higher risk of severe bronchiolitis and the complication of apnea. Other risk factors for a severe course include congenital heart disease, chronic lung disease, and poor immune function. Recent studies have demonstrated that environmental factors such as cigarette smoke exposure or air pollution may increase the risk for bronchiolitis.

### Pathophysiology

The pathophysiology of bronchiolitis is progressive obstruction of the distal airways caused by mucous production, airway edema, and direct cellular injury of the bronchiolar epithelium. Following viral infection, increased mucous production, airway edema, and impaired ciliary function result in varying degrees of intraluminal obstruction. This obstruction during the positive pressure phase of expiration may cause an audible wheeze. As the disease progresses, virus-induced injury to the bronchiolar lining leads to sloughed cells and distortion of the alveolar structure, resulting in air trapping and atelectasis. With the progression of lung atelectasis, mismatching of ventilation and perfusion occur, resulting in increased work of breathing and hypoxemia.

### Prevention

Breast-feeding infants (whether exclusive or partial) have demonstrated benefit in prevention of hospitalization resulting from bronchiolitis. Additionally, infants receiving breast milk who are hospitalized with bronchiolitis have shorter hospital admissions. Palivizumab (Synagis) is a human-derived immunoglobulin G monoclonal antibody directed against RSV. Use of Synagis has been shown to reduce the rate of hospitalization in premature infants. In 2014, the American Academy of Pediatrics (AAP) released guidelines for patients who should receive Synagis; these are listed in [Table 1](#). Patients receiving prophylactic therapy should receive 1 shot per month, 15 mg/kg per dose, for a maximum of 5 doses. This should be administered during the regional RSV season.

### Clinical Manifestations

Bronchiolitis begins with upper respiratory findings of congestion or rhinorrhea, which then progresses to involve the lower respiratory tract. An increased respiratory rate is the earliest and most sensitive vital sign change. On physical examination, the most important observation is the work of breathing. All patients should have the shirt lifted and the chest directly observed for retractions. Retractions may be visible in the subcostal, intercostal, or supracostal region. Head bobbing, grunting, “sighing,” and “singing” are signs of severe respiratory distress in infants. In very young infants, especially those with a history of prematurity, apnea alone may be the presenting sign as well as a complication of bronchiolitis. Auscultation can reveal a variety of findings,

**TABLE 1** Guidelines for Use of Palivizumab

DISEASE CONDITION	PALIVIZUMAB (SYNAGIS) PROPHYLAXIS
Prematurity	Recommended routinely in first year of life for infants born <29 weeks or <32 weeks with chronic lung disease defined as oxygen therapy for at least 28 days after birth. Recommended within second year of life for children with chronic lung disease who continue to require supplemental oxygen, diuretic therapy, or chronic corticosteroid therapy
Congenital heart disease	May be considered in first year of life for infants with hemodynamically significant heart disease
Congenital pulmonary abnormality	May be considered in first year of life for infants with impaired lung physiology
Neuromuscular disease	May be considered in first year of life for infants with impaired ability to clear secretions
Immunodeficiency	May be considered in first 2 years of life for patients with profound immunosuppression

from minimal sounds to a combination of wheezes, crackles, or referred upper airway congestion. Physical examination findings in bronchiolitis are characteristically dynamic, so they may vary from examiner to examiner. There are no robustly supported physical examination findings that have reliably correlated with clinical outcomes such as severity or disposition. Despite fully validated parameters, many institutions use bronchiolitis scoring tools to align resources with patients with more severe clinical symptoms. Respiratory rate, work of breathing, and hypoxia remain the most clinically significant parameters in determining illness severity.

### Diagnosis

Bronchiolitis remains a clinical diagnosis based on physical examination and history. Chest x-rays are not recommended for diagnosis. Patients with bronchiolitis often have abnormal appearing radiographs, with findings of hyperinflation, areas of atelectasis, and small infiltrates. These findings do not correlate with disease severity and do not change management. Obtaining chest x-rays has been associated with increased prescription of antibiotics, although a primary or concurrent bacterial pneumonia is rare in bronchiolitis. Viral testing similarly does not change management in the majority of clinical cases and should not be routinely obtained. There are a few clinical situations in which viral testing may aid management. Young infants (<60 days) may present with fever as a result of bronchiolitis. The risk of serious bacterial infection (SBI) in these infants is low; viral testing may support the provider in decreased additional testing, decreased administration of empiric antibiotics, and avoidance of unnecessary hospitalization. During the seasonal influenza epidemic, influenza testing may identify bronchiolitis secondary to influenza that may benefit from antiviral medications.

### Differential Diagnosis

The differential diagnosis for bronchiolitis includes a first episode of asthma, virus-induced wheezing, pertussis infection, chronic aspiration, congenital heart disease, and anatomic thoracic abnormalities. Separating clinical bronchiolitis from a primary asthma exacerbation remains particularly challenging, even for experienced providers. Epidemiologic data support that there is a large burden of virus-induced wheezing in young children, and only a small percentage of this large group will progress to a diagnosis

**TABLE 2** Summary of Evidence for Treatment of Bronchiolitis

MEDICATION	RECOMMENDATION	EVIDENCE QUALITY
Systemic corticosteroids	Not recommended	Cochrane systematic review shows that corticosteroids do not significantly reduce outpatient admissions when compared with placebo and do not reduce length of stay for inpatient admissions
Epinephrine	Not recommended	Cochrane meta-analysis systematically evaluated the evidence and found no evidence for utility in the inpatient setting
Albuterol	Not recommended	Meta-analyses and systematic reviews have shown that bronchodilators improve clinical symptom scores, but they do not affect disease resolution, need for hospitalization, or length of stay
Hypertonic saline	May consider	Meta-analysis of smaller studies has resulted in differing conclusions as to whether this therapy affects rate of hospitalization or length of stay.
Oxygen therapy	Provide supplemental oxygen if oxyhemoglobin saturation is <90%	
Nutrition and hydration	Administer intravenous or nasogastric fluid for infants unable to maintain hydration orally	

Modified from Ralston SL, Lieberthal AS, Meissner HC, et al.: Clinical practice guideline: the diagnosis, management and prevention of bronchiolitis, *Pediatrics* 134(5):e1474–e1502, 2014.

of asthma. It remains unclear whether bronchiolitis causes a lung injury leading to asthma or whether patients with severe bronchiolitis have preexisting differences predisposing them to a severe course and later diagnosis of asthma. Given the high prevalence of virus-induced wheezing in young children, a potential asthma diagnosis (and associated use of albuterol or potentially steroids) should only be considered in patients with risk factors for asthma including eczema, food allergies, or family history of atopy and demonstration of bronchospasm reversed by a bronchodilator. As bronchodilators are not recommended for bronchiolitis, the medical team should carefully assess for efficacy if a trial is performed. Pertussis should be considered in prolonged or atypical courses, especially if the infant has had contact with adults who have not received a booster vaccination. Children with an abnormal neurologic baseline should prompt consideration of chronic aspiration as an etiology or contributor to a prolonged course. Undiagnosed congenital heart defects may present with similar examination findings to bronchiolitis. Other anatomic abnormalities that may be considered include pulmonary malformations, vascular rings, or aspiration of a foreign body.

### Treatment

Treatment for bronchiolitis remains supportive therapy and includes the following measures:

- Improve comfort by clearing nasal secretions and administering antipyretics for fever.
- Administer oxygen to maintain oxygen saturations greater than 90%.
- Maintain hydration by administering intravenous fluids or placing a nasogastric tube.
- Support adequate nutrition.
- Educate caregivers on return-to-care precautions.

In 2014, the AAP published “Clinical Practice Guideline: The Diagnosis, Management and Prevention of Bronchiolitis,” a revised version of the 2006 guidelines. A summary of the recommended treatments is given in [Table 2](#).

### Outpatient Management

Outpatient management centers on parental education in supportive care that can be provided for the child while sick and emphasis on return-to-care precautions. The typical course for bronchiolitis begins with upper respiratory infection (URI) symptoms that will progress to lower respiratory symptoms (cough, increased work of breathing), which peak on days 3 to 5. Cough

is the last symptom to resolve, with the majority of patients having some resolving cough for up to 2 weeks and a minority extending to 4 weeks. Parents should be discouraged from administering over-the-counter cough suppressants. Clearance of the nasal passages by bulb syringe or a device of parent choice may increase the comfort of breathing and support feeding in infants. Fever is an expected complication of bronchiolitis and may be treated with antipyretics. Caregivers should monitor comfort with breathing; if persistent retractions are present, patients are unable to feed, or they appear to have distress, they should be evaluated immediately for inpatient supportive care.

### Inpatient Management

Inpatient admission to the hospital should be considered for patients with hypoxia, defined as oxygen saturation less than 90% on room air, dehydration, or moderate to severe respiratory distress manifested by tachypnea for age, retractions, grunting, or concern for apnea. Nasal clearance for comfort, oxygen therapy for hypoxia, and nutritional support remain the foundational therapy for inpatient care. Although nasal suction has not been robustly compared with withholding nasal suction, it has become the standard of care in most hospitals. Deep suction is not recommended and may be associated with longer lengths of stay. Medications including albuterol, corticosteroids, and racemic epinephrine are not recommended. Nebulized hypertonic saline (3%) has been studied as a therapeutic agent with conflicting trial results. These studies have suffered from design variability both within the United States and internationally. Current evidence does not demonstrate a clear benefit for patients with bronchiolitis. Patients with concurrent dehydration should have volume replacement with isotonic fluids. Bronchiolitis has been described as an independent stimulus for antidiuretic hormone release, placing these patients at risk for inappropriate retention of free water and development of hyponatremia. Isotonic fluid should be used in these patients to decrease the risk of iatrogenic hyponatremia. Aggressive nutritional support should be initiated for infants with poor feeding; nasogastric support should be given to any patient who is not able to meet caloric goals. Oxygen should be administered to maintain saturations greater than 90%. Humidified high-flow nasal cannula (HHFNC) oxygen therapy is frequently used as a safe method of increased respiratory support for hospitalized patients with moderate to severe work of breathing. HHFNC uses blended, humidified, heated air and

oxygen at higher flow rates used with nonhumidified oxygen. Systemic reviews support HHFNC as safe and well tolerated, with decreased association of intubation in ICU patients. Which non-ICU patients with bronchiolitis will receive benefit remains unclear. There has been association of use of HHFNC with prolonged lengths of hospitalization and pausing of feeds. There is high variability in the use and interpretation of pulse oximetry in patients with bronchiolitis. Although pulse oximetry readings are instrumental in determining the need for admission, continuous monitoring has been associated with increased length of stay. Patients should be transitioned to intermittent monitoring as soon as possible, and providers should focus on the clinical course over transient variations in oximetry. Chest physiotherapy is not recommended when managing hospitalized patients with bronchiolitis. Antibiotic therapy should only be used if there is concern for a secondary bacterial infection. Secondary bacterial infections in mild to moderate bronchiolitis are rare, but severe bronchiolitis may have a higher percentage of bacterial co-infection.

### Complications

The most common complication of bronchiolitis is acute otitis media, which should be treated according to current guidelines. A small percentage of bronchiolitis patients will progress to respiratory failure requiring intensive care support and mechanical ventilation. These patients may represent a unique cohort with a higher incidence of preexisting comorbid conditions, coinfection from multiple viral agents, or bacterial superinfection. Mortality resulting from RSV in the United States is rare, accounting for fewer than 100 children annually, but worldwide bronchiolitis remains a significant contributor to pediatric mortality in resource-limited countries.

## DIABETES MELLITUS IN CHILDREN

Gregory Goodwin, MD

### CURRENT DIAGNOSIS

- Random glucose >200 mg/dL and symptoms (polyuria, polydipsia)
- Fasting glucose >126 mg/dL
- 2-h glucose >200 mg/dL after glucose tolerance test
- Hemoglobin A1c >6.5%
- Diabetic ketoacidosis: pH <7.3, serum bicarbonate <15 mmol/L

### CURRENT TREATMENT

#### Type 1 Diabetes

- Basal/bolus regimen<sup>\*\*</sup>: rapid-acting insulin<sup>\*</sup> before meals and long-acting insulin<sup>†‡</sup> at bedtime
- Insulin pump therapy<sup>\*\*</sup>: continuous infusion of short-acting insulin
- NPH insulin at breakfast and bedtime, rapid-acting insulin before meals
- Premixed insulins (75/25<sup>§</sup> 50/50<sup>§</sup>) at breakfast and dinner
- Total daily insulin dose (TDD): 0.15–1.2 U/kg per day
  - Basal/bolus: 50% long acting, 50% rapid acting
  - NPH/rapid acting: two-thirds TDD in a.m., one-third TDD in p.m.
  - a.m. and p.m. doses: two-thirds NPH, one-third rapid-acting
  - Premixed insulins: two-thirds a.m., one-third before dinner

#### Diabetic Ketoacidosis

- Fluids: 10–20 mL/kg normal saline once, repeat if shock/poor perfusion. Ongoing fluids: one-half normal saline with 20 mEq/L K acetate and 20 mEq/L K phosphate at 1.5–2.0 times maintenance fluids
- Regular insulin infusion: 0.05–0.1 U/kg per hour
- Add dextrose (5%–10%) when glucose is below 300 mg/dL
- Urgent consultation with center experienced in treatment of pediatric ketoacidosis (if not available on site)

#### Type 2 Diabetes

- Aggressive dietary modification: lower total carbohydrates to 25%–40% of total calories
- Metformin (Glucophage): 500–1000 mg bid, titrate up to avoid gastrointestinal side effects
- The first two items on this list plus insulin therapy: either as single long-acting insulin at bed or full basal bolus regimen until stable glucose control
- Glucagon-like peptide-1 (GLP-1) agonist in obese insulin-resistant pediatric patients above 10 years of age

<sup>\*\*</sup>Preferred treatment.

<sup>\*</sup>Rapid-acting insulin: lispro (Humalog, Admelog), aspart (Novolog, Fiasp), glulisine (Apidra).

<sup>‡</sup>75% intermediate-acting insulin, 25% rapid-acting insulin (Humalog 75/25).

<sup>†</sup>Long-acting insulin: glargine (Lantus, Toujeo, Basaglar), detemir (Levemir), degludec (Tresiba).

<sup>§</sup>50% intermediate-acting insulin, 50% rapid-acting insulin (Humalog 50/50).

### Type 1 Diabetes: Introduction

Type 1 diabetes mellitus (T1DM) results from progressive autoimmune destruction of insulin-producing cells ( $\beta$  cells) of the pancreatic islets, ultimately leading to insulin deficiency and resulting in hyperglycemia and in some cases ketoacidosis.

The precise cause or causes of T1DM remains elusive, but an association with human lymphocytic antigens (HLAs) has been known for decades. Whole genomewide linkage studies have identified up to 60 genes associated with T1DM, and many are related to the immune response. However, identical twin studies show a concordance rate of only 30% to 60%, suggesting that unidentified environmental factors make up the remaining risk. Environmental factors implicated in T1DM risk include viral infections, toxins (nitrosamines), and dietary factors such as exposure to cow's milk and gluten-containing cereals in early infancy. However, recent prospective studies have shown no advantage of using elemental formulas or delaying the introduction of gluten until 1 year of life in infants at increased risk for development of T1DM. A large meta-analysis of 24 studies of over 4000 participants showed an almost 10-fold risk of reverse transcription polymerase chain reaction (RT-PCR)-determined enteroviral infections in T1DM patients versus controls, whereas the TEDDY study showed an almost 50% conversion of high-risk infants and children to expressing islet cell antibodies when more than five respiratory infections in the preceding 9 months were reported.

## Epidemiology

The prevalence of T1DM is about 1 per 300 individuals (0.3%) in the United States, with significant global and racial variations. The presence of a first-degree relative with T1DM, such as a sibling or parent, increases the chances of developing T1DM to 3% to 6%.

The highest incidence rates of T1DM in children are seen in early adolescence (10–14 years), followed by early childhood (5–9 years). The youngest age of onset of T1DM can be seen in infants below 1 year of age, but usually not before 6 months.

The incidence of T1DM has been increasing steadily by 2% to 5% per year over the past several decades in the United States, Europe, and Australia. Interestingly, in some but not all studies, the youngest age group (0–4 years) demonstrates the highest rates of increase.

The onset of T1DM is seasonal. In the northern hemisphere, the highest incidence of onset is in the fall and winter and the fewest are in the summer.

## Presentation

The classic symptoms of diabetes are polyuria, polydipsia, and nocturia, which is the result of an osmotic diuresis induced by hyperglycemia. Symptoms can be present for days to months, but the majority of patients present after 1 to 2 weeks of symptoms. Weight loss is a common finding on presentation because insulin plays an important role in the synthesis of protein and fat; therefore insulin deficiency results in the loss of muscle and fat stores. Weight loss also occurs because calorie loss from high concentrations of glucose in the urine can be substantial.

Abdominal pain, nausea, and vomiting are classic signs of ketoacidosis that can often be misdiagnosed as gastroenteritis. Approximately 70% of patients with new-onset diabetes have hyperglycemia without ketoacidosis at presentation, whereas some 25% to 30% of cases present in diabetic ketoacidosis (DKA), although there can be significant variations from various centers internationally.

## Diagnosis

A random glucose greater than 200 mg/dL in the presence of classic symptoms of diabetes is diagnostic of diabetes. A fasting glucose greater than 126 mg/dL is also diagnostic of diabetes; however, a fasting glucose or a glucose tolerance test is rarely necessary in the diagnosis of T1DM.

A venous pH below 7.3 or a serum bicarbonate below 15 mmol/L is diagnostic of DKA in the presence of hyperglycemia. Distinguishing type 1 from type 2 diabetes can sometimes be difficult at presentation, particularly in an overweight adolescent. In this circumstance islet cell autoantibodies are useful in making this distinction. Islet cell autoantibodies include anti-glutamic acid decarboxylase (GAD), anti-insulin, anti-insulinoma autoantigen 2 (IA-2), and anti-zinc transporter 8 (ZnT8). These antibodies are available in most commercial laboratories, but results are usually not available until weeks after initial presentation. The safest course of action in most pediatric patients with new-onset diabetes is to treat with insulin until islet antibodies and other parameters such as endogenous insulin production as assessed by c-peptide levels are available.

## Treatment of Type 1 Diabetes Mellitus

### Type 1 Diabetes Mellitus (Without Ketoacidosis or After Ketoacidosis Has Resolved)

Insulin is the mainstay of treatment for T1DM. Intensive insulin therapy has become the standard of care for patients with T1DM. Typically a long-acting basal insulin—such as glargine (Lantus, Toujeo, Basaglar), detemir (Levemir), or degludec (Tresiba)—along with premeal boluses of rapid-acting insulin—such as lispro (Humalog, Admelog), aspart (NovoLog, Fiasp), or glulisine (Apidra)—is instituted.

Required total daily insulin dosing (TDD) is dependent on age at presentation, pubertal stage, and the presence of acidosis at diagnosis. Total daily insulin requirements range from about 0.25 to 1.0 U/kg per day (Table 1). Long-acting or basal insulin is typically 50% of TDD; the remaining 50% is bolus insulin. Bolus rapid-acting insulin dosing is calculated by the following formulas (Fig. 1):

**TABLE 1** Suggested Total Daily Insulin Dosage in New-Onset Type 1 Diabetes

PATIENT CATEGORY	INSULIN DOSE (U/KG PER DAY)
Prepubertal without DKA	0.25–0.5 (<6 years, 0.15–0.25)
Prepubertal with DKA	0.5–0.75
Pubertal without DKA	0.5–0.75
Pubertal with DKA	0.75–1.2

DKA, Diabetic ketoacidosis.

### Patient Example 1

- 6 y.o. girl presents with 2 week history of polydipsia and polyuria.
- She is otherwise well with a normal exam.
- Serum glucose in the ER is 425 mg/dl and serum bicarbonate is 20.
- Weight in the ER: 20 kg.
- Total daily insulin = 20 kg X 0.3 u/kg/d = 6 units.
- 50% basal = 3.0 units (glargine, degludec)
- Target = 150
- Carbohydrate ratio: 500/6 = 83–80
- Correction factor: 1500/6 = 250

**Figure 1** New-onset type 1 diabetes in a 6-year-old girl who is not in diabetic ketoacidosis (DKA). Total daily insulin dosage is determined by multiplying body weight by recommended dosage requirements for a prepubertal girl who is not in DKA. One-half of the total daily insulin dose is given as long-acting insulin, which is 3.0 units in this example. Carbohydrate ratio and correction factors are calculated using formulas provided in the text. Calculated ratios can be adjusted up to 10% to simplify calculations.

To cover meal carbohydrates, a *carbohydrate ratio* is derived from the formula

500 divided by total daily insulin dose

To correct hyperglycemia, a *correction factor* is derived from the formula

1500 divided by total daily insulin dose

Correction doses should not be given more frequently than every 3 hours.

For new-onset patients, a *target glucose* of 150 mg/dL is assigned, whereas more established patients typically use 120 mg/dL. Correction at bedtime or during the night should be less aggressive and a higher target may be assigned—for example, 150 to 200 mg/dL.

Carbohydrate ratios, correction factors, and targets are adjusted on the basis of fasting and postprandial glucose levels. High postprandial glucose levels would require a lower carbohydrate ratio. High blood glucose levels that do not correct after a correction dose has been given would require a lowering of the correction factor. High morning fasting glucose levels would require an increase in the long-acting insulin dose.

Implicit in these recommended treatment regimen is that (1) the patient or family is able to count carbohydrates correctly, and (2) the family is able to calculate insulin dosing correctly using the carbohydrate ratio, correction factor, and target. If the patient or family is unable or unwilling to perform these calculations a simplified insulin regimen should be devised using fixed doses of intermediate-acting insulin and a sliding scale of rapid-acting insulin.

Less complex insulin regimens include NPH and rapid-acting insulin given at breakfast, dinner, and bedtime (Fig. 2). NPH and rapid-acting insulin are given at breakfast (no insulin at lunch if glucose <200 mg/dL), rapid-acting insulin at dinner, and NPH at bedtime. This regimen can be used to avoid giving insulin at lunchtime. Typically, two-thirds of the daily dose is given in the morning; then two-thirds NPH, one-third rapid-acting insulin, and one-third of the daily dose is given in evening. The evening dose is divided, with one-third rapid-acting before dinner and two-thirds NPH at bedtime. The patient should, however, consume a relatively fixed amount of carbohydrate at each meal. Consistency in meal content and portion size is very important in overall glycemic control. A simplified sliding scale of rapid-acting insulin may be added to the NPH and rapid-acting insulin regimen.

**Patient Example 2**

- 8 y.o. boy—2 week history of polydipsia, polyuria and vomiting for for the past 24 hours.
  - In doctors office: glucose 380 mg/dl and urine ketones are large.
  - In emergency room serum HCO<sub>3</sub><sup>-</sup> 9, anion gap 25.
  - Admitted to ICU for insulin drip, IV fluids, and frequent monitoring.
  - At 7 am the following morning: glucose 120, HCO<sub>3</sub><sup>-</sup> 20.
  - Weight: 25
  - Family would like to avoid insulin at lunch as school nurse not available.
- Total daily dose:  $0.6 \times 25 \text{ kg} = 15$  units
  - 2/3 am = 10 units
    - 2/3 NPH ~ 6.5 units
    - 1/3 rapid acting 3.5 units
  - 1/3 pm = 5 units
    - 1/3 rapid acting ~ 1.5 units before dinner
    - 2/3 NPH 3.5 units at bedtime
  - Supplement with sliding scale: 0.5 unit rapid-acting insulin per 50 mg/dl above 200 mg/dl.

**Figure 2** An 8-year-old boy who presented in diabetic ketoacidosis. He was treated with an insulin drip overnight and his acidosis had resolved by morning. The parents requested a regimen that would not require insulin at lunch time. The total daily insulin dose is shown in Table 1.

**Patient Example 3**

- 14 y.o. boy with cognitive delays presents with 3-week history of polydipsia and polyuria and 10 lb weight loss.
  - Glucose 625 mg/dl in ER
  - Bicarbonate 19 meq/L
  - Tanner 4 on exam
  - Weight 44 kg
  - Parents also have cognitive impairments
- Total daily dose:  $44 \text{ kg} \times 0.6 \text{ u/kg/d} = 26.4$  units per day.
  - Medical team decides fixed mixed 75/25 insulin regimen may be best.
  - 2/3 TDD given before breakfast = 17 units
  - 1/3 before dinner = 9 units
  - Sliding scale rapid acting: 1 unit per 50 mg/dl over 200 mg/dl.

**Figure 3** A 14-year-old boy with intellectual impairments presents with new-onset type 1 diabetes without diabetic ketoacidosis. Because of cognitive delays in both the patient and his parents, a simplified two-injection regimen was derived using the previously described calculations. This regimen may be supplemented with a sliding scale of rapid-acting insulin.

In certain challenging cases where there are significant compliance or cognitive deficits, fixed doses of premixed intermediate- and rapid- or short-acting insulin such as Humalog mix (75/25) can be used before breakfast and before dinner (Fig. 3). Premixed 75/25 insulin preparations come in vials or pens and consist of 75% intermediate-acting neutral protamine hagedorn; (NPH) and 25% rapid-acting (lispro) insulins. Insulin pens are a very convenient way to give insulin, but in some cases, because of patient preference or insurer restrictions, dosing by syringe is preferred or required.

**Treatment of Diabetic Ketoacidosis**

There are critical differences in the treatment of DKA between children and adults. A major complication of the treatment of DKA in children is cerebral edema, a complication rarely seen in adults. Although a relatively infrequent complication (<1% of DKA episodes), cerebral edema can be associated with serious morbidity and mortality.

Risk factors for the development of cerebral edema include new-onset diabetes, younger age at diagnosis, longer duration of symptoms before diagnosis, and severity of acidosis—manifested as DKA with hypocapnia, high blood urea nitrogen, bicarbonate boluses, and failure for the corrected serum sodium to rise as treatment for DKA progresses. For these reasons, overly aggressive fluid resuscitation and boluses of bicarbonate are avoided in the treatment of pediatric DKA.

Judicious fluid replacement with a bolus of normal saline—initially 10 mL/kg and, if necessary, a second 10-mL/kg bolus of saline solution—may be given in the first hour of treatment. Thereafter half normal saline with 40 mEq/L of potassium acetate or potassium phosphate at a fluid rate of no more than 1.5 to 2.0 times maintenance is administered (Table 2). Potassium should not be added to intravenous fluid until the K is <5 meq/L. The two-bag system for fluid management of DKA—in which two bags contain identical

**TABLE 2** Formulas for the Calculation of Maintenance Fluids for Infants and Children

For infants 3.5–10 kg, daily fluid requirement = 100 mL/kg

For children 11–20 kg, daily fluid requirement = 1000 mL + 50 mL/kg for every kg over 10 years of age

For children >20 kg, daily fluid requirement = 1500 mL + 20 mL/kg for every kg over 20, up to a maximum of 2400 mL daily

electrolytes but differ in that one bag contains no dextrose and the second bag contains 10% dextrose—can be useful. The relative contribution of each bag is then titrated depending on the blood glucose level. Although estimates of fluid deficit in DKA are between 5% and 10% of body weight, intravascular volume is often preserved in the hyperosmolar state; hence hypovolemic shock is uncommon in DKA. The goal is to replace the fluid deficit slowly over 24 to 48 hours. Frequent neurologic checks are highly recommended in the first 24 hours of treatment. Altered mental status or the development of a severe headache during treatment for DKA is a potentially serious sign of cerebral edema.

Insulin plays a critical role in the treatment of DKA, not only in lowering serum glucose levels but also in the paramount role of shutting down ketogenesis in the liver. The standard insulin drip for pediatric DKA is 0.1 U/kg per hour; however, treatment with 0.05 U/kg per hour has also been effective. Human regular insulin remains the standard insulin in the intravenous treatment of DKA.

Once the acidosis has resolved, as reflected by a normal anion gap and serum bicarbonate greater than 15 mmol/L and pH greater than 7.35, the insulin drip can be discontinued. Hyperchloremic non-anion gap acidosis (HCO<sub>3</sub><sup>-</sup> <15 but normal anion gap <12) can occur during the recovery phase of DKA. Hyperchloremic metabolic acidosis is likely due to a large amount of chloride administered in intravenous fluids as both NaCl and KCL supplementation. For this reason many centers typically give 50% of the potassium replacement as potassium phosphate. Once the acidosis is resolved and the patient can tolerate oral intake, subcutaneous insulin can be started per the section, Treatment of Type 1 Diabetes Mellitus, earlier in this chapter. The most convenient time to do so is just before a meal.

Importantly, treatment of pediatric DKA should ideally occur in centers with experienced pediatric intensivists, endocrinologists, and nursing staff. If referral to a pediatric center is not practical, then early contact with a pediatric endocrinologist for treatment guidance is highly recommended.

Finally, the most common causes of pediatric DKA are (1) new-onset diabetes presenting in DKA and (2) infusion site failure in a patient on an insulin pump or missed long-acting insulin injections in a patient on insulin injections. Infections including gastroenteritis and febrile illnesses are infrequently the exclusive cause of DKA in pediatrics.

**Diabetes Self-Management Education**

Children and adolescents with type 1 diabetes should receive outpatient care by multidisciplinary teams including an endocrinologist, certified diabetes educator, nurse, registered dietician, and licensed clinical social worker. Provision of comprehensive education at the time of diagnosis is essential because this is the time when the patient and family are most receptive and impressionable. Patients who do not receive proper early education often fall into habits of suboptimal diabetes care, which can be hard to undo once established.

Important educational topics that must be rapidly learned by the family and patient (in addition to glucose monitoring and insulin administration) include diet and carbohydrate counting, prevention and treatment of hypoglycemia, emergency glucagon, exercise and hypoglycemia, prevention of ketoacidosis, and sick day management. Learning to count carbohydrates accurately can be a particular challenge.

### Mental Health Considerations in Type 1 Diabetes Mellitus

Diabetes “burnout” issues are common in the treatment of youth with diabetes, particularly during the adolescent years. Conflicts between parents and teens can often arise during this time. It is important for the parents to maintain a healthy supporting role with their child or teenager in a manner appropriate to the child’s age and level of development. Recognition of relatively common mental health comorbidities—such as depression, anxiety, and eating disorders—is essential to the overall well-being of the pediatric patient with T1DM.

### Goals of Therapy for Patients With Type 1 Diabetes Mellitus

The number-one goal of the diabetes health care team is to prevent readmission to the hospital for severe hypoglycemia or ketoacidosis. Resumption of the full range of daily activities, including returning to school and work as well as engaging in essentially all meaningful activities that preceded the diagnosis of diabetes, is to be expected.

Although the goal in the pediatric age group is to reduce hemoglobin A1c to below 7.5%, less than 25% of pediatric patients in the United States are able to achieve that goal. The average hemoglobin A1c in the pediatric population is approximately 8.2%, whereas in 19-year-olds the average hemoglobin A1c is 9.2%.

The Diabetes Control and Complications Trial (DCCT) in 1993 showed convincingly that lowering the hemoglobin A1c from 9% to 7.1% resulted in significantly less diabetes-related retinopathy, nephropathy, and neuropathy. Most patients in the DCCT trial who were randomized to the intensively treated group used insulin pumps to achieve tighter control, but tight control was achieved with injectable insulin regimens as well.

### Sick Day Management

Patients with T1DM who have intercurrent infectious illnesses are prone to develop hyperglycemia with ketosis and also hypoglycemia, depending on the nature of the illness. Blood glucose levels should be monitored every 1 to 3 hours during illnesses. Rapid-acting insulin may need to be administered every 2 to 4 hours for hyperglycemia, especially in the presence of serum or urine ketones. Rapid-acting insulin can be dosed at 0.1 to 0.2 U/kg per dose in this setting. Improvement in hyperglycemia and particularly in ketosis using this treatment regimen can be invaluable in preventing ketoacidosis or hospitalization. Patients with persistent vomiting who are unable to keep fluids down need to be referred to the emergency department for intravenous hydration and assessment for DKA.

For patients on an insulin pump, ketosis with nausea and vomiting is often a sign that the insulin infusion set is not properly functioning. Insulin therefore should be given by syringe or pen device until the ketones have cleared and a new infusion set has been placed.

Poor oral intake during a gastrointestinal illness may result in hypoglycemia. Frequent small volumes of sugar-containing fluids such as juice or sports drinks may be necessary to keep the blood glucose above 70 mg/dL, and basal insulin requirements may need to be decreased by 10% to 50%. Low-dose glucagon may be used in the setting of recurrent hypoglycemia and poor oral intake. Glucagon can be dosed at 1 unit on an insulin syringe for every year of age, using a standard 1-mg/mL glucagon preparation. The dose may be repeated every 15 minutes as needed. In some cases, persistent low glucose levels (<70 mg/dL) in the setting of recurrent vomiting may be best managed in an emergency department or hospital setting where intravenous dextrose-containing fluids are readily available.

### Risk for Additional Autoimmune Disorders

Patients with one autoimmune disorder are at increased risk for the development of one or more additional autoimmune conditions. Children and adolescents with T1DM are particularly at risk for thyroid and celiac disorders. Screening for thyroid disorders with serum TSH and free T<sub>4</sub> should occur in the first 6 months after the T1DM diagnosis and every 1 to 2 years thereafter. Celiac

disorder should also be screened in the first year after the T1DM diagnosis. Most cases of celiac disorder are detected within the first 5 years after the diagnosis of T1DM, and the majority of cases are asymptomatic. Recent American Diabetes Association recommendations include screening for celiac disorder at diagnosis and again at 2 and 5 years after diagnosis. Elevated serum tissue transglutaminase levels should be referred to a pediatric gastroenterologist. Because celiac disorder is a lifelong condition, it is advised to obtain a small bowel biopsy. Autoimmune adrenal (Addison) disease rarely occurs with T1DM but has the unique presentation of recurrent hypoglycemia, necessitating significant reductions in daily insulin requirements. Sending simultaneous adrenocorticotrophic hormone and cortisol levels on a morning blood specimen will usually render the diagnosis of Addison disease.

### Screening for Complications of Type 1 Diabetes Mellitus

Microvascular complications of T1DM are infrequent in the pediatric age group, although background retinopathy and microalbuminuria become more prevalent in the late-adolescent and young-adult age ranges. Proactive early screening regimens are advocated to detect diabetes complications early so that medical interventions can prevent more serious diabetes-related complications such as proliferative retinopathy and end-stage renal disease.

Annual screening for microalbuminuria with a random urine specimen should be performed at puberty or at age 10 years and above once the child has had diabetes for 5 years. Elevated urine albumin/urine creatinine (>30 mg/g creatinine) ratios should be repeated two to three times over a 6-month period to confirm the diagnosis because transient microalbuminuria is a common finding. Variables such as exercise or recent illness can lead to microalbuminuria; therefore a repeat study after recovery and on a first morning specimen will often yield a normal result. In addition, individuals with the benign condition of orthostatic albuminuria can be identified by finding completely normal albumin excretion on a first morning voided specimen, whereas a random specimen will often be frankly proteinuric. When urinary albumin/creatinine ratios are found to be consistently elevated, treatment with an angiotensin converting enzyme inhibitor is recommended. Referral to a pediatric nephrologist should be arranged in complex cases.

Annual dilated eye examinations are recommended after age 10 or at pubertal onset (whichever comes first) once the patient has had diabetes for 3 to 5 years. Referral to an eye care professional with expertise in diabetic retinopathy is recommended.

Cardiovascular risk factors including blood pressure and lipid profiles should be monitored in patients with T1DM. Blood pressure should be obtained at each visit.

High blood pressure is defined as systolic or diastolic blood pressure above the 90th percentile, and hypertension is defined as above the 95th percentile for age, sex, and height. Blood pressure measurements should be obtained using an appropriate cuff size, particularly in the overweight patient. White-coat hypertension can be problematic in the adolescent population. Such patients will often demonstrate an elevated heart rate as a clue to stress-induced hypertension. Monitoring blood pressure in a nonthreatening environment, such as at home, using an accurate home blood pressure monitor, may be helpful. When white-coat hypertension is suspected, 24-hour home blood pressure monitoring can be very useful.

Initial management of high blood pressure includes salt restriction and weight-control measures. For persistent hypertension, treatment with an antihypertensive medication (lisinopril) may be necessary.

Shortly after diagnosis and once glucose control has been established, it is important to obtain nonfasting total and high-density lipoprotein cholesterol readings. If total cholesterol is high, a fasting morning lipid panel should be obtained. If low-density lipoprotein (LDL) cholesterol is below 100, it would be reasonable to repeat it in 5 years. For LDL cholesterol above

100, dietary measures are taken, along with efforts to improve metabolic control. For patients beyond 10 years of age with an LDL cholesterol above 130 to 160 in whom lifestyle changes have resulted in inadequate control, statin therapy may be considered. Referral to a pediatric preventive cardiology program would also be appropriate.

### Technologic Changes in the Care for Patients With Type 1 Diabetes Mellitus

Technological changes have revolutionized the care of patients with T1DM. Unheralded changes such as the emergence of ultrafine lancet technology coupled with glucose test strips requiring less than 10  $\mu\text{L}$  of blood resulted in rapid, essentially painless fingerstick glucose monitoring. Ultrafine insulin syringes and pen needles helped usher in widespread adoption of intensive insulin regimens with rapid-acting insulin taken before all meals and snacks.

The insulin pump further advanced diabetes care in making insulin dosing before meals and snacks even less challenging, especially for children. The development of a tubeless insulin pump (Omnipod) led to an even wider array of choices.

Continuous glucose monitoring (CGM) has evolved into a very powerful and widely used technology in T1DM. Subcutaneous fluid glucose levels are determined every 5 minutes and the user is provided with meaningful feedback to influence diabetes self-management decisions in real time. Particularly useful are alarm functions for impending low glucose levels; these can be invaluable in the prevention of hypoglycemia. Alarms for hyperglycemia are also used with this technology. The accuracy of glucose determinations by CGM technology is now approaching subcutaneous blood glucose technology, and the improved accuracy has led the US Food and Drug Administration (FDA) to approve insulin-dosing decisions based on CGM data (e.g., the Dexcom G6 products). It is important to remember, however, that subcutaneous glucose levels lag behind whole blood glucose levels by about 15 minutes. This fact is particularly important when glucose levels are changing rapidly, so the user is advised to pay attention to the glucose trend. Alarms for predicting hypoglycemia are very important in this regard.

A drawback to CGM technology had been the need to calibrate the device accurately with periodic fingerstick glucose checks. However, the Dexcom G6, which was released to market in 2018, and the Abbot Libre, are factory-calibrated and do not require consumer calibration. Remarkably, patients using calibration-free CGM devices may no longer be required to check fingerstick glucose levels! A CGM sensor placed on the arm or abdomen will last for 10 to 14 days before having to be changed.

The most remarkable technologic change emerging in the care of patients with T1DM is the coupling of CGM and real-time adjustments to insulin delivery. Thus insulin delivery is suspended when hypoglycemia has occurred or is likely to occur, and basal insulin can be significantly increased when hyperglycemia is predicted to occur or has occurred. *Hybrid closed-loop* refers to the fact that some aspects of management, such as carbohydrate counting and manual bolusing for meals, are still required. The first hybrid closed-loop insulin pump was FDA approved in 2016 (Medtronic 670G). Prevention of postprandial hyperglycemia is particularly problematic, but prebolusing rapid-acting insulin 10 to 30 minutes before eating will help to limit postprandial hyperglycemia. Prebolusing of insulin is often difficult in view of modern lifestyles. Use of the Medtronic 670G insulin pump has proven to be challenging in the real-world setting due to frequent calibration requirements and forced exits from the automatic insulin delivery mode. The Tandem insulin pump with Control IQ technology was FDA approved in 2019. This hybrid closed-loop system is user friendly, with no calibration requirements or forced exits from automated insulin delivery. Hybrid closed-loop technology can be particularly useful for optimizing glycemic control

overnight, the time when many patients and families are most fearful of hypoglycemia. Despite the remarkable technological achievements of hybrid closed-loop technology, actual improvements in hemoglobin A1c are modest and are on the order of 0.2% to 0.3% lower hemoglobin A1c. Additional hybrid closed-loop systems are currently in clinical trials or awaiting FDA approval (Omnipod Horizon, Beta Bionic iLet). The community of patients with diabetes can look forward to further refinements and improvements in these technologies in the years to come.

### Type 2 Diabetes in Children

Since the 1990s, type 2 diabetes mellitus (T2DM) in patients below 18 years of age has risen dramatically. The increased incidence of type 2 diabetes has coincided with the obesity epidemic. Children from minority populations (non-Hispanic blacks, Hispanics, and Native Americans) and those patients with a positive family history of T2DM are at the greatest risk. The majority of pediatric T2DM is found in adolescents and children above 10 years of age.

Diagnosis of T2DM can be made with a fasting glucose above 126 mg/dL, random glucose above 200 mg/dL, and the 2-hour glucose from an oral glucose tolerance test above 200 mg/dL. A hemoglobin A1c greater than 6.5% is indicative of diabetes as well and is a particularly convenient test in the outpatient setting. An elevated fasting or random glucose and an elevated hemoglobin A1c are diagnostic of T2DM in high-risk patients.

Pediatric patients with T2DM are often symptom free at diagnosis but can present acutely with classic diabetes symptoms and even ketosis or mild ketoacidosis. Distinguishing the latter group from T1DM can be difficult initially, but the absence of  $\beta$  cell antibodies and very stable glycemic control after diagnosis are often telltale signs of T2DM.

In individuals who present with marked hyperglycemia (hemoglobin A1c  $>8.5\%$ ), ketosis, or both, stabilization with insulin initially may be required. Basal bolus regimens using a combination of long- and short-acting insulins can be instituted. Insulin resistance may be quite significant at the time of diagnosis, and relatively high doses of insulin can be required to achieve target glucose levels.

Metformin (Glucophage) is the mainstay of treatment for T2DM in those below 18 years of age. Maximal dosing is 1000 mg bid or 2000 mg/day of the extended-release preparation. Gastrointestinal side effects are relatively common, and metformin should be taken with meals. Initial dosing can be 500 mg bid or 1000 mg extended-release daily; the dose can be titrated upward as needed and tolerated. **Dietary modifications such as weight control and exercise are of fundamental importance in the treatment of T2DM.** Liraglutide (Victoza), a glucagon-like peptide (GLP-1) agonist, was FDA approved in 2019 for the treatment of T2DM for patients above 10 years of age. GLP-1 agonists are associated with early satiety, weight loss, and improved glycemic control in adults with T2DM; however, side effects such as nausea are common, and an increased risk of pancreatitis is well recognized. Adherence to a healthy diet in combination with metformin alone, insulin therapy, or both often results in very stable glycemic control in T2DM in pediatrics. In many cases, bolus short-acting insulin and even long-acting insulin therapy can be withdrawn safely 6 to 12 months after diagnosis. However, resumption of lax dietary and self-care habits can result in significant decline in glycemic control and the need to restart insulin. Therefore patients with T2DM need to be as vigilant as patients with T1DM, in monitoring their glucose levels regularly and following up every 3 to 6 months with their healthcare teams.

### Monogenic or Maturity-Onset Diabetes of Youth

Single gene mutations leading to diabetes are referred to as *maturity onset diabetes of youth (MODY) diabetes* or *monogenic diabetes*. More than 30 different genes have been

identified that are associated with MODY, although some 80% of cases are due to glucokinase and *HNF1A* and *HNF1B* gene mutations. Patients can be diagnosed at any age but are usually diagnosed before age 35 years. Routine laboratory testing or laboratory testing during an illness may lead to the detection of MODY diabetes incidentally. Patients with MODY are often lean, and the family history may reveal two to three affected generations. Testing for islet cell antibodies is universally negative.

Glucokinase diabetes is a very mild form of MODY diabetes that is nonprogressive and does not require treatment, whereas *HNF1A* and *HNF1B* forms of MODY diabetes are progressive; these patients can develop long-term complications of diabetes. HNF diabetes is uniquely sensitive to sulfonylureas, and hence the diagnosis can be life changing in an individual who has been treated with insulin prior to definitive diagnosis.

Genetic panels for MODY diabetes are available commercially, and genetic testing is increasingly covered by insurance companies in the United States. It is important to test for both mutations and deletions of the most common forms of MODY. A full list of laboratories that offer MODY testing is available at the NCBI Genetic Testing Registry (<http://www.ncbi.nlm.nih.gov/gtr/>).

Neonatal diabetes can also be due to monogenic forms of diabetes, and these infants are usually diagnosed before 6 to 9 months of age. Testing for monogenic forms of diabetes should be considered in infants below 9 to 12 months of age whose islet cell autoantibodies are negative. Single gene mutations in the K-ATP channel of the  $\beta$  cell leading to neonatal diabetes can be remarkably responsive to oral sulfonylureas. Transient forms of neonatal diabetes in an infant born with intrauterine growth retardation and macroglossia are often associated with imprinting abnormalities on chromosome region 6q24. This type of diabetes usually resolves by 18 months but can recur at adolescence.

## ENCOPRESIS

Method of  
Sarah Houssayni, MD

### CURRENT DIAGNOSIS

- Voluntary or involuntary passage of stools into inappropriate places at least once a month for 3 consecutive months once a chronologic or developmental age of 4 years has been reached.
- Encopresis can be primary when it persists from infancy onward or secondary when it appears after toilet training.
- The behavior is not due to the direct effects of a substance such as a laxative or a general medical condition except those associated with constipation.
- Distinguishing subtypes is essential because treatment differs:
  - Retentive encopresis: occurs as a result of involuntary leakage of liquid stools due to severe constipation and impaction.
  - Nonretentive encopresis: children pass bowel movements into their underwear due to their refusal to use the toilet.
  - Children occasionally fail to wipe after bowel movements and the secondary soiling should be distinguished from encopresis.

### CURRENT THERAPY

#### Retentive Encopresis

##### Initial Disimpaction

- Hyperphosphate enemas (Pedia-Lax Enema) (one daily for 2 or 3 days):
  - Less than 1 year old: 60mL.<sup>3</sup>
  - Greater than 1 year old: 6mL/kg, up to 135mL twice.<sup>3</sup>
- Glycerin suppositories (Glycerin Pediatric Suppositories) for infants and toddlers.

##### Older Children—Slow Disimpaction

- Polyethylene glycol with electrolytes (Golytely, Colyte)<sup>1</sup> ingested over 2–3 days: 25mL/kg/hr up to 1L/hr until stooling clear bowel movements. (This is not approved for bowel cleansing for children.)
- Over 5–7 days:
  - Mineral oil<sup>1</sup> 3mL/kg twice a day for 1 week. (Mineral oil is not approved for use in children younger than 6 years of age.)
  - Lactulose<sup>1</sup> 2mL/kg twice a day for 1 week.
  - Magnesium hydroxide (Milk of Magnesia) 2mL/kg twice a day for 1 week.
  - Polyethylene glycol without electrolyte (MiraLax)<sup>1</sup> 1.5g/kg/day for 3 days.

##### Maintenance Therapy

- Polyethylene glycol 3350 (MiraLax)<sup>1</sup> age greater than 1 month: 0.7g/kg divided into 1–2 doses daily.
- Lactulose or sorbitol 70% solution age greater than 1 month: 1–3mL/kg/day divided into 1–2 doses daily for 1–3 months.
- Sennosides (Senna, Senna-GRX, Senexon) are habit forming, doses vary greatly in the different available formulations, and they can only be used for short-term treatment. Give at bedtime for a morning bowel movement. Dose is 5mL (1 tablet) for 1–1 to 5-year-olds and 2 tablets for 5- to 15-year-olds for a maximum of three tablets daily. (Sennosides are not approved for use in children younger than 2 years of age.)
- Glycerin enemas and bisacodyl suppositories (Dulcolax) can be used for short-term constipation treatment.

- Glycerin/saline enema in patients greater than 10 years of age: 20–30mL/day (solution of 1/2 glycerin and 1/2 normal saline).
- Bisacodyl suppositories in patients greater than 10 years of age: 10mg daily.

#### Nonretentive Encopresis

- **NO** medical treatment.
- Clean up soiling immediately, involve the child.
- Ensure adequate water and dietary fiber intake.
- Avoid use of stool softeners and laxatives.
- **STOP** all reminders, make child responsible for own toilet habits.
- Use rewards when child defecates in toilet.
- Refer to health care professional when refractory (refuses to sit on toilet and older than 5 years of age, refuses to take medication, is older than 8 years of age with nonretentive encopresis).

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Exceeds dosage recommended by the manufacturer; manufacturer-recommended doses are: 5–11 y, 1 bottle (60 mL); 2–4 y, half bottle (30 mL); <2 y, do not use.

Encopresis is the voluntary or involuntary passage of stools at least once a month for 3 consecutive months once a chronologic or developmental age of 4 years has been reached. Encopresis is classified as primary when it persists from infancy onward or secondary when it appears after toilet training. Retentive encopresis occurs as a result of involuntary leakage of liquid stools due to severe constipation and fecal impaction. Nonretentive encopresis occurs in children who pass stool into their underwear due to their refusal to use the toilet. It is important to distinguish between the types of encopresis, because treatment differs.

#### Epidemiology

The prevalence of encopresis is reported to be 4% in 5- to 6-year-olds and 1.5% in 11- to 12-year-olds. Affected boys outnumber girls by a factor of anywhere from 3:1 to 5:1 depending on the source. Encopresis tends to decrease with age. A large number of children with encopresis go unreported due to the shame associated with the condition and underdiagnosis of the condition.

#### Diagnosis

The diagnosis of encopresis includes the following four criteria: (1) Repeated passage of feces into inappropriate places such as in clothing or on the floor, whether intentional or involuntary. (2) At least one event a month for at least 3 months. (3) A chronologic age of at least 4 years or an equivalent developmental level. (4) The behavior is not due exclusively to the direct physiologic effects of a substance such as a laxative or a general medical condition other than constipation.

#### Differential Diagnosis

Retentive encopresis is organic in less than 5% of the affected patients. Organic causes include hypothyroidism, hypercalcemia, cerebral palsy, abnormal anatomy of the anus, Hirschsprung's disease, cystic fibrosis, and neuropathy with secondary impaired voiding sensation. Spinal cord conditions such as tethered cord, spina bifida occulta, and spinal cord dysplasia affect stooling through diminished bowel sensation and secondary fecal retention.

#### Pathophysiology

Patients who are severely constipated hold stools back because of the pain associated with defecation. This becomes a vicious cycle of constipation, rectal dilation, and secondary encopresis. Frequently, emotional problems emerge due to the fear and shame

associated with the problem. Control issues with parents trying to take the stooling issues at hand may worsen the constipation problem.

From 10% to 20% of encopretic patients are not constipated. They are frequently preschoolers or school-age children who are postponing their bowel movements too long because they are distracted or because they associate the bathroom with an unpleasant experience (i.e., fear or disgust).

#### Clinical Manifestations

##### History

The history should assess for size and consistency of stools, as well as stooling intervals. Families often confuse soiling with stooling, leading to inaccurate reporting of the frequency of bowel movements. Characteristic symptoms of retentive and nonretentive encopresis differ (Table 1).

In retentive encopresis the physician may elicit a history of difficult or painful defecation, crying with bowel movements, and posturing that suggests the child is deliberately holding back stools due to the pain associated with passage.

Children may suddenly become still or hide during play, cross their legs, grimace, or shift their position in an attempt to retain stools. The physician should assess for a history of enuresis and urinary tract infections, anorexia, sensations of bloating, fullness, and abdominal pain leading to the patient's avoidance of food and weight loss. Obtain a dietary history including fiber, fluid, and dairy intake. The historian needs to inquire about streaks of blood on toilet paper and underwear. With retentive encopresis, when the child does pass stool, it may be of large caliber and hard, indicative of constipation.

With nonretentive encopresis, the history often reveals bowel movements of normal size and consistency passed into the underwear once or twice a day. Symptoms of constipation are usually absent. A history of behavioral problems, child-parent struggles, and history of abuse may be elicited. Toilet avoidance is common.

Patients with encopresis eventually develop secondary emotional problems, which can be elicited from the history taking.

##### Physical Examination

##### Retentive Encopresis

In retentive soiling the physical examination should assess for abdominal distention and tenderness on palpation. A mass can be occasionally felt in the midline in the suprapubic area. This mass of hardened fecal matter most commonly involves the rectosigmoid area and can sometimes extend throughout the entire colon. If the patient is anxious or in pain and tightens the rectus

**TABLE 1** Characteristic Symptoms of Retentive and Nonretentive Encopresis

##### Retentive Encopresis

- Constipation
- Stained underwear
- Fewer than three bowel movements per week
- Large-caliber or hard stools
- Abdominal pain, reports of bloated sensation
- Odor of feces from leakage onto underwear
- Difficult or painful defecation
- Enuresis
- Overflow incontinence
- Anorexia

##### Nonretentive Encopresis

- Passage of stools in inappropriate places without presence of constipation
- Refusal to sit on toilet even though old enough to (older than 5 years, even older than 8 years at times)
- Refusal to take medications
- Child may be depressed

abdominis, this mass can be missed. Rectal examination is a must; it can be done with minimal discomfort. Rectal examination assesses the dilation of the rectum, which may be 6 to 10cm wide. It is usually packed with stools with clay-like consistency. Visually inspect the anal opening for tone, fissure, and hemorrhoids.

### Nonretentive Encopresis

The child with nonretentive encopresis typically has a normal abdominal examination, is likely to have a rectal vault that is not dilated, and the stool will be of normal caliber and consistency. The rectal vault may be empty if the child has just passed a bowel movement. The anal opening may reveal protruding fecal material in children who are deliberate stool holders.

### Treatment

Encopresis is treated through a multistep approach. First, clearing the colon of fecal material will allow the dilated rectal vault and rectosigmoid colon to return to normal. The rectal cleanout can be achieved in different ways (see Current Therapy). Enemas and stool softeners are often used in combination.

Maintenance is achieved by keeping stools soft and ensuring daily bowel movements with mineral oil and hyperosmolar agents (e.g., Miralax<sup>1</sup>) that are very safe and can be used from a very young age and are not habit forming. The goal is painless stools once or twice a day with no associated withholding behavior.

Education is key for families so that they understand the physiology and process of stool elimination. Frustration is associated with failure, guilt, and depression and should be replaced with a positive attitude if success is to be achieved.

- Patients should sit daily on the toilet for 5 minutes after meals twice a day.
- Families need to keep a record of the events, as well as a record for success.
- Soiled underwear should be changed as soon as noticed and the child should be cleaned and changed in a timely, emotionally neutral fashion.
- As soon as compliance wanes, the problem is expected to return and is sometimes worse than the previous episode.
- The care provider's continued involvement in titrating medication with the patient's symptoms is necessary.
- Pain-related impaction can be cured in the majority of cases with medical management of the initial presentation. The success rate is reported to be about 70% with psychogenic impaction.
- With nonretentive encopresis, behavioral modification is essential. Stress reduction, effective coping techniques, relaxation training, and a combination of individual and family therapy is sometimes indicated.

<sup>1</sup>Not FDA approved for this indication.

## EPILEPSY IN INFANTS AND CHILDREN

Method of

Adam L. Hartman, MD

### CURRENT DIAGNOSIS

- At initial diagnosis, determine whether the event was a seizure or a non-epileptic event.
- If appropriate, diagnose an epilepsy syndrome.
- Age of onset aids in the development of a differential diagnosis.

### CURRENT THERAPY

- Selection of an antiseizure medicine should be made based on the type of seizure.
- General principles include the use of a single agent at the lowest effective dose with the goal of no side effects.
- Epilepsy can be associated with comorbidities, including depression and anxiety. Successful management includes referrals and/or management of these and associated psychosocial issues.

A seizure can be defined as clinical signs or symptoms resulting from abnormal neuronal firing. Epilepsy is defined as either (1) at least two unprovoked seizures occurring >24 hours apart; (2) one unprovoked seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (3) diagnosis of an epilepsy syndrome. There may be associated psychological, social, and cognitive consequences. Approximately 3% to 5% of the US population have had a seizure (mostly febrile seizures). Nearly 1% of the US population are being treated actively for seizures at any given time. Infants and children represent one of the two major peaks in seizure incidence, making this a very common diagnosis in pediatric practice.

### Risk Factors

The primary risk factors for epilepsy in any age group include a history of meningitis, encephalitis, brain trauma, complicated perinatal course, and febrile seizures. Other risk factors for seizures include cortical or developmental malformations, certain inborn errors of metabolism or genetic syndromes, congenital infections, stroke, intracranial hemorrhage, acute metabolic abnormalities, and drug withdrawal.

### Pathophysiology

Because the primary abnormality is abnormal neuron firing, many different types of pathology can lead to seizures. Abnormalities in neuronal networks (e.g., cortical malformations), structure (e.g., abnormal dendrite structure in trisomy 21), or ion channels (e.g., *KCNQ2*) can lead to seizures. In many cases, an underlying cause of seizures cannot be identified. Some forms of epilepsy have been linked to various pathogenic genetic variants, although the exact relationship between specific genotypes and phenotypes is unclear for most.

### Clinical Manifestations

Broadly speaking, the clinical manifestations of seizures vary depending on which brain structures are involved. Although most people think of seizures only as generalized tonic-clonic seizures (GTCS), a wide variety of signs and symptoms can be caused by seizures. Furthermore, a GTCS may be the initial manifestation of a seizure (i.e., as seen in primary generalized epilepsy) or it may be the end result of a seizure that started in one brain location and then spread to the rest of the brain (e.g., a focal-onset

seizure with spread to other broad cortical regions of the brain). These two broad categories (generalized versus focal onset) are approached somewhat differently from a diagnostic and therapeutic perspective.

Signs of a generalized seizure (i.e., those involving abnormal neuronal firing in both sides of the brain) include loss of interaction or staring (absence seizures), myoclonus, tonic posturing, and/or tonic-clonic seizures. Signs of focal-onset seizures can involve specific regions controlling motor, sensory, or autonomic function, a loss of interaction and/or awareness, or automatisms (chewing, lip smacking, repetitive hand motions), to name a few. Patients with focal seizures might have an aura (a warning sign just prior to the seizure). The aura is an altered sensory function that can include salty or metallic taste, tingling sensations, rising sensation in the abdomen, *déjà vu*, *jamais vu*, sense of fear, or a nonspecific feeling that something is about to happen. After a seizure, patients also can have a period of postictal lethargy, confusion, or irritability. The latter can be misinterpreted by bystanders as disruptive behavior and has led to inappropriate interventions, even by law enforcement. This becomes a safety issue for the patient. Education about this type of behavior, if present, is critical.

The initial symptoms or signs of a seizure are the most important in determining whether a seizure is generalized or focal in origin because they often localize the anatomic site of pathology. Thus, it is the beginning of a seizure, rather than its end, that is most useful in making a specific diagnosis.

## Diagnosis and Management

### History and Physical Examination

A detailed history is usually more valuable than any expensive test in diagnosing a seizure or epilepsy. In addition to a description of the actual event, it is useful to inquire about subtle signs that might not be recognized by observers as a seizure, including staring spells, myoclonic jerks, loss of time, and unexplained nocturnal tongue biting, enuresis, or emesis. The presence of postictal weakness can help localize the hemisphere of onset after a focal seizure, even if secondarily generalized. Making the diagnosis of a specific epilepsy syndrome allows the clinician to develop a plan for further diagnosis and treatment and to counsel about prognosis. On physical examination, any signs of focal neurologic deficits can indicate an underlying lesion. A skin examination might identify a neurophakomatosis, such as tuberous sclerosis complex or Sturge Weber syndrome.

### Diagnostic Studies

In selected cases, typical clinical findings in the right clinical context strongly support the diagnosis of epilepsy, but an electroencephalogram (EEG) may be required to confirm the diagnosis. Even if the patient does not have a seizure during the EEG recording, interictal findings (when the patient is not having a seizure) can provide enough evidence to make the diagnosis of epilepsy. Under ideal circumstances, a single EEG can detect epileptiform activity in a patient with untreated generalized epilepsy about 75% of the time, making it a very sensitive test. In contrast, an EEG can detect epileptiform activity in a patient with focal-onset seizures only 50% of the time (although this number increases to about 90% after three EEGs have been done). Conversely, a single normal interictal EEG (particularly one that includes sleep and provocative maneuvers such as intermittent photic stimulation and hyperventilation) in an untreated patient suggests, but is not necessarily diagnostic of, a focal rather than generalized onset.

Other ancillary studies can show underlying structural lesions that lead to epilepsy or provide physiologic information. Magnetic resonance imaging (MRI) can be useful in detecting lesions such as tumors, cortical dysgenesis, and strokes (both ischemic and hemorrhagic). Recent advances in image analysis have substantially improved the ability to find subtle regions of cortical dysgenesis that may be the source of seizures. Positron-emission tomography (PET) scans may show regions of abnormal metabolism that might not be evident on MRI. Another nuclear medicine

study, single photon emission tomography (SPECT), can be used to identify the region of onset of a seizure. Functional MRI (fMRI) studies show regions involved in a specific task (e.g., motor or language).

Magnetoencephalography, when combined with MRI, can be useful in detecting areas of abnormal electrical activity that might not be evident on a scalp EEG recording. Neuropsychology evaluations can aid in localization of regions of dysfunction and also aid in determining risk for loss of function if surgery is performed. The intracarotid amobarbital (Amytal)<sup>1</sup> test (Wada test) or intracarotid methohexital (Brevital)<sup>1</sup> test is used to lateralize language function and memory; fMRI is being investigated as a replacement for aspects of this invasive test. Some institutions use intracranial electrodes to localize the onset of a seizure prior to a surgical resection and to identify regions of eloquent neurologic function (regions where critical function would be lost if they were resected).

### Specific Epilepsy Syndromes

Some of the more common syndromes are described here, listed by typical age at presentation.

#### Neonatal Seizures

Seizures in neonates can be caused by any type of neurologic pathology, including infections (prenatal or postnatal), strokes, hemorrhages, electrolyte abnormalities, cortical dysgenesis, inborn errors of metabolism (including vitamin B<sub>6</sub> dependency), genetic syndromes, drug (illicit and licit) withdrawal, and medications. Some neonatal seizure syndromes (benign idiopathic neonatal seizures and benign familial neonatal seizures) are benign in terms of resolution of seizures; early infantile epileptic encephalopathy (Ohtahara syndrome) and early myoclonic encephalopathy frequently are refractory to medical treatment and have a poor prognosis for development. Neonatal seizures should be managed in conjunction with specialists.

#### Febrile Seizures

Febrile seizures are the most common type of seizure, occurring in 3% to 5% of people in the United States. Febrile seizures, even though they can recur, are not diagnostic of epilepsy because they are provoked (i.e., by fever). With an onset between 1 month and 5 years of age (and almost always outgrown by 6 to 7 years of age), these seizures can be generalized or focal in onset. Meningitis and encephalitis also can manifest with seizures and fever and thus are exclusion criteria for febrile seizures because the prognosis and treatment are completely different. Febrile seizures that last longer than 15 minutes, have a focal onset, or occur more than once in a febrile illness are complex febrile seizures (only one of the three criteria are needed to make the diagnosis). Patients with complex febrile seizures are at a higher risk for developing epilepsy, although the overall risk is still low (4%). In patients who lack all three of these factors (i.e., simple febrile seizures), routine imaging, blood work, lumbar puncture, and EEG are not necessary for diagnosing the cause of the seizure. Rather, the workup should be guided by other concerns, such as dehydration, concern for occult bacteremia, or, in the appropriate clinical context, meningitis.

Approximately one-third of patients have a recurrence of a febrile seizure. Factors that increase the recurrence risk include very young age at onset, family history of febrile seizures, low-grade fever at onset of the seizure, frequent febrile illnesses, or the occurrence of the seizure in the first hour of the fever. Febrile seizures always are outgrown, so typically long-term seizure prophylaxis is not used. Oral diazepam (Valium) prophylaxis<sup>1</sup>, started at the onset of fever, prevents febrile seizures but can lead to excessive sedation. Patients who have prolonged febrile seizures can benefit from rectal diazepam gel (Diastat) or other benzodiazepines given soon after the onset of a febrile seizure to prevent additional prolonged seizures or febrile status epilepticus.

<sup>1</sup>Not FDA approved for this indication.

A similarly good prognosis is seen in infants and children who have febrile seizures in the setting of acute gastroenteritis (whether febrile or not). The risk of epilepsy is increased after a febrile seizure in the setting of a complex febrile seizure, abnormal development, frequent febrile seizures, or a family history of epilepsy.

### Infantile Spasms

With an onset typically around 4 to 8 months of age, infantile spasms consist of a triad of typical seizures (head drops and brief flexor and/or extensor spasms occurring in clusters around sleep transitions), a highly disorganized multifocal EEG pattern called hypsarrhythmia, and developmental delays. Between 70% and 90% of patients have identifiable underlying neurologic pathology associated with this syndrome. This is one of the most medically intractable epilepsy syndromes, and the prognosis for seizure control and development is very poor, except in a small subset of patients with no identifiable underlying pathology. Treatment typically is with corticosteroids (prednisolone [Orapred]<sup>1</sup> or ACTH [Acthar HP]), or vigabatrin (Sabril), which is commonly the first-line treatment in infants with tuberous sclerosis complex (Box 1).

### Dravet Syndrome

The typical presentation for Dravet syndrome is a prolonged febrile seizure involving one side of the body (hemiclonic) or recurrent GTCS in a previously normal infant. After a relatively quiescent period, seizures (including myoclonic, focal, and absence) may appear in the second year of life. Additional features include developmental abnormalities, ataxia, and extrapyramidal signs. Seizures induced by heat (either with fevers or exogenous) may be noted.

Genetic testing for mutations in the *SCN1A* gene is recommended because this eliminates the need for other extensive testing for an underlying diagnosis and allows the clinician to prognosticate. The EEG may be normal initially but later shows generalized spike-and-wave complexes and may show focal abnormalities. Treatment typically is with antiseizure medications; drugs that block sodium channels are typically avoided because they may exacerbate seizures. The ketogenic diet may be useful. Heated environments might need to be avoided and accommodations (e.g., air-conditioned buses and classrooms) may be recommended in some cases.

### Lennox–Gastaut Syndrome

Typically occurring between the ages of 1 and 8 years, Lennox–Gastaut syndrome is characterized by mixed seizure types, a markedly abnormal EEG, and abnormal development. Virtually any type of brain pathology can be seen as an antecedent of Lennox–Gastaut syndrome. The syndrome of infantile spasms is a common antecedent. Patients with Lennox–Gastaut syndrome typically have combinations of tonic, atonic, and absence seizures, although focal-onset seizures and GTCS also occur. The EEG shows slow (less than 2.5 Hz) spike-and-wave complexes and occasionally a paroxysmal fast pattern, although background slowing also is very common. The vast majority of patients have developmental delays. Diagnosis is made in the setting of typical findings. Seizures are very difficult to control, but treatment commonly includes medicines and/or nonpharmacologic options (see Box 1). The prognosis for seizure control and development is poor. The differential diagnosis of Lennox–Gastaut syndrome also includes Doose syndrome, which is characterized by myoclonic and atonic seizures (although other seizure types can occur). In Doose syndrome, patients often have normal development and a good prognosis once seizures are controlled.

### Childhood and Juvenile Absence Epilepsy

Most clinicians are familiar with childhood and juvenile absence epilepsy. The typical age of onset is 4 to 14 years, and there is a

## BOX 1 Recommendations for Treatment

### Infantile Spasms, West Syndrome

Oral steroids<sup>1</sup>  
 Adrenocorticotropic hormone  
 Ketogenic diet  
 Topiramate (Topamax)<sup>1</sup>  
 Valproate (Depakote)<sup>1</sup>  
 Zonisamide (Zonegran)<sup>1</sup>  
 Pyridoxine<sup>1</sup>  
 Benzodiazepines<sup>1</sup>  
 Surgery (if there is a lesion)  
 Vigabatrin (Sabril) (may use first if patient has tuberous sclerosis)

### Dravet Syndrome

Valproate<sup>1</sup>  
 Topiramate<sup>1</sup>  
 Stiripentol (Diacomit)  
 Cannabidiol (Epidiolex)  
 Fenfluramine (Fintepla)  
 Ketogenic diet  
 Benzodiazepines<sup>1</sup>

### Lennox–Gastaut Syndrome

Valproate<sup>1</sup>  
 Clobazam (Onfi)  
 Lamotrigine (Lamictal)  
 Topiramate  
 Benzodiazepines  
 Rufinamide (Banzel)  
 Felbamate (Felbatol)  
 Ketogenic diet  
 Vagus nerve stimulator  
 Surgery

### Doose Syndrome

Valproate<sup>1</sup>  
 Ketogenic diet  
 Lamotrigine<sup>1</sup>  
 Ethosuximide (Zarontin)<sup>1</sup>  
 Vagus nerve stimulator

### Childhood Absence Epilepsy

Ethosuximide  
 Valproate  
 Lamotrigine<sup>1</sup>

### Juvenile Absence Epilepsy

Valproate  
 Ethosuximide  
 Lamotrigine<sup>1</sup>

### Childhood Epilepsy with Centrottemporal Spikes

Levetiracetam (Keppra)  
 Carbamazepine (Tegretol)  
 Zonisamide  
 Oxcarbazepine (Trileptal)  
 Lacosamide (Vimpat)

### Juvenile Myoclonic Epilepsy

Valproate<sup>1</sup>  
 Levetiracetam  
 Topiramate  
 Zonisamide<sup>1</sup>  
 Lamotrigine

<sup>1</sup> Not FDA approved for this indication.  
 Adapted from Muthugovindan D, Hartman AL: Pediatric epilepsy syndromes. *Neurologist* 2010;16:223–237.

<sup>1</sup>Not FDA approved for this indication.

slight female predominance. The most common type of seizure is an absence seizure, characterized by staring and loss of interaction lasting 5 to 20 seconds, occurring tens to hundreds of times per day. Patients also can have GTCS (particularly if they present later in childhood) and/or myoclonic seizures. There is no aura and there are no postictal behavior changes. Absence seizures can be induced with 3 to 4 minutes of hyperventilation at the bedside. The interictal EEG shows a 3Hz generalized spike-and-wave pattern. Treatment includes ethosuximide (Zarontin) if the patient has not had a GTCS (see [Box 1](#)). Valproate (Depakene) is the first choice if the patient has had a GTCS. Nearly two-thirds of patients grow out of their seizures by young adulthood.

### *Childhood Epilepsy With Centrottemporal Spikes and “Benign” Occipital Epilepsy*

One of the more common epilepsies in childhood, childhood epilepsy with centrottemporal spikes (also known commonly as benign rolandic epilepsy), first occurs between the ages of 3 and 13 years. The typical seizure involves the face and/or hand, but GTCS also are common. The most common time for a seizure is within the first few hours of sleep, but a minority of patients only have daytime seizures. The diagnosis is made based on a typical seizure history and EEG (which shows spikes over bilateral central and temporal regions). Learning disabilities, which may be very subtle, are fairly common in patients with this syndrome, so extra vigilance is warranted.

Panayiotopoulos syndrome (also known as “benign” occipital epilepsy) can occur between the ages of 1 and 14 years (with a peak at 4 to 5 years) with autonomic symptoms such as emesis, pallor, flushing, or tachycardia, as well as focal-onset or generalized seizures. Patients also can have visual symptoms. The EEG can show sharp waves in the occipital regions, but abnormal activity has been reported in other brain regions as well.

Because most patients have fewer than six seizures in both syndromes, medicine usually is not prescribed. Seizures typically are outgrown by adolescence. Patients with frequent seizures are treated with medicine. Gastaut occipital epilepsy (not to be confused with Lennox–Gastaut syndrome) occurs in older children and can require medication treatment because of seizure recurrence.

### *Juvenile Myoclonic Epilepsy*

The most common form of generalized seizures in adolescents, juvenile myoclonic epilepsy first occurs between the ages of 12 and 20 years. Most patients have brief myoclonic seizures that tend to cluster in the early morning hours (but may occur at any time of day). Patients often are unaware that these are seizures but on careful questioning report loss of control of a toothbrush or spoon. Many patients also have absence seizures. The interictal EEG typically shows a 4 to 5Hz generalized spike-and-wave pattern. The prognosis for lifelong remission of seizures is poor, although most patients’ seizures are controlled easily with medicines (see [Box 1](#)). There is a subgroup of patients (many of whom previously had childhood absence epilepsy) whose seizures are very challenging to control.

### *Other Epilepsy Syndromes With a Poor Prognosis*

Landau–Kleffner syndrome and epileptic encephalopathy with continuous spike-and-wave during sleep are syndromes characterized by mild seizures, nearly continuous epileptiform activity during sleep, and neuropsychological deterioration. Progressive myoclonus epilepsy represents a family of disorders characterized by medically intractable epilepsy (commonly including myoclonic seizures) and significant neurologic deterioration. Underlying diagnoses include myoclonus epilepsy with ragged red fibers (MERRF), Unverricht–Lundborg disease, and Lafora disease, among others. Gelastic (laughing) seizures can be caused either by hypothalamic hamartomas or temporal lobe seizures.

The prognosis depends on response to medication and/or surgery but is not always bad. Rasmussen syndrome is characterized by medically intractable epilepsy, progressive unilateral neurologic deficits, and cortical atrophy on MRI. Because they are so rare, any suspicion of these diagnoses should prompt referral to a pediatric epilepsy center with expertise in diagnosing and managing these conditions.

### *Tumors*

Brain tumors can manifest with seizures and are covered in a separate chapter. Certain developmental tumors are seen with an increased frequency in pediatric epilepsy clinics, including dysembryoplastic neuroepithelial tumors (DNET) and gangliogliomas. These tumors typically manifest with seizures and can be associated with malformations of cortical development. EEG can show abnormalities over the involved region but can be falsely localizing as well. MRI shows the location of the tumor but can underestimate the extent of surrounding abnormal tissue. If seizures are not controlled with medicine, or if there is progression in tumor size, resection surgery is recommended.

### *Cortical Dysgenesis*

Abnormal brain development can lead to inappropriately wired brain circuitry, which can be the underlying substrate for seizures. Two forms of abnormal cortical development include lissencephaly (abnormally smooth, or simplified, gyral pattern) and polymicrogyria. Another form of cortical dysgenesis, malformations of cortical development, is graded based on both dyslamination of the normal six-layer neocortex and the occurrence of abnormal cell types (including balloon cells). EEG shows epileptiform abnormalities over the involved region. MRI shows the anatomic location of the involved tissue in more severe cases but may be normal if the abnormality is mild. In patients with focal abnormalities, if seizures are not controlled with medicine, resection surgery is an option. Patients with more extensive abnormalities can try nonpharmacologic options if medicines do not work.

### *Mesial Temporal Lobe Epilepsy With Hippocampal Sclerosis*

The mesial temporal structures (particularly the hippocampus) can become scarred, and the remaining neurons develop abnormal connections. This can lead to medically intractable seizures. EEG shows interictal epileptiform activity over the temporal head regions. Imaging studies show atrophic mesial temporal structures with increased signal on T2-weighted FLAIR (fluid-attenuated inversion recovery) images. A temporal lobectomy should be considered as an option for patients who do not respond to two appropriately chosen and tolerated medications for seizure control.

### *Comorbidities*

The definition of epilepsy includes comorbidities, which in turn can have a significant impact on quality of life. Clinicians must actively probe for these underlying conditions in order to optimize outcomes. People with epilepsy have increased rates of depression and anxiety compared to the general population. Developmental disorders and learning disabilities are more common in children with epilepsy, as are attention-deficit/hyperactivity disorder and migraines. Once identified, these conditions should be managed by clinicians experienced with their treatment.

### *Differential Diagnosis*

The differential diagnosis of seizures depends largely on age. In infants, opisthotonic posturing can be seen in gastroesophageal reflux disease (Sandifer syndrome). Some infants have benign myoclonus or shuddering attacks. The EEG in all these disorders is normal, but the diagnosis can be made based on the history. Brief resolved unexplained events can appear to be seizures,

although apnea rarely is the only manifestation of a seizure. Hyperekplexia is an exaggerated startle response that can be due to abnormal glycine receptor subunits in the spinal cord. Because of potential involvement of the diaphragm, this disorder can be lethal. In children, stereotypies can be paroxysmal and persistent, but the behaviors during these episodes are typical enough that the diagnosis usually is made based on the history.

Breath-holding spells may be associated with an older infant or toddler who is upset, followed by unresponsiveness and either facial pallor or mild cyanosis, lasting less than 1 to 3 minutes. These episodes are typical enough that the history is all that is usually needed to make the diagnosis. Children with pallid breath-holding spells are at higher risk for vasovagal syncope in the adolescent and young adult ages.

Night terrors, one of the parasomnias, occur in toddlers and young children. Persistent screaming (lasting minutes to 1 hour) and lack of memory of the event are seen commonly; the latter raises a question of whether the child had a seizure. Most commonly, these are outgrown by the late preschool years.

Patients with syncope may have a few mild clonic twitches, but this typically does not represent epilepsy. Screening orthostatic blood pressures should be done to rule out one of the orthostatic syndromes. Consideration also should be given to an electrocardiogram or a cardiology consultation in the appropriate clinical context.

Older children and adolescents can have psychogenic nonepileptic events, also known as psychogenic nonepileptic seizures. Cognitive behavioral therapy is helpful in some patients. This is a very important diagnosis to make so that patients receive appropriate treatment and are not exposed to medicines where the risks outweigh the benefits.

In all age groups, focal lesions such as infarctions, hemorrhages, and infections should be considered in the differential diagnosis, although the diagnostic workup should be guided by the history and physical examination.

## Treatment

The goals for treatment are to maximize efficacy and minimize side effects. Medication is the first line of therapy for most patients. Nearly 70% to 80% of children are treated successfully by one of the first two medications tried. Practically speaking, neurologists try to use a single agent at the lowest tolerated dosage. Suggested medicines for the epilepsy syndromes discussed previously are listed in [Box 1](#). Details about specific medicines are listed in [Table 1](#). If one of the first two medicines tried does not work, there are three major options.

### 1. Trials of Additional Medication

Although the first two medicines might not work, new medicines often are introduced into the market. Clinical trials often show that a modest number of patients respond well to newer medicines, although the positive response to newer medicines is no greater overall than response to older medicines, despite lower rates of adverse effects and drug–drug interactions.

### 2. Surgery

Any patient who fails to respond to two appropriately-selected medications should be assessed for surgery. In patients with a potentially resectable lesion, surgery offers the greatest chance of seizure freedom. Ideal surgical candidates have identifiable lesions on imaging studies and a seizure onset zone that is distinct from eloquent cortex. Patients without identifiable lesions or those with multifocal or generalized seizures are poor candidates for resection surgery. Options for these patients include the vagus nerve stimulator, which has outstanding compliance and adherence because it is surgically implanted. Although this device significantly decreases seizure frequency in some patients, it only rarely leads to seizure freedom. Neurostimulation devices, some of which also include

seizure detectors, are being introduced into clinical practice for adults and are being investigated in children.

### 3. Diet Therapy

The concept of fasting to improve seizure control dates back to Hippocrates, but in modern times, dietary management of epilepsy is implemented using a high-fat, low-carbohydrate (adequate protein) ketogenic diet. A modified Atkins diet and a low glycemic index treatment have been used successfully as well. These diets require varying degrees of clinical supervision at centers experienced in their implementation.

## Monitoring

Seizure calendars (which can take the form of notebooks or electronic tools) are very useful for tracking frequency of events, especially if they are completed on a daily basis. There has been a recent explosion in wearable devices and other types of biotechnology for monitoring seizures and vital signs during seizures (for home use). Monitoring for medication-related adverse effects and comorbidities should continue during treatment. In addition, some comorbidities can occur even if seizures have stopped; there is good evidence for this in patients with childhood absence epilepsy, which typically is considered a “benign” syndrome because seizures typically resolve by adulthood. Patients taking certain medicines are screened periodically for evidence of renal and/or hepatic abnormalities and abnormal blood cell counts. Scenarios for testing drug levels include the following:

- Assessing adherence to a prescribed drug regimen
- Testing whether symptoms result from drug toxicity
- Determining whether a patient can benefit from higher amounts of medicine when the administered doses are already high (i.e., fast metabolizers)

Reminders about seizure-related safety should be reinforced periodically. GTCS counseling typically includes instructions about safety for the patient, including protecting the head and airway (putting the patient on his or her side to prevent aspiration) and not putting anything in the patient’s mouth. Other safety topics include water safety and wearing helmets, as well as discouraging participation in certain sports (e.g., scuba diving). Periodic assessments of bone health should be considered for patients taking enzyme-inducing or enzyme-inhibiting medicines. Patients of an appropriate age should be counseled about local driving laws. Adolescent females should be counseled about the effect of antiseizure medicines on hormonal forms of contraception (and vice versa). Consideration should be given to prescribing folate in this group, as well.

## Complications

Single GTCS can lead to trauma (e.g., from a fall), tongue biting, pneumothorax, fractures of the vertebrae or limbs, and joint dislocations. A brief physical examination can rule out the more serious complications of a single GTCS. Adverse effects of medications are listed in [Table 1](#). Surgical resections can lead to a variety of neurologic deficits, depending on which tissue is involved. Vagus nerve stimulator surgery can lead to hoarseness and coughing. Unsupervised diet therapy also can have adverse effects; such therapy should be undertaken only by centers with experience. Rarely, patients with epilepsy can die unexpectedly from no apparent cause, known as sudden unexplained death in epilepsy (SUDEP). The cause is unknown, but most (not all) patients have epilepsy that is resistant to medications. Counseling about this condition should be provided by an epilepsy expert.

**TABLE 1** Summary of New Commonly Used Antiseizure Drugs

DRUG	MAINTENANCE DOSAGE*	STARTING DOSAGE*	HALF-LIFE (H)	COMMON SIDE EFFECTS	SERIOUS IDIOSYNCRATIC SIDE EFFECTS
Brivaracetam (Briviact)	> 16y, 25–100mg bid	50mg bid	9	Agitation, behavioral disinhibition, dizziness	Suicidality
Cannabidiol (Epidiolex)	5mg/kg bid (can go up to 10mg/kg bid)	2.5mg/kg bid	56–61	Somnolence, decreased appetite, diarrhea, transaminase elevations (check before initiating therapy), fatigue, rash, sleep disorders, infections	Severe encephalopathy leading to respiratory depression and oversedation, hepatic injury, suicidality
Cenobamate (Xcopri; adults only)	200mg once/day	12.5mg once daily, titrate per manufacturer	50–60	Somnolence, dizziness, aphasia, dysarthria, vertigo, diplopia, vomiting, constipation, diarrhea, transaminase elevations	Hyperkalemia, appendicitis, QTc shortening, DRESS, suicidality
Fenfluramine (Fintepla)	Maintenance >2y, w/o stiripentol: 0.1–0.35 mg/kg/dose bid; >2 y, w/ stiripentol and clobazam, 0.1–0.2 mg/kg/dose bid;	Starting 0.1 mg/kg/dose bid	20	Anorexia, diarrhea, fatigue, echocardiographic abnormalities, weight loss, blood pressure change, behavior changes, tremor, irritability, gastroenteritis, URL, rash	serotonin syndrome, suicidality, hypertension, angle-closure glaucoma
Clobazam (Onfi)	> 2y, < 30kg: 10mg bid > 2y, > 30kg: 20mg bid	> 2y, < 30kg: 5mg/d > 2y, > 30kg: 5mg bid	Parent drug: 36–42 Active metabolite: 71–82	Sedation irritability Needs to be tapered off slowly	Respiratory depression, benzodiazepine withdrawal, Stevens–Johnson syndrome
Eslicarbazepine (Aptiom)	4–17y (11–21kg), 400–600mg once/day 4–17y (22–31kg), 500–800mg once/day 4–17y (32–38kg), 600–900mg once/day 4–17y (>38kg), 800–1200mg once/day >17y, 800–1600mg once/day	4–17y (11–21kg), 200mg once/day 4–17y (22–31kg), 300mg once/day 4–17y (32–38kg), 300mg once/day >4y (>38kg), 400mg once/day	13–20	Somnolence, dizziness, hyponatremia, thyroid dysfunction	Stevens-Johnson, toxic epidermal necrolysis, withdrawal seizures if stopped abruptly
Lacosamide (Vimpat)	4–16y (11–<30kg), 3–6mg/kg bid 4–16y (30–50kg), 2–4mg/kg bid >4y (>50kg), 100–200mg bid	4–16y (<50kg), 1mg/kg bid >4y (≥50kg), 50mg bid	13	Somnolence, fatigue, headache	Cardiac conduction abnormalities, Stevens-Johnson syndrome, cytopenias
Levetiracetam (Keppra)	20–60mg/kg/d	10mg/kg/d, incr in 10-mg/kg increments	6–8	Agitation, behavioral disinhibition, rashes	Suicidal ideation
Oxcarbazepine (Trileptal)	30–60mg/kg/d	8–10mg/kg/d, incr by 10–15mg/kg increments	Parent drug: 2 Metabolite: 9	Hyponatremia, somnolence, lethargy, dizziness, blurred vision	Rash
Perampanel (Fycompa)	> 12y, 8–12mg at bedtime	> 12y, 2–4mg at bedtime	105h	Somnolence, headaches	Serious psychiatric and behavior reactions
Rufinamide (Banzel)	45mg/kg/d	10mg/kg/d	6–10	Nausea, vomiting, somnolence	Seizures, QT shortening
Stiripentol (Diacomit; to be used as a clobazam adjunct)	Up to 3g/day	25mg/kg bid	4.5–13	Somnolence, decreased appetite, agitation, ataxia, tremor, cytopenias, vomiting, weight gain	Suicidality, cytopenias, withdrawal seizures
Vigabatrin (Sabril)	50–150mg/kg/d	50mg/kg/d	7.5 (5.7 in infants)	Headache, dizziness, fatigue, tremor, swallowing problems, T2-weighted or DWI hyperintensities	Vision loss
Zonisamide (Zonegran)	> 16y: 100–600mg/d	> 16y: 100mg once/day	63	Somnolence, irritability, cognitive slowing, weight loss, renal stones, oligohidrosis	Rash

Abbreviations: DWI = diffusion-weighted imaging; incr = increase.

\*Dosages should not exceed maximum adult dosages.

## INFANT HYPERBILIRUBINEMIA

Method of

Sheevaun Khaki, MD

### CURRENT DIAGNOSIS

- As bilirubin levels rise during the newborn period, jaundice appears and progresses caudally from head to toe.
- Hyperbilirubinemia is classified as conjugated or unconjugated; conjugated hyperbilirubinemia is always considered pathologic.
- Universal screening for hyperbilirubinemia with a total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) should be performed for all newborns within the first 24 hours of life.
- The bilirubin level should be interpreted based on the newborn's hours of age, gestational age, and absence or presence of risk factors for hyperbilirubinemia.
- Standardized nomograms should be used to monitor the newborn's degree of hyperbilirubinemia and to initiate treatment.
- Newborns born to mothers with blood type O should have a blood type and Coombs' test performed to assess for possible ABO incompatibility when the bilirubin is approaching phototherapy threshold.

### CURRENT THERAPY

- Newborn feeding should be emphasized to maintain hydration and promote clearance of bilirubin.
- Phototherapy should be initiated when the newborn has met the hour-specific phototherapy threshold.
- Newborns within 2 to 3 mg/dL of the exchange transfusion threshold should be hospitalized for initiation of phototherapy, possible intravenous fluid rehydration, and close monitoring.
- Occasionally, intravenous immunoglobulin (IVIg)<sup>1</sup> is used to manage hemolytic disease of the newborn due to ABO or Rhesus factor (Rh) incompatibility.

<sup>1</sup>Not FDA approved for this indication.

## Background

Neonatal hyperbilirubinemia is common during the newborn period, with approximately 50% of term newborns developing jaundice in the first week of age. As bilirubin levels increase, clinical signs of jaundice develop due to deposition of bilirubin in the skin and mucous membranes. For the majority of newborns, this is a transient condition that does not require medical intervention. However, a small portion of late preterm and term newborns will develop hyperbilirubinemia that may require close monitoring and/or medical intervention. The goal of treating neonatal hyperbilirubinemia is to prevent bilirubin-induced neurologic dysfunction, acute bilirubin encephalopathy (ABE), and chronic bilirubin encephalopathy (CBE) or kernicterus. Various screening and monitoring strategies exist to prevent these serious outcomes.

## Risk Factors

Prior to hospital discharge, all newborns should be systematically assessed for the risk of hyperbilirubinemia requiring intervention. The American Academy of Pediatrics (AAP) has developed a list of major and minor risk factors for the development of hyperbilirubinemia (Table 1). As part of this risk assessment, all mothers' blood types should be reviewed to determine whether the baby is at risk for hyperbilirubinemia due to ABO or Rhesus factor (Rh) incompatibility. The newborn's gestational age (GA) is particularly important as late preterm infants (GA 34w0d–36w6d) have additional feeding difficulties and relatively immature red blood cells (RBCs) and hepatic cells, which lead to both increased production and decreased clearance of bilirubin. A thorough family history may provide additional information regarding inheritable conditions such as glucose-6-phosphate dehydrogenase (G6PD) deficiency that lead to hemolysis and, therefore, hyperbilirubinemia. Additionally, there are certain factors that decrease the newborn's risk of developing severe hyperbilirubinemia, including GA  $\geq$  41 weeks, exclusive bottle feeding, black race, and hospital discharge after 72 hours of age.

## Pathogenesis

An understanding of bilirubin metabolism is essential in determining the etiology of neonatal hyperbilirubinemia. Bilirubin results from the breakdown of heme, the majority of which comes from catabolism of hemoglobin from RBCs. There are multiple steps involved in the removal of bilirubin from the bloodstream. Initially, bilirubin is bound to albumin and transported to the liver where it is conjugated by uridine diphosphate glucuronosyltransferase (UGT1A1). Conjugated bilirubin is excreted into the biliary system and ultimately the gastrointestinal system. Finally, conjugated bilirubin is either deconjugated in the intestines by bacteria and reabsorbed back into the circulation or excreted as stool. A disturbance in any of the above steps of bilirubin clearance can lead to hyperbilirubinemia. Hyperbilirubinemia is classified into unconjugated (indirect) and conjugated (direct) forms.

## Unconjugated Hyperbilirubinemia

Unconjugated hyperbilirubinemia results from either increased production or decreased clearance of indirect (unconjugated) bilirubin. Physiologic jaundice results from a combination of these processes. In this condition, bilirubin levels rise from increased number and turnover of RBCs due to the shorter life span of fetal RBCs, decreased activity of UGT1A1 in the liver, and increased enterohepatic circulation due to poor feeding and relative gut sterility. Breastfeeding jaundice results from increased enterohepatic circulation and mild dehydration as breastfeeding is established. Additionally, there are many pathologic conditions that may result in unconjugated hyperbilirubinemia. Hemolytic diseases such as isoimmune-mediated hemolysis (ABO or Rh incompatibility), RBC membrane defects (hereditary spherocytosis), or RBC enzyme defects (G6PD deficiency) contribute to significant morbidity. Decreased clearance of bilirubin may result from a defect in UGT1A1 (Crigler-Najjar syndrome types I and II, Gilbert syndrome), increased enterohepatic circulation due to impaired intestinal motility and poor milk intake, and breast milk jaundice.

**TABLE 1** Major and Minor Risk Factors for the Development of Severe Hyperbilirubinemia

MAJOR RISK FACTORS	MINOR RISK FACTORS
Pre-discharge TSB or TcB level in the high-risk zone	Pre-discharge TSB or TcB level in the high-intermediate-risk zone
Jaundice observed in the first 24 hours	Gestational age 37–38 weeks
Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency), elevated end tidal carbon monoxide (ETCO)	Jaundice observed before discharge
Gestational age 35–36 weeks	Previous sibling with jaundice
Previous sibling received phototherapy	Macrosomic infant of a diabetic mother
Cephalohematoma or significant bruising	Maternal age $\geq 25$ years
Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive	Male gender
East Asian race	

TcB, Transcutaneous bilirubin; TSB, total serum bilirubin.

From American Academy of Pediatrics, Subcommittee on Hyperbilirubinemia. Management of Hyperbilirubinemia in the Newborn Infant 35 or More Weeks of Gestation. *Pediatrics*. 2004;114:297–316.

### Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia is always considered pathologic. It is defined as a direct bilirubin concentration that is  $\geq 20\%$  of the total serum bilirubin (TSB). Direct bilirubin should be measured when the TSB is not responding appropriately to phototherapy or when jaundice persists past 2 weeks of age. Broadly, cholestatic jaundice can be divided into obstructive and hepatocellular etiologies. Obstructive etiologies include biliary atresia and choledochal cysts. Hepatocellular etiologies include endocrinopathies (thyroid abnormalities), metabolic disorders (galactosemia, tyrosinemia), and infection (sepsis, congenital infections). For newborns with jaundice past 2 weeks of age, total and direct bilirubin levels should be obtained to rule out biliary atresia, a diagnosis that deserves prompt identification and treatment.

### Prevention

While mild physiologic jaundice cannot be prevented in most instances, more severe cases of indirect hyperbilirubinemia can be avoided. Starting in the prenatal setting, all pregnant women should be tested for ABO and Rh blood types and red blood cell antibodies to identify mothers whose newborns may be at risk of developing isoimmune hemolytic disease. Mothers who are Rh-negative should receive Rho(D) immune globulin (RhoGAM) to prevent the development of antibodies after exposure to Rh-positive blood. Mothers should receive at least one dose between 26 and 28 weeks of pregnancy and another within 72 hours after delivery if the baby is found to be Rh-positive. All newborns born to Rh-negative mothers should have their blood type tested to allow for timely administration of RhoGAM. Additionally, mothers should receive RhoGAM after maternal or fetal bleeding during pregnancy, abdominal trauma, an invasive procedure, and with each pregnancy, including an ectopic pregnancy. If administered correctly, the risk of hemolytic disease of the fetus and newborn is significantly reduced. Pregnancies where mothers have an O blood type are considered to be a “setup” for ABO incompatibility.

Early identification of ABO incompatibility may prevent more severe cases of hyperbilirubinemia.

Postnatally, provision of adequate nutrition helps prevent readmission for phototherapy. During the newborn hospitalization, mothers who intend to breastfeed should receive information and support to establish an adequate milk supply. Early and sustained skin-to-skin contact should be emphasized to promote lactogenesis and maternal-newborn dyads should be assessed for risks of delayed lactogenesis. Serial newborn weights should be obtained to document weight loss as an early sign of inadequate intake. The newborn early weight loss tool, NEWT, (<https://www.newbornweight.org>) may be used to identify newborns 36 weeks of gestation and greater who have lost an excessive amount of weight and incorporated into the decision to initiate supplemental feeds. Prevention of dehydration in the early newborn period may help prevent clinically significant hyperbilirubinemia.

### Diagnosis

During the newborn hospitalization, the newborn should be assessed clinically for visible jaundice with all routine vital sign checks, preferably next to a well-lit window. The newborn who is jaundiced within the first 24 hours of age should have a TSB level drawn immediately as this finding is considered to be pathologic. It should be understood that while visual assessments are important to gauge progression of jaundice as it proceeds caudally from head to toe, they are particularly problematic in estimating the degree of hyperbilirubinemia and should not solely be relied upon. Rather, all newborns should undergo routine bilirubin testing either by TSB or transcutaneous (TcB) measurement within the first 24 hours of life. A TcB screening device offers the ability to estimate the bilirubin level quickly and avoids a painful procedure. However, providers must understand the limitations of their specific device (including decreased accuracy at higher bilirubin levels) and decide on thresholds where a serum level should be obtained.

The current AAP guidelines recommend plotting the measured bilirubin level on an hour-specific nomogram (Figure 1) to designate the newborn's risk for developing hyperbilirubinemia requiring treatment. A newborn's bilirubin level should be interpreted to determine what level of risk—low, low intermediate, high intermediate, high—they have of developing hyperbilirubinemia that requires phototherapy. Newborns in the high-intermediate or high-risk zones deserve additional consideration for the presence of risk factors that may be contributing to hyperbilirubinemia. Specifically, a blood type and direct Coombs' test should be obtained for newborns whose mothers are blood type O. If the baby is blood type A, B, or AB, this is referred to as a “setup” for ABO incompatibility. In this setting, a Coombs' test will evaluate the presence of anti-A or anti-B antibodies on the surface of the newborn's red blood cells that may be causing hemolysis. A positive Coombs' test does not automatically result in hyperbilirubinemia and, equally, a negative Coombs' test may be present in the setting of active hemolysis (e.g., G6PD deficiency).

The bilirubin risk zone can be used to help determine when the newborn should be reassessed for hyperbilirubinemia. As bilirubin levels peak around 3 to 5 days of age, determination of the newborn's risk is especially important for those discharged from the hospital prior to 72 hours of age as this will inform the decision regarding timing of outpatient follow-up. In general, newborns discharged prior to 24 hours of age should be seen by 72 hours, while those discharged between 24 and 48 hours of age should be seen by 96 hours. The majority of newborns will be discharged between 48 to 72 hours of age and they should be reevaluated in the outpatient setting by 120 hours of age. Those who have additional risk factors such as significant weight loss or an elevated bilirubin risk zone should be seen earlier in the outpatient clinic. After discharge, it is important for guardians to monitor their newborns for clinical

**Figure 1** Hour-specific nomogram indicating risk zone for serum bilirubin levels for newborns that predicts the likelihood that a subsequent bilirubin level will exceed the 95th percentile.

**Figure 2** Hour-specific nomogram indicating phototherapy thresholds for various risk categories for newborns  $\geq 35$  weeks' gestation.

signs of jaundice that may necessitate earlier medical follow-up care.

Both in the inpatient and outpatient settings, the TcB or TSB should be plotted on the hour-specific nomogram (Figure 2) to determine the level at which phototherapy should be initiated. The nomogram makes use of three separate curves that correspond to various risk factors for ABE, specifically isoimmune hemolytic disease, G6PD deficiency, asphyxia, lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0 g/dL. Those who are defined as lower risk are GA  $\geq$  38 weeks and well; medium risk are GA  $\geq$  38 weeks and have risk factors or are GA 35 to 37  $\frac{1}{7}$  weeks and well; higher risk are GA 35 to 37  $\frac{1}{7}$  weeks and have risk factors.

### Treatment

The treatment of hyperbilirubinemia is focused on effective and efficient removal of bilirubin from the bloodstream to prevent ABE and kernicterus. Guardians should be encouraged to feed their newborns frequently, a minimum of 8 to 12 times per day, especially for those who are breastfed, as frequent feeding will help establish the mother's milk supply. The newborn's weight and urine and stool output should be assessed daily during the inpatient hospitalization to determine adequate milk transfer. Mothers who intend to breastfeed but experience delayed lactogenesis should work with a lactation specialist and provide supplemental feeds (either in the form of formula or human donor milk) at appropriate volumes to decrease the enterohepatic circulation of bilirubin caused by low intake.

### Phototherapy

When a newborn's TSB surpasses the phototherapy threshold, phototherapy should be administered. Phototherapy removes bilirubin by converting it into lumirubin, a water-soluble molecule that can bypass the liver and be excreted in urine or stool. Phototherapy can be delivered using overhead lights or fiberoptic blankets that provide light in the 430 to 490 nanometer wavelength, which is most strongly absorbed by the bilirubin molecule. The total body surface area that is exposed to light should be maximized for effective phototherapy. To accomplish this, the newborn should receive phototherapy while only wearing eye protection and a diaper. The newborn's temperature and hydration status should be monitored. The manufacturer's instructions should be followed to safely administer phototherapy. It is important to remember that the clinical appearance of jaundice will be affected by phototherapy and thus cannot be used to estimate the degree of hyperbilirubinemia.

Bilirubin levels should be monitored as the newborn is receiving phototherapy. TcB measurements will not be accurate after phototherapy is initiated and the provider must rely on serum levels. For newborns being admitted for phototherapy after hospital discharge, the provider should obtain a baseline TSB prior to starting treatment. A repeat serum bilirubin level is typically obtained within 12 hours of phototherapy initiation to ensure that it is not continuing to rise. Subsequent checks can be ordered at the discretion of the clinician. For newborns with ongoing hemolysis or whose bilirubin levels are close to the exchange transfusion threshold, consideration should be given to earlier and more frequent TSB checks. A bilirubin level that continues to rise despite appropriate phototherapy should prompt the provider to consider other etiologies for hyperbilirubinemia. The provider should consider verifying a normal metabolic screen with the state lab and additional laboratory evaluation, including a direct bilirubin.

While the newborn is receiving phototherapy, every effort should be made to optimize feeding. For a breastfeeding mother, she may be encouraged to express milk either manually or using a pump as the newborn may be too inactive for effective milk transfer. The expressed milk can be fed back to the baby and additional supplementation may be offered if needed.

The duration of phototherapy will vary based on the newborn's age, presence of hemolysis, and other risk factors. There is no clear guidance as to when phototherapy should be stopped. Some providers will discontinue phototherapy when the TSB is at least 3 mg/dL below the phototherapy threshold. However, for those with ongoing hemolysis, an even lower level may be desirable due to concern for rebound hyperbilirubinemia. Rebound hyperbilirubinemia occurs when the TSB returns to or exceeds the AAP phototherapy threshold within 72 hours of terminating phototherapy. A calculator by Chang et al. has been developed (<https://pediatrics.aappublications.org/content/139/3/e20162896>) to help determine the probability of rebound hyperbilirubinemia for late preterm or term newborns.

### Exchange Transfusion

In the current era of universal screening for hyperbilirubinemia, the need for double volume exchange transfusion is rare for late preterm and full-term newborns. Exchange transfusion should be considered when the serum bilirubin exceeds the hour-specific threshold on the exchange transfusion nomogram (Fig. 3). The AAP recommends that any newborn whose TSB meets the exchange transfusion threshold or is at a level of 25 mg/dL, be admitted directly to the inpatient unit for treatment to avoid delays through the emergency department. A TSB at this level is considered a medical emergency and must be treated aggressively.

Exchange transfusion is a procedure where small, calculated aliquots of the newborn's blood are removed and replaced with donated reconstituted RBCs with plasma, preferably through two central lines, in an effort to remove the circulating bilirubin and antibodies. The procedure is continued until the total blood volume has been replaced twice. This is a risky procedure that must only be performed in a neonatal intensive care unit. The procedure carries a complication rate of about 12% and includes coagulopathy, infection, electrolyte imbalance, and even death. The newborn requires close monitoring during and after the procedure.

### Pharmacologic Treatment

For newborns with ongoing hemolysis due to ABO or Rh incompatibility whose TSB is continuing to rise despite phototherapy or for those approaching the exchange transfusion threshold, intravenous gamma globulin (IVIG, Gammagard)<sup>1</sup> may be administered. IVIG should be administered at 0.5 to 1 g/kg over 2 hours and repeated after 12 hours if necessary. Studies have shown that IVIG for newborns with hemolytic disease may reduce the need for exchange transfusion.

### Complications

The spectrum of complications associated with hyperbilirubinemia and its treatments range from mild to severe. Many newborns with hyperbilirubinemia who are approaching the phototherapy threshold may become increasingly tired and not feed effectively. This perpetuates the poor feeding and dehydration that contributed to their hyperbilirubinemia in the first place. Once phototherapy is initiated, efforts are made to maximize exposure to phototherapy, which results in maternal-newborn separation and may also compromise the breastfeeding relationship. Phototherapy has been shown to result in a small reduction in breastfeeding at 12 months and exclusivity at 1, 2, and 4 months.

The feared complications of severe hyperbilirubinemia, formerly termed kernicterus, are ABE and CBE. Bilirubin encephalopathy results from unconjugated bilirubin that crosses the blood-brain barrier and deposits in the brain tissue. The exact incidence of ABE is

<sup>1</sup>Not FDA approved for this indication.

**Figure 3** Hour-specific nomogram indicating exchange transfusion thresholds for various risk categories for newborns  $\geq 35$  weeks' gestation.

unknown, but in a large cohort of around half a million newborns in Northern California, less than 0.001% presented with ABE and all had TSB levels greater than 35. The symptoms of ABE typically progress through three stages: early, intermediate, and advanced. In the early stage, newborns may present with increased sleepiness, hypotonia, and a high-pitched cry. As symptoms progress to the intermediate stage, the newborn may be lethargic, jittery, and develop backward arching of the neck and trunk (retrocollis and opisthotonos). Finally, in the advanced stage, the newborn develops seizures, hypertonicity, and inconsolability. Death often results from seizures or respiratory failure.

CBE refers to the permanent sequelae of bilirubin-induced neurotoxicity and develops during the first year after birth. In the same cohort in Northern California, newborns who developed cerebral palsy all had TSBs that were at least 5 mg/dL above the exchange transfusion threshold. Additional symptoms of CBE include sensorineural hearing loss, gaze abnormalities, and dental enamel hypoplasia.

Recently, reports have been published regarding potential long-term complications associated with phototherapy. In a study analyzing data of nearly half a million patients, an increased risk of epilepsy was seen, though only in boys. Two studies with very large datasets looked at the potential associations between phototherapy and cancer. After accounting for confounding variables, an association persisted for myeloid leukemia, but this was based on two newborns who received higher doses of phototherapy. For newborns with Down

syndrome who have a baseline risk of cancer that is 10 times higher than the general population, extra caution when initiating phototherapy is warranted. Mechanical issues related to phototherapy are rare but do include hypothermia. For patients with porphyria, phototherapy can result in a blistering skin reaction and is therefore an absolute contraindication.

## MITOCHONDRIAL DISEASE

Method of

Sonal Sharma, MD; Amy Goldstein; and Marni J. Falk, MD

### CURRENT DIAGNOSIS

- Mitochondrial disease diagnosis may be a challenge due to their extensive phenotypic and genotypic heterogeneity.
- Biochemical analyses of blood, urine, and cerebrospinal fluid are utilized to evaluate for evidence of mitochondrial dysfunction that may be present in some cases. However, there are no highly specific or sensitive biomarkers applicable for all forms of mitochondrial disease.
- Diagnosis predominantly relies on next generation sequencing molecular analyses for pathogenic variants in hundreds of genes in both nuclear DNA and mitochondrial DNA (mtDNA). Front-line genomic testing is performed in noninvasive tissues (blood, urine, saliva, etc.).
- Invasive tissue-based diagnostic testing may be beneficial when noninvasive tissue genetic and biochemical testing is inconclusive. Muscle, liver, and/or fibroblast histology, immunohistochemistry, electron microscopy, electron transport chain enzyme activity analyses, fatty acid oxidation analysis, biochemical analyte analyses such as coenzyme Q10 level analysis, mtDNA genome sequencing and deletion quantitation, and mtDNA content analysis are specific tests that may be indicated.

### CURRENT THERAPY

- No cures exist for mitochondrial disease.
- Symptom management is the mainstay of mitochondrial disease care.
- Clinicians employ a variety of mitochondrial medicine regimens consisting of vitamins, enzyme cofactors, antioxidants, and metabolic modifiers to enhance electron transport chain enzyme function and reduce toxic metabolites. The use of mitochondrial medicine therapies is based on contemporary understanding of mitochondrial disease pathophysiology to improve resiliency and prevent decompensation, although their clinical efficacy has not been proven in randomized clinical trials. In some cases, mitochondrial medicines may alter disease progression, such as oral arginine to prevent recurrent metabolic strokes.
- Targeted treatment therapies for mitochondrial diseases are increasingly being developed for specific molecular subtypes.
- An increasing array of clinical treatment trials evaluating small molecules and genetic therapies are underway or being planned to develop effective treatment strategies that improve health in patients with primary (genetic-based) mitochondrial disease.

### Epidemiology

Mitochondrial diseases are a clinically heterogeneous group of genetic disorders that are characterized by impaired energy production. Primary mitochondrial diseases are caused by pathogenic variants in nuclear DNA (nDNA) or mitochondrial DNA (mtDNA) genes that play a vital role in mitochondrial structure and function. The prevalence of childhood-onset mitochondrial disease (<16 years of age) has been estimated as 5 to 15 cases per 100,000 individuals. A study in North East of England reported the prevalence of mitochondrial disease per 100,000 individuals in adults due to mtDNA mutations as 9.6 cases and those due to nDNA mutations as 2.9 cases. However, prevalence of some mitochondrial disease

subtypes may be higher in regions with specific genetic founder effects.

### Pathophysiology

Mitochondria are double membrane-bound organelles present in all nucleated eukaryotic cells. The fundamental function of mitochondria is energy production through the process of oxidative phosphorylation (OXPHOS) that occurs in the respiratory chain. In this aerobic process, reducing equivalence generated through the biochemical processing of cellular nutrients enter the electron transport chain (ETC) that is composed of complexes I, II, III, and IV, with oxygen serving as the final electron acceptor (Figure 1). Electron transfer powers complexes I, III, and IV to generate a proton gradient across the inner mitochondrial membrane, which is dissipated to drive the production of energy by complex V (ATP synthase) in the chemical form of adenosine triphosphate (ATP).

Independent from the nuclear genome, mitochondria have their own mtDNA genome composed of 37 genes. Multiple mitochondria exist per cell, with multiple mitochondrial genome copies in each mitochondrion. Of the 37 genes, 13 encode proteins that are all core structural subunits of ETC complexes, while 22 encode transfer RNAs and two encode ribosomal RNAs to assist in the mitochondrial translation of these 13 protein-coding subunits. Nuclear genes are fundamentally important to mitochondria structure and function, with up to 1500 total proteins comprising mitochondria in different tissues. Thus there exists remarkable heterogeneity in the candidate genes that may directly disrupt mitochondrial dysfunction. Indeed, primary mitochondrial diseases are currently known to result from pathogenic variants in any of the 37 mtDNA genes, single or multiple large-scale deletions of mtDNA involving multiple mtDNA genes, and pathogenic variants in at least 350 nuclear genes. As mtDNA genomes are inherited through the maternal germ cells (oocytes), mtDNA disorders are maternally inherited, or rarely may occur de novo in the affected individual. By contrast, nDNA gene disorders may variably be inherited in an autosomal dominant, autosomal recessive or X-linked pattern. The majority of pathogenic variants cause mitochondrial disease by disrupting OXPHOS, which results in lowered ATP production, increased oxidative stress, and dysfunction of other interlinked metabolic pathways such as fatty acid oxidation. Some nuclear gene pathogenic variants may also cause mitochondrial diseases known as mtDNA depletion syndromes, which result from mtDNA genome instability and reduction in the mtDNA genome content in each mitochondrion.

A pathogenic mtDNA variant is usually present only in a proportion of all mtDNA genomes within a cell or tissue. This phenomenon of harboring healthy or “wild-type” mtDNA genomes as well as affected or “mutant” mtDNA genomes is termed heteroplasmy. Many mtDNA pathogenic variants only cause clinical manifestations when present in a given tissue at a certain level of heteroplasmy, which is known as “threshold effect.” The precise threshold for symptom occurrence is not clear for every disease-causing mtDNA pathogenic variant. A general rule-of-thumb is that heteroplasmy levels above 70% are more likely to manifest with severe mitochondrial disease symptoms. However, this depends on the specific pathogenic variant and tissue tested, as some pathogenic variants may cause severe disease at much lower heteroplasmy levels discernible in peripheral tissues, and some may appear at much higher levels even including homoplasmic mutant (with no wild-type copies present) with little to no clinical symptoms. Environmental stressors such as intercurrent infections, fevers, fasting, and lifestyle choices such as nutrition, exercise, and medication or environmental exposures may all influence the onset and progression of clinical symptoms in individuals harboring pathogenic variants in mtDNA.

### Clinical Manifestations

Due to impairment of the common pathway of energy production, mitochondrial diseases have wide-ranging variability, even among affected family members, in their age of onset and particular organ system involvement. Secondary mitochondrial

**Figure 1** Mitochondrial respiration. The mitochondrial electron transport chain consists of four protein complexes (I–IV) embedded in the inner mitochondrial membrane that are coupled to a fifth (V) unlinked complex, ATP synthase. Reducing equivalents such as NADH and FADH<sub>2</sub> generated from other biochemical pathways, mainly the tricarboxylic acid (TCA) cycle and fatty acid oxidation, are oxidized by complex I and II. Electrons from complex I and II are transported to reduce coenzyme Q10 (CoQ10), which transports electrons to complex III, then to cytochrome C and finally to complex IV. The electrons are transferred by complex IV to molecular oxygen in a process that generates water. Complex I, III, and IV pump protons, which result from these reactions from the mitochondrial matrix into the intermembrane space, thereby creating a proton gradient. These protons reenter the matrix through complex V and drive the reaction to synthesize adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and inorganic phosphate. Energy stored in the phosphate bonds of the ATP molecule power multiple cellular reactions. Adapted from Hagberg H, Mallard C, Rousset CI, Thornton C: Mitochondria: hub of injury responses in the developing brain. *Lancet Neurol* 13(2):217–232, 2014.

dysfunction may also occur in other genetic or complex classes of disease that affect energy production or upon exposure to certain environmental factors and medications. Patients with mitochondrial disease report an average of 16 symptoms involving different organ systems, with a range of 7 to 35 symptoms per patient (Figure 2). Common symptoms include fatigue, exercise intolerance, muscle weakness, developmental delay or regression, poor growth, metabolic strokes, intellectual disability, seizures, dysautonomia, cardiomyopathy, arrhythmia, sensorineural hearing loss, endocrinopathies (diabetes mellitus, thyroid abnormalities, pancreatic, and adrenal dysfunction) as well as impairment of vision, immune, gastrointestinal, liver, and kidney function. It is prudent for primary care physicians to suspect mitochondrial disease in patients who present with typical “red-flag” symptoms of mitochondrial disease or unexplained symptoms involving three or more unrelated organ systems, although in some cases only single organ dysfunction may be present at presentation. It is also important to recognize that disease onset in a given individual may occur at any age from prenatal to adult, and the severity of symptoms tends to worsen in a nonlinear, progressive manner. There can be episodes of acute decline triggered by infection or other stressors, followed by periods of stability.

Emergencies in mitochondrial disease include acute decompensation that may result from increased metabolic demand secondary to physiologic stressors including ongoing infection, systemic illness, fasting, dehydration, surgery, and/or anesthesia. The presence of neurologic regression, focal neurologic deficits, altered mental status, or seizures should raise concern for acute metabolic stroke. It is also vital to recognize signs of severe metabolic acidosis in patients

with primary mitochondrial disease, which include altered mental status, hyperpnea, bradycardia, arrhythmia, hypotension, nausea, vomiting, and severe lethargy.

An additional challenge to the recognition of mitochondrial disease is the complex relationship between genotype and clinical phenotype. A specific gene pathogenic variant can result in different clinical symptoms. A clear example is the m.3243A>G pathogenic variant in *MT-TL1*, which can cause chronic progressive external ophthalmoplegia (CPEO), mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS), or maternally inherited diabetes and deafness (MIDD). Similarly, a specific syndrome can result from numerous genetic etiologies such as Leigh syndrome (subacute necrotizing encephalomyelopathy), which can be caused by pathogenic variants in approximately 100 nuclear and mtDNA genes. The clinical symptoms of common mitochondrial diseases are described in Table 1.

## Diagnosis

### Noninvasive Biochemical Analysis

The diagnosis of mitochondrial disease requires a thoughtful, stepwise approach (Figure 3). Noninvasive laboratory screening using blood and urine samples involves chemistry and biochemistry tests to determine the patient’s metabolic stability as well as other organ involvement. Standard biochemistry profiling tests include comprehensive metabolic profile, plasma lactate, plasma pyruvate, lactate to pyruvate ratio, quantitative plasma amino acid analysis, plasma carnitine levels and acylcarnitine profile, ammonia, plasma glutathione level, GDF-15 level, and quantitative urine organic

**Figure 2** Clinical symptoms in mitochondrial disease are variable and usually involve multiple high-energy demand organ systems. Gorman GS, Chinnery PF, DiMauro S, et al: Mitochondrial diseases. *Nat Rev Dis Primers* 2:16080, 2016.

acid analysis. Tests for secondary organ involvement may include complete blood count with differential, creatine kinase, hemoglobin A1c, lipoprotein profile, iron profile and ferritin, thyroid screen, cortisol, adrenocorticotropic hormone, parathyroid hormone, amylase, lipase, fecal elastase, immunoglobulin levels, and

urinalysis. However, these tests are not specific for mitochondrial disease and none have sufficiently high sensitivity and specificity to be useful as a biomarker sufficient to confirm or refute the diagnosis of mitochondrial disease. For example, elevated plasma lactate may occur in mitochondrial disease, but levels may also be normal

**TABLE 1** Presentation Overview of Common Mitochondrial Disease Clinical Syndromes

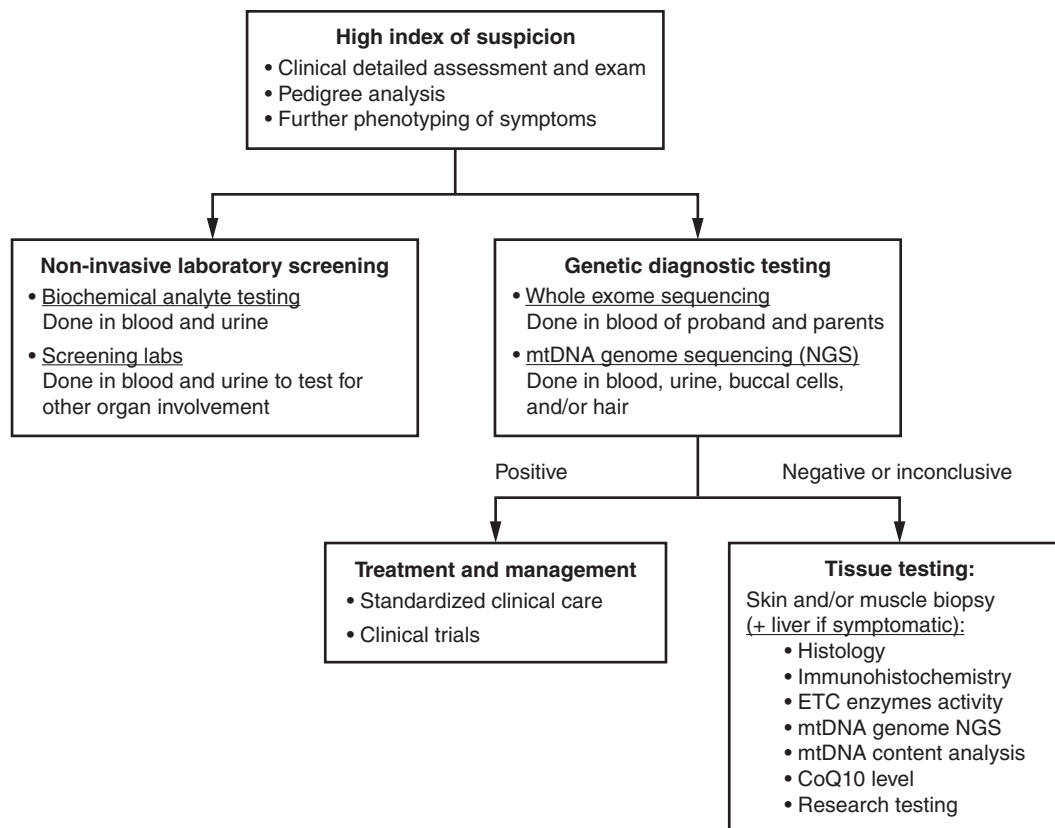

DISEASE	GENETIC ETIOLOGY	CLINICAL FEATURES	OTHER FINDINGS	NEUROIMAGING	SPECIFIC TREATMENT
Mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes (MELAS)	80%: m.3243A>G variant in <i>MT-TL1</i> ; <10%: variants in <i>MT-ND5</i> ; less common—15 other mitochondrial disease genes	Seizures, recurrent headaches, stroke-like episodes, cortical vision loss, muscle weakness, recurrent vomiting, short stature, hearing impairment, impaired thinking, diabetes mellitus (type 1 or 2), developmental delay	Lactic acidemia or acidosis in blood and cerebrospinal fluid (CSF), elevated CSF protein, Muscle biopsy: Ragged red fibers, ETC: Low complex I and/or complex IV activities	MRI: asymmetric, T2 hyperintensity not corresponding to specific vascular distribution during stroke-like episodes with predominant posterior cerebrum involvement, slow spreading of stroke like lesion over weeks; MRA: usually normal; MRS: elevated N-acetylaspartate (NAA) and lactate; CT: basal ganglia calcification	Acute or subacute stroke episode: intravenous (IV) arginine <sup>1</sup> 500 mg/kg/day over 60 min for 3–5 days; Prevention of recurrent stroke: oral arginine <sup>7</sup> 150–300 mg/kg/day
Leigh syndrome (subacute necrotizing encephalomyelopathy)	>80 nuclear genes (most common <i>SURF1</i> , in up to 10% of Leigh syndrome cases) 14 mtDNA genes ( <i>MT-ATP6</i> associated with ~50% of all mtDNA-based Leigh syndrome)	Psychomotor retardation or regression, usually provoked by illness followed by a period of stabilization, hypotonia, spasticity, movement disorders, cerebellar ataxia, peripheral neuropathy, hypertrophic cardiomyopathy	Lactic acidosis in blood and CSF during intercurrent illness, ratio of lactate to pyruvate is normal to low in pyruvate dehydrogenase (PDH) deficiency, increased alanine on plasma amino acids reflective of persistent hyperlactic acidemia, respiratory chain complex I, II, III, IV, or V deficiency depending on genetic etiology	MRI: bilateral symmetric T2 signal hyperintensities in the basal ganglia and/or brainstem; spinal cord involvement can appear as demyelinating lesions involving white matter or ischemic/infectious lesions involving gray matter MRS: elevated lactate	Biotin-thiamine responsive basal ganglia disease associated with mutation of <i>SLC19A3</i> : oral biotin <sup>7</sup> (5–10 mg/kg/day) and thiamine <sup>1</sup> (in doses ranging from 300–900 mg/day); Biotinidase deficiency: oral biotin 5–10 mg/day; Coenzyme Q10 (CoQ10) deficiency: ubiquinol <sup>7</sup> (reduced) formulation preferred, at dose up to 8 mg/kg/day If ubiquinol <sup>7</sup> (oxidized) formulation is used, oral CoQ10 10–30 mg/kg/day in children, 1,200–3,000 mg/day in adults
Neuropathy, Ataxia, and Retinitis Pigmentosa (NARP)	<i>MT-ATP6</i>	Continuum of clinical spectrum of Leigh syndrome, muscle weakness, neuropathy, ataxia, seizures, retinitis pigmentosa or optic atrophy, learning difficulty	Electromyography (EMG)/Nerve Conduction Velocity (NCV) studies: sensory or sensorimotor axonal polyneuropathy	MRI: cerebral and/or cerebellar atrophy	
Myoclonic Epilepsy associated with Ragged Red Fibers (MERRF)	>80%: m.8344A>G variant in <i>MT-TK</i> , 7 other mtDNA genes also associated with MERRF phenotype	Myoclonus is often the first symptom followed by generalized epilepsy, ataxia, weakness, exercise intolerance, dementia, peripheral neuropathy, hearing loss, short stature, optic atrophy, ptosis, ophthalmoplegia, retinitis pigmentosa, cardiomyopathy, dysrhythmias such as Wolff-Parkinson-White syndrome, multiple lipomas	Lactic acidemia or acidosis in blood and CSF, lactate and pyruvate are elevated at rest and increase excessively after moderate activity, elevated CSF protein, Electron transport chain (ETC) enzyme activity studies: deficiency of respiratory complexes I, III, or IV with mtDNA- encoded subunits Muscle biopsy: ragged red fibers, hyperactive fibers with succinate dehydrogenase stain	MRI: brain atrophy, basal ganglia lesions, bilateral putaminal necrosis, brainstem and cerebellum atrophy	

(Continued)

**TABLE 1** Presentation Overview of Common Mitochondrial Disease Clinical Syndromes—cont'd

DISEASE	GENETIC ETIOLOGY	CLINICAL FEATURES	OTHER FINDINGS	NEUROIMAGING	SPECIFIC TREATMENT
Leber's Hereditary Optic Neuropathy (LHON)	>90%: m.3460G>A in <i>MT-ND1</i> , m.11778G>A in <i>MT-ND4</i> , or m.14484T>C in <i>MT-ND6</i> . Six other mtDNA genes may also be causal	Bilateral, painless, subacute visual failure (starts as central visual field blurring in one eye followed by involvement of other eye 2–3 months later), males are four–five times more likely to be affected than females, penetrance 15% in females and 50% in males, with penetrance exacerbated by smoking and alcohol exposure, visual acuity is reduced to counting fingers or worse, optic disc atrophy after acute phase, ataxia, peripheral neuropathy, myopathy, movement disorders, multiple sclerosis-like illness, cardiac arrhythmias	ECG: pre-excitation syndrome, Visual field testing: enlarging dense central or centrocecal scotoma, ETC enzyme activity analysis: m.3460G>A in <i>MT-ND1</i> associated with severe complex I deficiency	MRI: white matter lesions and/or a high signal within the optic nerves	Treatment of raised intraocular pressure Idebnone (available in Europe, not in the United States) and/or antioxidant vitamin supplementation (N-Acetylcysteine, <sup>1</sup> vitamin E, B12, and C) may be tried to stabilize visual loss and/or accelerate visual recovery to improve final visual outcome
Chronic Progressive External Ophthalmoplegia (CPEO)	Single, large scale mtDNA deletion syndrome (single large-scale deletion ranging in size from 1.1–10 kilobase): can be identified in skeletal muscle, and multiple mtDNA deletions may be seen in <i>POLG</i>	Ptosis, ophthalmoplegia, oropharyngeal weakness, proximal limb weakness, exercise intolerance		MRI: leukoencephalopathy, cerebral or cerebellar atrophy, basal ganglia and brainstem lesions (Leigh syndrome pattern)	Eyelid slings and/or ptosis repair for severe ptosis, eyeglass prisms for diplopia, eye drops for dry eye
Kearns-Sayre syndrome (KSS)	Single large-scale mtDNA deletion syndrome can be identified in blood leukocytes, buccal sample, urine sediment, or muscle	Pigmentary retinopathy, progressive ophthalmoplegia, cerebellar ataxia, impaired intellect, sensorineural hearing loss, oropharyngeal and esophageal dysfunction, muscle weakness, exercise intolerance, cardiac conduction block, endocrinopathy (diabetes mellitus, hypothyroidism, hypoparathyroidism, adrenal insufficiency), renal impairment	Lactic acidemia or acidosis in blood and CSF, elevated CSF protein, Muscle biopsy: ragged red fibers, ETC enzyme activity analysis: reduced activity of complexes I, III, and/or IV	MRI: Leukoencephalopathy, cerebral or cerebellar atrophy, basal ganglia and brainstem lesions (Leigh syndrome pattern)	Prophylactic placement of cardiac pacemakers in individuals with cardiac conduction block, Folic acid supplementation <sup>1</sup> in individuals with KSS with low CSF 5-methyltetrahydrofolate, Pancreatic enzyme replacement Hearing aids and/or cochlear implants for sensorineural hearing loss
Pearson syndrome	Single, large scale mtDNA deletion syndrome can be identified in blood leukocytes	Infancy or early childhood onset, sideroblastic anemia typically transfusion-dependent until resolution in early childhood, growth failure, and exocrine pancreatic dysfunction	Macrocytic, sideroblastic anemia with a variable degree of neutropenia and thrombocytopenia (pancytopenia), normocellular bone marrow, hemosiderosis, and ringed sideroblasts	MRI: white matter involvement	Pancreatic enzyme replacement, Transfusion therapy for sideroblastic anemia

<sup>1</sup>Not FDA approved for this indication.

**Figure 3** Algorithm for clinical diagnostic evaluation of mitochondrial disease. Muraresku CC, McCormick EM, Falk MJ: Mitochondrial disease: Advances in clinical diagnosis, management, therapeutic development, and preventative strategies. *Curr Genet Med Rep* 6(2):62–72, 2018.

or only intermittently increased under some scenarios or in certain disease subtypes. Further, elevated lactate results in individuals without primary mitochondrial disease from poor tissue perfusion, stroke, sepsis, seizures, or improper handling of the sample.

### Neuroimaging

Mitochondrial disease patients with clinical CNS involvement may have nonspecific brain and spine magnetic resonance imaging (MRI) abnormalities. Bilateral, symmetric involvement of deep gray structures in the absence of hypoxia, ischemia, or infection should raise suspicion for mitochondrial dysfunction. However, patients with CNS involvement can have a normal MRI depending on the timing of the scan, as some findings may fluctuate, both resolving or newly occurring over time. Certain mitochondrial disease syndromes can be associated with hallmark neuroimaging findings. Leigh syndrome is associated with progressive signal abnormality (T2 hyperintensity, T1 hypointensity) most commonly in the lentiform nuclei (putamen and globus pallidus) and caudate nuclei of the basal ganglia. Signal abnormalities in Leigh syndrome may also involve the thalamus, periaqueductal gray, tegmentum, red nuclei, and dentate nuclei. In some cases, there can also be extensive gliosis and cystic degeneration of white matter and marked global atrophy as the disease progresses. MELAS syndrome is associated with landmark MRI affecting gray matter and not confined to any specific vascular territory. While any cortical location may be involved in MELAS, a predilection for the occipital lobes exists, with clinical correlate of vision loss during a stroke-like episode. Diffuse white matter involvement, particularly in the periventricular and centrum semiovale region, may also occur in multiple mitochondrial disease clinical syndromes such as MELAS, Kearns-Sayre syndrome, and mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) syndrome.

### Genetic Diagnostic Testing

Over the past decade, substantial advancements have occurred in the accessibility, affordability, clinical utility, and diagnostic yield of whole exome sequencing (WES) for mitochondrial disease diagnosis. WES is now considered to be the first-line genetic test, with demonstrated improved performance over gene panel-based approaches due to the rapid pace of gene discovery that requires frequent updating of gene panels, as well as the clinically heterogeneous nature of mitochondrial disorders that would otherwise require sequential use of multiple different gene panels. Trio-based WES testing is preferred, as this incorporates analysis of proband and both parental samples to allow accurate segregation analysis of multiple variants identified in a proband as well as determination of autosomal dominant disorders with de novo occurrence in the proband. An important application of WES raw data is reanalysis at a future date, which may identify novel gene disorders that were previously not recognized by the diagnostic laboratory at the time of the initial WES report. This is particularly important in pediatric patients, in whom nDNA mutations are the underlying cause of 75% of mitochondrial disease. Appropriate use of WES in the clinical setting requires genetic counselor support for completing informed consent, to understand testing limitations and choices in the type of results that will be returned. Lack of insurance coverage may limit the ability to pursue WES for a specific patient, which may often require insurance preauthorization and escalated coverage requests and justification by the clinician. WES has limitations in the types of genetic errors that may be found, as it may miss certain gene regions not targeted and analyzed, is unable to detect genomic copy number variation, and is unable to be used for triple repeat size analysis. For these reasons, whole genome sequencing (WGS) is emerging as a new clinical test that is able to provide a more comprehensive “exome” than WES, as well as evaluate for these other types of genetic mutations. Further, while WES does not include the mtDNA genome unless it is specifically targeted for

capture and analysis, WGS coverage inherently does include the entire mtDNA genome.

Commonly, mtDNA genome sequencing is performed by next-generation sequencing (NGS) methodologies, which can be performed in a stand-alone fashion or in many cases ordered concurrently with WES. Approximately 75% of mitochondrial disease among adults result from pathogenic variants in the mtDNA genome. NGS-based tests may accurately detect single nucleotide variants as well as single or multiple large-scale deletions or duplications down in many cases to 1% heteroplasmy levels. NGS testing detects the breakpoints of large-scale rearrangements in mtDNA but is not reliable for their heteroplasmy quantitation due to polymerase chain reaction (PCR)-based overamplification of deleted genomes; thus performance of additional clinical tests such as digital droplet PCR is required to accurately quantify the mtDNA deletion(s) heteroplasmy level in a given tissue. While most mtDNA mutations are detectable in blood, saliva, or urinary sediment, it is important to note that some mutations, such as single large-scale deletions and other mtDNA single nucleotide variants may only be discernible in postmitotic or symptomatic tissues like muscle; thus a normal mtDNA genome sequence test in a peripheral tissue may need to be followed by symptomatic tissue-based mtDNA genome sequencing if clinical suspicion remains. Additionally, the blood heteroplasmy level of some mtDNA point mutations may decline with age, as is known to commonly occur at a rate of 1% per year for the m.3243A>G mutation. mtDNA genome depletion detectable on PCR-based mtDNA content analysis of muscle or liver may also occur, which when found is indicative that any of dozens of known nuclear gene etiology are present that underlies imbalance in the mtDNA genome and nucleotide pools.

If a mtDNA mutation of uncertain significance is identified, heteroplasmy levels of that variant should be tested by ordering clinical testing in as many tissues as possible (e.g., blood, buccal or saliva, fibroblast cells, urine sediment, muscle, etc.). Commonly, pathogenic variants have higher heteroplasmy levels found in clinically symptomatic but are only rarely homoplasmic. Measuring levels of heteroplasmy of the suspected pathogenic variant in tissues of both affected and unaffected maternal relatives may also be beneficial to aide in its pathogenicity assertion determination. The presence of the same or higher heteroplasmy level of a specific mutation in unaffected maternal relatives decreases its likelihood of being pathogenic in the proband.

### Invasive Tissue Testing

When genetic diagnostic testing in noninvasive tissues is unrevealing or identifies variants of uncertain significance, tissue biopsies may be useful to obtain sample in which to perform extensive histologic, immunohistochemical, electron microscopy, genetic, and biochemical analysis. Ideally, the most profoundly affected tissue in a patient is the best option. Muscle is commonly affected in mitochondrial disease patients and can be obtained by open biopsy or percutaneous needle biopsy; the right leg vastus lateralis tissue is the standard sample in which normative values have been obtained for biochemical testing of mitochondrial function. While skin is a less metabolically active tissue, skin-derived primary fibroblast cell lines are readily obtainable without general anesthesia and have been widely demonstrated to have utility for a wide array of biochemical analyses that may be informative about mitochondrial function. Liver biopsy can be beneficial in select patients with hepatic involvement.

All three tissues can be clinically tested for respiratory chain enzyme activity spectrophotometric analyses and (where available) high-resolution respirometry studies of integrated OXPHOS capacity. Histologic and immunohistochemical analysis of muscle can reveal evidence of myopathy or lipid or glycogen storage. Ragged-red fibers on modified Gomori trichrome staining may also be seen as red granular deposits of mitochondria in the subsarcolemmal space, which are suggestive of a mitochondrial proliferative response often occurring in response to mtDNA-based disorder. Immunohistochemical analysis of muscle involves several stains to screen mitochondrial enzymatic activities such as NADH

dehydrogenase for evaluation of complex I activity, succinate dehydrogenase (SDH) for complex II activity, and cytochrome c oxidase (COX) for complex IV activity. COX-deficient fibers are a nonspecific finding that may be indicative of a mtDNA disorder. Stains are also used to evaluate for a host of other muscle diseases that may aid in the differential diagnosis of mitochondrial disease. Electron microscopy study of muscle in patients with mitochondrial disease may reveal increased mitochondrial number and size, distorted or absent cristae, and paracrystalline or “parking lot” inclusions. Liver histology may reveal microvesicular or macrovesicular steatosis as well as eosinophilic granulations, representing proliferation of mitochondria. Additional biochemical analysis may include quantification of coenzyme Q10 that plays an important role in ETC; while the concentration of coenzyme Q10 varies greatly in tissues, leukocyte Q10 levels have been shown to be most indicative of tissue coenzyme Q10 deficiency.

Quantitative PCR analysis of mtDNA content in liver or muscle tissue is important to identify mtDNA depletion syndromes. mtDNA genome sequencing is also informative, as above, to complete the evaluation for a suspected mtDNA disorder.

## Treatment

### Acute Symptom Management

Maintenance of adequate hydration through enteral or intravenous (IV) fluids with dextrose to prevent a catabolic state is an important intervention to consider during an episode of acute decompensation. If a stroke-like lesion is identified on brain MRI, treatment should be pursued with IV arginine<sup>1</sup> to aid in vasodilation through its conversion to nitric oxide mediated by nitric oxide synthase. Arginine has proven effective in decreasing severity of stroke like symptoms, reducing frequency of stroke-like episodes, and reducing tissue injury in patients with MELAS and also found to be effective in pediatric Leigh syndrome, particularly those with hemiplegic symptoms, with 50% of patients in a recent study at our center back to their neurologic baseline by hospital discharge. High-dose steroids may also be considered for treatment of vasogenic edema, which can be associated with stroke-like lesions. If severe metabolic acidosis is identified, subspecialty consultation with metabolic medicine, intensive care, or nephrology should be pursued and buffers such as sodium bicarbonate<sup>1</sup> therapy should be considered.

Additional acute symptoms should be managed by organ-based specialists, such as neurology for acute epilepsy or stroke, nephrology for acute renal failure, ophthalmology for acute visual changes, gastroenterology for obstruction or dysmotility, and cardiology for arrhythmia or cardiac failure.

### Chronic Management

Unfortunately, no FDA approved treatments exist for mitochondrial disease at this time. Consensus expert opinion has guided the therapeutic dosing of mitochondrial supplemental medicines, colloquially referred to as a “cocktail,” based on underlying known pathophysiology of mitochondrial disease, animal or cellular experimental studies, and expert clinical experience. Vitamins and nonvitamin cofactor serve essential roles for several cellular reactions. These include vitamin B1 (thiamine, a cofactor for the pyruvate dehydrogenase complex), vitamin B2 (riboflavin, promotes assembly of complex I), vitamin B3 (niacin or nicotinic acid, a precursor of nicotinamide adenine dinucleotide that serves as the primary electron donor to complex I), vitamin B7 (biotin, cofactor for mitochondrial carboxylases), and vitamin B9 (folic acid, where cerebral folate deficiency is associated with white matter changes in mitochondrial disease that may be responsive to folinic acid that crosses the blood–brain barrier). Antioxidants are empirically used to reduce oxidative stress both in the mitochondria and throughout the cell that occurs commonly in mitochondrial disease, including vitamin E, alpha-lipoic acid,<sup>1</sup> coenzyme Q10,<sup>1</sup> taurine,<sup>1</sup> and N-acetylcysteine (Acetadote).<sup>1</sup> Amino acid therapies commonly used to prevent stroke-like episodes in mitochondrial disease patients include arginine,<sup>1</sup> citrulline,<sup>1</sup> and/or

<sup>1</sup>Not FDA approved for this indication.

taurine. High-dose biotin<sup>1</sup> and thiamine<sup>1</sup> may be indicated in biotin-thiamine-responsive basal ganglia disease. L-creatine<sup>1</sup> may be helpful in myopathy to improve phosphocreatine energy stores. Lutein<sup>1</sup> is commonly recommended in individuals with pigmentary retinopathy.

While L-carnitine (Carnitor)<sup>1</sup> has historically been widely used in mitochondrial disease, its use is associated with long-term risk of coronary artery disease in the general population, so is not used in mitochondrial disease patients only for documented carnitine deficiency or in specific fatty acid oxidation disorders. As the molecular basis for specific patient's symptoms are increasingly recognized, additional therapies may be rationally considered to address their unique cellular pathophysiology. Additional, optimizing nutrition, hydration, and exercise are key components of optimizing long-term management and health outcomes in mitochondrial disease.

### Preventative Therapies

Preimplantation genetic diagnosis is available for nuclear gene causes of primary mitochondrial disease when the causal gene pathogenic variant(s) are known in advance in a given family. Preimplantation genetic diagnosis for mtDNA pathogenic variants has become increasingly available and reliably performed in several European countries but remains limited in the United States at the time of this writing. Utilizing mitochondrial replacement therapies (MRT) to not just diagnose but actively reduce the heteroplasmy level for a known pathogenic mtDNA variant in oocytes or early-stage embryos remains legally prohibited in the United States at the time of this writing but is being performed under strict government oversight for select patients in the United Kingdom.

### Future Therapies

Therapies under active development for mitochondrial diseases include gene-editing techniques to correct specific pathogenic variants in nuclear and mtDNA genes, intramitochondrial RNA or protein delivery (to replace mutated mitochondrial proteins), cellular therapies to shift mtDNA heteroplasmy levels (selectively damaging mutated mtDNA to increase proportion of wild type mtDNA), and a host of pharmacologic drug therapies for a wide range of mitochondrial disease molecular causes, clinical subtypes, and health outcomes. Clinical trials for mitochondrial disease can be explored on <https://clinicaltrials.gov>.

### Monitoring

Annual monitoring with cardiology, audiology, ophthalmology, and endocrinology is recommended to evaluate for the development of often-treatable organ-specific manifestations of mitochondrial disease. Growth and development should be closely monitored in children.

Specialists commonly needed to care for mitochondrial disease patients include a complex care coordinating primary care physician, geneticist or mitochondrial medicine clinician, neurologist, gastroenterologist, cardiologist, ophthalmologist, physiatrist, and therapists with expertise in physical, occupational, and speech/swallowing therapy. Other specific evaluations such as nephrology, neuropsychology, psychiatry, or exercise physiology evaluation may be helpful to pursue based on symptoms present. Laboratory measurement of certain analytes such as glutathione<sup>1</sup> (to support administration and dose optimization of n-acetylcysteine), leukocyte CoQ10 (for dosing of coenzyme Q10), and plasma amino acids (for dosing of arginine or citrulline) is helpful for management of mitochondrial supplements.

### Considerations

There are few absolute medication prohibitions in mitochondrial disease, with careful consideration of the health status and potential benefit and risk of each medication the most prudent course. However, some medications are contraindicated in specific mitochondrial disease disorder, such as valproic acid that may induce fulminant liver failure in *POLG*-related disease and aminoglycosides, which can cause ototoxicity in certain mitochondrial diseases (m.1555A > G and m.1494C > T). Further, statins may induce or exacerbate

myopathy by impairing coenzyme Q10 synthesis and inducing mtDNA depletion that may be reversible over time when statin therapy is discontinued. Prolonged use of certain anesthetics such as propofol (Diprivan) (for longer than 30–60 minutes) and volatile anesthetics (sevoflurane [Ultane], isoflurane [Forane, Terrell], etc.) should be carefully administered by knowledgeable clinicians or avoided as they can inhibit complex I activity. Indeed, a recent consortium review found that many medications previously “contraindicated” were being needlessly avoided by the mitochondrial disease patient population and rather, should each be discussed thoroughly with the individual treating clinicians.

### Conflicts of Interest

SS and AG have no relevant conflicts of interest to declare. MJF is coinventor on International Patent Application No. PCT/US19/39631 entitled “Compositions and Methods for Treatment of Mitochondrial Respiratory Chain Dysfunction and Other Mitochondrial Disorders and Methods for Identifying Efficacious Agents for the Alleviating Symptoms of the Same,” filed in the name of The Children’s Hospital of Philadelphia on June 27, 2019. MJF is a scientific advisory board member with equity interest in RiboNova, Inc., and scientific board member as paid consultant with Khondrion and with Larimar Therapeutics.

MJF has previously been or is currently engaged with several companies involved in mitochondrial disease therapeutic preclinical and/or clinical stage development as a paid consultant (Astellas [formerly Mitobridge] Pharma, Inc., Casma Therapeutics, Cycleron Therapeutics, Imel Therapeutics, Minovia Therapeutics, NeuroVive Pharmaceutical, Reneo Therapeutics, Stealth BioTherapeutics, Zogenix, Inc.) and/or a sponsored research collaborator (AADI Therapeutics, Astellas [formerly Mitobridge] Pharma, Inc., Cycleron Therapeutics, Epirium Therapeutics, Khondrion, Imel Therapeutics, Minovia Therapeutics Inc., Mission Therapeutics, NeuroVive Pharmaceutical, Raptor Therapeutics, REATA, Inc., RiboNova, Inc., Standigm Therapeutics, and Stealth BioTherapeutics), and has served as a paid speaker on mitochondrial disease (Platform Q).

# MULTISYSTEM INFLAMMATORY SYNDROME IN CHILDREN ASSOCIATED WITH SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2 INFECTION

Method of

Ian Ferguson, MD; and Carlos R. Oliveira, MD

## CURRENT DIAGNOSIS

- Multisystem inflammatory syndrome in children (MIS-C) is a rare hyperinflammatory complication of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection that is associated with multiorgan dysfunction and hemodynamic compromise.
- Clinicians should suspect MIS-C in a child or adolescent with a recent SARS-CoV-2 infection or exposure who has a persistent fever and at least two other suggestive clinical features such as cardiovascular dysfunction, gastrointestinal symptoms, peripheral edema, rash, oral mucosal changes, conjunctivitis, or neurocognitive symptoms.
- It is recommended that a tiered approach be used for evaluation. The initial laboratory tests aim to screen for evidence of systemic inflammation and confirm active or recent infection. Subsequent tests aim to evaluate for potential organ-specific dysfunction and include cardiac tests, coagulation tests, and hemophagocytosis tests.

## CURRENT THERAPY

- Immunomodulatory treatment with intravenous immunoglobulin (IVIG [Gammagard])<sup>1</sup> and glucocorticoids is considered the mainstay of treatment.
- High-dose glucocorticoids and/or biologic agents, such as interleukin or tumor necrosis factor inhibitors, should be considered in patients with refractory disease.
- Unless there are contraindications, all patients with MIS-C should receive thrombosis prevention with aspirin.<sup>1</sup> Anticoagulation with enoxaparin (Lovenox)<sup>1</sup> should also be considered in patients with documented thrombosis and in those with risk factors for thrombosis.
- Given that treatment guidelines are constantly evolving, management decisions should be made in consultation with a multidisciplinary team of pediatric subspecialists.

The U.S. Centers for Disease Control and Prevention (CDC) defines a case of MIS-C as an individual less than 21 years of age who presents with fever, elevated inflammatory markers, multisystem (>2) organ involvement, and evidence of SARS-CoV-2 infection or exposure within 4 weeks of symptom onset. The CDC definition also specifies that children must have a clinically severe illness (requiring hospitalization) and have no plausible alternative diagnosis.

## Epidemiology

The first pediatric case of coronavirus disease 2019 (COVID-19), the respiratory disease associated with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, was reported in the United States on March 2, 2020. Although children with acute COVID-19 infection fared relatively better than adults, their outcomes have not been universally benign, and some became critically ill. In April 2020, several reports were published describing a more severe clinical phenotype of SARS-CoV-2 in

which children presented with systemic hyperinflammation and rapid-onset circulatory shock. This inflammatory phenotype is commonly known as multisystem inflammatory syndrome in children (MIS-C). Early estimates suggest that MIS-C is a relatively rare complication of SARS-CoV-2 in children, occurring in approximately 1 of 3000 infections. Most cases have occurred in previously healthy children 6 to 12 years of age. Black and Hispanic children have been disproportionately affected by MIS-C in the United States, although it remains unclear if these disparities in MIS-C will continue with time. The only known way to prevent MIS-C is by avoiding infection in the first place, which can be effectively accomplished with immunization.

## Pathophysiology

The pathophysiology of MIS-C has not yet been established. Although some patients with MIS-C test positive for the virus by polymerase chain reaction (PCR), nearly all have SARS-CoV-2-specific antibodies at the time of presentation, which suggests that MIS-C is a postinfectious process. This is further corroborated by a clear epidemiologic link wherein clusters of MIS-C cases in the community are often observed 2 to 5 weeks following a peak in COVID-19 cases.

The current thinking is that the virus may directly activate cells in the innate immune system, which causes uncontrolled inflammation. Another potential etiology is the generation of autoreactive antibodies during the infection. These autoantibodies could mediate disease by damaging the endothelium and microvasculature. This is a conceivable mechanism as some of the manifestations that are characteristic of MIS-C, like the propensity for myocardial injury and thrombosis, suggest a degree of endothelial involvement.

## Clinical Manifestations

There is considerable heterogeneity in the clinical manifestations of MIS-C. Symptoms typically begin 2 to 6 weeks after an acute SARS-CoV-2 infection. Fever is the most common MIS-C symptom and can last for 4 to 6 days. Gastrointestinal symptoms such as abdominal pain and emesis are also common, and this serosal inflammation may resemble appendicitis. Some of the classic Kawasaki disease (KD) findings, like non-purulent conjunctivitis, edema of the hands and feet, mucous membrane lesions, and diffuse erythematous rash, can also be present in MIS-C. There is no standard pattern for the rash, but morbilliform, maculopapular, or diffuse erythema can be present. Retropharyngeal edema is also commonly associated with MIS-C and can present with severe throat pain, cervical lymphadenopathy, and torticollis. Neurocognitive symptoms like lethargy, confusion, and headaches are frequently noted. Severe neurologic manifestations are rare but have also been reported, including seizures, ataxia, strokes, encephalopathy, and cerebral edema. Myocardial dysfunction can occur in 50% to 90% of cases and often leads to hypotension and shock. Children with MIS-C rarely manifest respiratory symptoms, and chest imaging is usually normal. If pulmonary abnormalities are present on imaging, they are usually patchy opacities or pulmonary edema that can be attributable to cardiovascular dysfunction. Most children with MIS-C will have elevated laboratory markers of inflammation, such as C-reactive protein (CRP), ferritin, or procalcitonin. Other common laboratory abnormalities include lymphopenia, thrombocytopenia, hypoalbuminemia, transaminitis, and hypertriglyceridemia.

## Diagnosis

The first step to effectively managing MIS-C is making an accurate diagnosis. There are no specific laboratory tests that are diagnostic of MIS-C, and the diagnosis is largely clinical. However, the initial signs and symptoms of MIS-C are not unique to this illness (Table 1). Thus laboratory investigations must be done to rule out alternative diagnoses. KD and toxic shock syndrome (TSS) are the two clinical entities with the most overlap with MIS-C, though the differential can be considerably larger. A tiered

approach to laboratory evaluation for patients suspected of having MIS-C has been recommended by the American College of Rheumatology (ACR) and the American Academy of Pediatrics (AAP). The first step is to determine which children should be evaluated for MIS-C. It is recommended that children with unremitting fever, an epidemiologic link to SARS-CoV-2, and at least two suggestive clinical features (e.g., hypotension, rash, gastrointestinal symptoms, edema of the hands and feet, mucocutaneous changes, conjunctivitis, lymphadenopathy, or neurologic symptoms), undergo the initial tier of laboratory testing for MIS-C (Table 1). The evaluation for MIS-C must include a thorough differential diagnosis to rule out other potential etiologies. Thus these patients should ideally be managed by a multidisciplinary team of specialists, including pediatric rheumatology, cardiology, infectious diseases, and depending on clinical severity and symptom development, intensive care, hematology, nephrology, neurology, and gastroenterology.

### Initial Evaluation

Tier 1 includes measuring inflammatory markers, testing for SARS-CoV-2 antibodies, and performing a complete blood count and a metabolic panel. Uncontrolled inflammation is characteristic of MIS-C, and elevations in CRP or erythrocyte sedimentation rate (ESR) are nearly always observed. Patients with inflammatory activation will also often have cytopenias and other marrow abnormalities. The presence of lymphopenia has been consistently reported in the medical literature as a predictor of severity. However, a severe reduction in any cell line can be associated with uncontrolled inflammation and may indicate progression into macrophage activation syndrome (MAS) pathophysiology.

The diagnosis of MIS-C also requires an epidemiologic link to SARS-CoV-2. This link can take the form of recent close contact with a confirmed COVID-19 case, a positive PCR or antigen test (suggestive of active infection or recent past infection), or a positive serologic test. In patients who have been vaccinated against SARS-CoV-2, the presence of nucleocapsid antibodies is suggestive of a recent infection, whereas in patients who have not been vaccinated, either spike protein or nucleocapsid antibodies could be used to determine if the patient had a previous infection. Approximately 15% of patients suspected of having MIS-C will have PCR positivity. Because the clinical features of acute SARS-CoV-2 infection can overlap with MIS-C, it is important to rule out acute COVID-19 pneumonia in this group as the treatment approach for active COVID-19 will differ from MIS-C. Serology can be helpful in this context as children with active COVID-19 are less likely to have measurable anti-SARS-CoV-2 immunoglobulin G (IgG) antibodies on presentation.

### Subsequent Evaluations

Patients proceed to tier 2 of testing if they are suspected of having MIS-C, have an elevation of CRP or ESR, and have at least one additional laboratory abnormality, such as lymphopenia, thrombocytopenia, hyponatremia, neutrophilia, or hypoalbuminemia. Patients who present with severe manifestations, such as shock, are also recommended to proceed to tier 2 diagnostic evaluations. Tier 2 assessments aim to evaluate for potential organ-specific damage and can be useful for evaluating other diseases in the differential that may also be affected by treatment. These assessments include cardiac tests (troponin, brain natriuretic peptide [BNP], electrocardiogram, and echocardiogram), coagulation tests (fibrinogen,

\*Additional treatment for neurologic, respiratory, and renal abnormalities may also be required.

<sup>†</sup>Can be divided over 2 days if there is concern for fluid overload.

<sup>‡</sup>Consider a 2- to 3-week taper.

<sup>§</sup>Hold other nonsteroidal antiinflammatory drugs while on aspirin, and hold aspirin for active bleeding and thrombocytopenia.

<sup>II</sup>Coordination with pediatric specialists in cardiology, rheumatology, hematology, and infectious diseases is recommended.

BID, Twice a day; CA, coronary arteries; ECMO, extracorporeal membrane oxygenation; EF, ejection fraction; IV, intravenously; IVIG, intravenous immunoglobulin; PO, by mouth; SC, subcutaneously.

D-dimer, prothrombin time, and activated partial thromboplastin time), and hemophagocytosis tests (ferritin, blood smear, lactate dehydrogenase, triglycerides, and cytokine panel). The signs and symptoms of MIS-C can mimic those of other infectious diseases, such as sepsis or TSS. Thus tier 2 tests should also include microbiologic tests (urine analysis, blood cultures, and other viral tests) based on clinical suspicion and specific symptoms.

### Cardiac Tests

The feared complication of MIS-C is the development of coronary artery aneurysms. Although coronary vasculitis can occur in MIS-C, it is less common than myocardial involvement resulting in systolic dysfunction and cardiogenic shock. Cardiac evaluations should be completed as soon as possible. Elevation in the BNP or N-terminal pro-BNP suggests systolic dysfunction, and elevation in troponin suggests damage to cardiac myocytes. Elevation in BNP may continue with fluid resuscitation and medication administration, particularly intravenous immunoglobulin (IVIg), as it has a large infusion volume. Electrocardiogram abnormalities, such as abnormal ST- or T-wave segments or first-degree atrioventricular block, are also not uncommon in MIS-C.

### Coagulation Tests

Hypercoagulability and thrombosis risk also must be assessed at the onset. Elevation of the D-dimer greater than five times the upper limit of normal is an independent risk factor for developing thrombosis and may help guide decisions around antithrombotic therapy. Uncontrolled inflammation in the vasculature is also associated with hyponatremia and hypoalbuminemia. These findings are worth noting as they have been associated with a high risk of IVIG resistance in KD. Transaminase elevation is common in uncontrolled inflammation, and aspartate transaminase (AST) or alanine transaminase (ALT) elevation greater than three times the upper limit of normal suggests liver vasculature involvement.

### Hemophagocytosis Tests

MIS-C can occasionally progress to a state in which the patient cannot turn off or reduce the endogenous immune response, leading to further organ damage. This dysregulation of the immune system

is termed *macrophage activation syndrome*. Key to the diagnosis of this serious immune condition is pancytopenia and evidence of bone marrow destruction. Associated laboratory findings can include high levels of lactate dehydrogenase (LDH), hyperferritinemia, and hypertriglyceridemia. A blood smear can also show pancytopenia and, importantly, should not show any evidence of peripheral neoplasm, which would require different therapy than that for MIS-C. The cytokine panel can also be used, if available, to determine the level of inflammation (particularly the interleukin-6 level). However, cytokine panels often take several days to return, and treatment should not be withheld for these results.

## Treatment

### Immune Modulators

Children with moderate to severe disease and who require hospitalization should receive immune-modifying therapy with intravenous immunoglobulin (IVIg [Gammagard])<sup>1</sup> and corticosteroids (Table 2). The recommended initial dose of IVIG is 2 g/kg, with a maximum dose of 100 g. This medication is infused with a relatively large fluid load; thus the patient's systolic function must be assessed before administration and closely monitored afterward. The immune modulation effects of IVIG are best achieved with a single dose, but if there is a concern for volume overload, the doses may be divided into 1 g/kg aliquots over 2 days with diuresis. We recommend pretreatment with acetaminophen and an antihistamine when IVIG is used, as it can frequently cause infusion reactions. In addition to IVIG, hospitalized patients with MIS-C should receive glucocorticoids. Initial therapy is with methylprednisolone (Solu-Medrol)<sup>1</sup> at a dose of 1 to 2 mg/kg/day. Glucocorticoids should ideally be given before IVIG as they may also help reduce the risk of potential IVIG infusion reactions.

The dose of corticosteroids can be increased to 10 to 30 mg/kg/day in patients who have a persistent fever or ongoing end-organ damage despite initial therapy with IVIG and glucocorticoids. Biologic immune therapies, such as interleukin (IL) blockers or tumor necrosis factor (TNF) inhibitors, should be considered in patients with recalcitrant disease or in those who have a contraindication

<sup>1</sup>Not FDA approved for this indication.

to corticosteroids. The ACR recommends anakinra (Kineret),<sup>1</sup> an IL-1 receptor antagonist, as first-line therapy for recalcitrant MIS-C. It is administered at a starting dose of 4 mg/kg/day and can be escalated up to 8 to 12 mg/kg/day as needed. An alternative biologic agent is infliximab (Remicade, Inflectra, Renflexis, Ixifi, Avsola),<sup>1</sup> an anti-TNF-alpha monoclonal antibody, which can be given as a single dose of 5 mg/kg/day. Much like IVIG, infliximab doses should be pretreated with acetaminophen and antihistamine to reduce the risk of an infusion reaction. As symptoms improve and inflammatory markers wane, corticosteroids should be carefully tapered over 2 to 3 weeks to avoid rebound inflammation. It is also important to consider withdrawal symptoms from cortisol deficiency in patients who have received high-dose pulse therapy.

### Antithrombotic Therapy

In addition to immune modulators, all patients with MIS-C should be given antithrombotic therapy, provided that they have no known contraindications and their risk of bleeding is not high (e.g., no bleeding diathesis, no thrombocytopenia, or active bleeding). Initial thrombosis prophylaxis should be with aspirin<sup>1</sup> (3 to 5 mg/kg/day, maximum 81 mg/day) and continued for at least 4 to 6 weeks. Longer courses of aspirin may be needed for patients who have cardiac abnormalities or those who have reactive thrombocytosis on follow-up evaluation. Aspirin is frequently avoided in pediatrics because of the risk of Reye syndrome. However, this is less of a concern when low doses are used (<81 mg/day). Another important toxicity to monitor when using aspirin is liver toxicity, which can be exacerbated by concurrent hypoalbuminemia.

Therapeutic anticoagulation with enoxaparin (Lovenox)<sup>1</sup> may also be needed in some patients with MIS-C. Our recommendations for treatment dosing of enoxaparin are provided in Table 2. Generally, patients with evidence of thrombosis, coronary artery changes (z-score >10), or severely low systolic function (ejection fraction <35%) require the addition of enoxaparin. Prophylactic-dose enoxaparin should be considered in patients with MIS-C who do not have the aforementioned findings yet remain at high risk for thrombosis, such as those admitted to an intensive care unit, those with a markedly elevated D-dimer (>5 times the upper limit of normal), or those who are older than 12 years of age.

### Adjunctive Therapies

The need for additional support varies greatly on the initial clinical presentation. In cases in which there is significant cardiovascular disease, both vasopressors and inotropic supporting medications are commonly required. Fluid resuscitation should be used judiciously in these settings as large boluses can negatively affect respiratory status. Because MIS-C can have a similar presentation to that of sepsis, empiric broad-spectrum antibiotics are also often indicated, pending cultures. However, antivirals are rarely needed as MIS-C is often not an active viral process. However, given the phenotypic overlap of MIS-C and acute SARS-CoV-2, distinguishing patients with an active infection from those with postinfectious MIS-C can sometimes be challenging. When there is uncertainty, such as in cases of severe pulmonary involvement with negative serology, we recommend consultation with an experienced infectious disease specialist.

### Monitoring

As children with MIS-C can decompensate quickly, close observation and judicious use of laboratory tests are needed

to monitor progression. We recommend follow-up laboratory tests every 6 to 12 hours for patients who are critically ill or those who have severe cardiac dysfunction. For patients who are not critically ill, we encourage daily laboratory tests to ensure that treatment is effectively reducing inflammation and normalizing organ dysfunction. There are no clear discharge criteria, but in general, patients should be afebrile without antipyretics (excluding corticosteroid and aspirin) and have down-trending inflammatory markers. For patients with cardiac manifestations, there should also be an improvement in laboratory markers of cardiac strain and an improvement in imaging studies.

Follow-up with a primary care physician should occur within 2 to 3 days of discharge. At our center, follow-up laboratory tests and cardiac imaging are performed 7 to 14 days postdischarge and again after 4 to 6 weeks to ensure that inflammation does not reaccumulate, assess cardiac function, and trend the size of coronary arteries. Aspirin is typically stopped at the 6-week visit if there is no rebound thrombocytosis and follow-up cardiac imaging is normal. Patients who presented with shock or developed coronary changes may require additional follow-up testing, such as a cardiac MRI to assess for scars, fibrosis, or aneurysms. Cardiac stress testing is also encouraged in patients who had a significant troponin leak during initial hospitalization. Three months postdischarge, after the cardiac function returns to normal, we also encourage SARS-CoV-2 immunization if age-eligible.

### Complications

Data on long-term outcomes from MIS-C have been limited. However, existing data suggest a mortality rate between 1% and 2% among those treated. The long-term outcomes among survivors have been generally favorable. Follow-up studies have found that nearly all children completely recover by 8 to 10 weeks. Among the few patients with prolonged post-treatment symptoms, most had complaints such as headaches, fatigue, abdominal distress, and anxiety. Whether these persistent symptoms are causally related to MIS-C remains an open question.

## NOCTURNAL ENURESIS

Method of

Alexander K.C. Leung, MBBS

**Note:** This chapter has been published in part in *Common Problems in Ambulatory Pediatrics: Specific Clinical Problems*, volume 1, with permission from Nova Science Publishers, Inc.

### CURRENT DIAGNOSIS

- Nocturnal enuresis is defined as involuntary nighttime bedwetting in a child at least 5 years of age.
- Primary nocturnal enuresis is present when the child has never achieved a period of nighttime dryness greater than 6 consecutive months. Secondary nocturnal enuresis is present when the child has experienced a period of nighttime dryness of at least 6 consecutive months.
- The most common causes of primary nocturnal enuresis are a deep sleep pattern, nocturnal polyuria, and a small-capacity bladder or nocturnal detrusor overactivity.
- A urinalysis is warranted to rule out urinary tract infection, glycosuria, and a defect in the ability to concentrate urine.
- Ultrasound examination of the bladder (prevoid and postvoid) can be used to evaluate bladder dysfunction and functional bladder capacity.

### CURRENT THERAPY

- Desmopressin (DDAVP, 1-deamino-8-arginine vasopressin) is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with nocturnal polyuria and normal bladder function.
- Enuretic alarm is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with a small bladder capacity or in children with severe enuretic symptoms refractory to desmopressin therapy.
- Behavioral therapy such as encouraging the child to urinate frequently during the daytime, emptying the bladder before bedtime, and restricting fluid in the evening may increase the success rate of pharmacologic therapy or enuretic alarm therapy.

*Nocturnal enuresis* is defined as involuntary nighttime bedwetting in a child at least 5 years of age. Primary nocturnal enuresis is present when the child has never achieved a period of nighttime dryness greater than 6 consecutive months. Secondary nocturnal enuresis is present when the child has experienced a period of nighttime dryness of at least 6 consecutive months. For the majority of children with secondary nocturnal enuresis, the pathogenesis is no different from that of primary nocturnal enuresis.

Nocturnal enuresis is a common problem that is frustrating for children, parents, and physicians alike. The condition may affect the child's self-esteem and may lead to reduced social interaction and behavioral problems.

### Epidemiology

It has been estimated that 15% to 25% of 5-year-old children and 5% to 10% of 7-year-old children have nocturnal enuresis. Without specific treatment, approximately 15% of affected children become dry each year. The male-to-female ratio is approximately 3:1.

### Risk Factors

Encopresis, daytime wetting (diurnal enuresis), and male gender are significant risk factors. Constipation, emotional stress, developmental delay, bladder dysfunction, sleep deprivation,

adenotonsillar hypertrophy, and attention-deficit/hyperactivity disorder also play a role.

### Pathogenesis

The most common causes of primary nocturnal enuresis are a high arousal threshold, nocturnal polyuria, and a small-capacity bladder or nocturnal detrusor overactivity. Although these causes may overlap, it is important to conceptualize them separately, because this differentiation will help the physician to understand the problem, to educate both the parents and child, and to plan an appropriate treatment program.

It has been shown that enuretic children have a high arousal threshold and a reduced prepulse inhibition of startle. In most children, arousability from sleep improves with maturation of the central nervous system.

In most circumstances, the rate of secretion of antidiuretic hormone from the posterior pituitary gland is increased at night. This circadian variation is usually established when the child is 3 to 4 years old. Some children with primary nocturnal enuresis have a lack of this circadian variation with an abnormally low nocturnal secretion of antidiuretic hormone with resultant nocturnal polyuria. Other causes of nocturnal polyuria include fluid and solute overload in the evening.

Children with a small-capacity bladder or nocturnal detrusor overactivity often have primary nocturnal enuresis. Conditions that may reduce the functional bladder capacity include cystitis and constipation.

There is a strong genetic component to nocturnal enuresis. The child of parents who were both enuretic has a 77% chance of developing enuresis. If one parent was enuretic, there is up to a 44% occurrence rate. If neither parent was enuretic, the occurrence rate is only 15%. Twin studies also support a genetic basis for nocturnal enuresis: the concordance rate is much higher in monozygotic twins (68%) when compared with dizygotic twins (36%). Linkage studies have suggested possible genetic markers for primary nocturnal enuresis located on chromosomes 12, 13, and 22.

A neurogenic bladder is one of the few anatomic abnormalities that can cause primary nocturnal enuresis. Congenital urethral obstruction is another infrequent anatomic cause of primary nocturnal enuresis. The enuresis in these children is due to an overflow phenomenon from a poorly compliant bladder. The most common cause of urethral obstruction in the male is posterior urethral valves. Girls and boys with significant congenital urethral stenosis may also present with this problem. An ectopic ureter or vesicovaginal fistula is an infrequent anatomic cause of primary nocturnal enuresis in girls.

A defect in the ability of the kidney to concentrate urine can cause primary nocturnal enuresis. The causes of concentrating defects include any cause of chronic renal failure and diabetes insipidus.

### Diagnosis

#### History

#### *Onset and Frequency*

The timing of the onset and the frequency of nocturnal enuresis are important historical clues to the etiology. Secondary nocturnal enuresis and intermittent nocturnal enuresis are not usually associated with structural abnormalities in the urinary tract. Nocturnal enuresis due to a structural abnormality of the urinary tract is usually present from birth and is not associated with periods of remission.

#### *Timing, Frequency, and Volume per Episode*

A history of soaking absorbent underpants in the morning suggests nocturnal polyuria. Parents of children with nocturnal polyuria often remark that the volume of urine associated with the enuretic episode or the first morning void is very large. Frequent episodes of nocturnal enuresis with a small volume of urine suggest bladder dysfunction such as may occur with a urethral obstruction or a neurogenic bladder. Several episodes of nocturnal enuresis with a large volume suggest diabetes mellitus or

diabetes insipidus. Constant wetting suggests an ectopic ureter or vesicovaginal fistula.

### **Associated Symptoms**

Nocturnal enuresis associated with daytime urinary frequency, urgency, incontinence, and difficulties in initiating the urinary stream suggests urethral obstruction. Daytime urinary frequency, urgency, incontinence, squatting behavior, constipation, encopresis, gait disturbance, and a history of spina bifida or spinal trauma suggest a neurogenic bladder. Constant dampness in the underwear by day and night in a female suggests an ectopic ureter or vesicovaginal fistula. Secondary nocturnal enuresis associated with dysuria, urinary frequency, urgency, fever, suprapubic/loin pain, or cloudy, foul-smelling urine suggests a urinary tract infection. Polyuria, polydipsia, polyphagia, and weight loss suggest diabetes mellitus. Polyuria, polydipsia, and episodes of dehydration in a child with a history of central nervous system disease suggest diabetes insipidus. A history of constipation is important because the condition is associated with a reduced functional bladder capacity.

### **Volume of First Morning Void**

Most children with nocturnal enuresis void only a small or average amount of urine in the morning after an enuretic episode. A large volume of urine voided following a significant episode of nocturnal enuresis may be a clue to the presence of low nocturnal secretion of antidiuretic hormone.

### **Soundness of Sleep**

Children with nocturnal enuresis often sleep more deeply than other family members. Some children only wet when they are overtired. Conversely, children who are usually enuretic may be continent during periods of wakeful sleep such as during intercurrent illnesses.

### **Past Health**

A child with a history of a structural abnormality of the urinary tract or neurogenic bladder may have nocturnal enuresis due to these causes. A history of spinal trauma may indicate a neurogenic bladder as a cause of enuresis. A history of central nervous system disorder may indicate neurogenic diabetes insipidus. Certain medications such as methylxanthines and caffeine may be associated with nocturnal enuresis.

### **Family History**

A family history of nocturnal enuresis should be sought because nocturnal enuresis tends to run in the family. A family history of diabetes mellitus, diabetes insipidus, or kidney disease suggests the corresponding disorder. Any stressful events in the family such as birth of a sibling and parental disharmony should be explored, especially in children with secondary nocturnal enuresis.

### **Physical Examination**

Height and weight should be measured and plotted onto standard growth charts. All children should have their blood pressure checked, which, if elevated, might indicate renal disease. A thorough physical examination should include examination of the abdomen and genitalia and a complete neurologic examination. In chronic constipation, fecal masses are often palpable in the left lower quadrant of the abdomen and in the suprapubic area.

In the majority of children with primary nocturnal enuresis, the physical examination is unremarkable. An abnormal physical examination is only present when primary nocturnal enuresis is due to a structural cause. A myelomeningocele is usually obvious at birth; however, subtle spinal defects may also be associated with primary nocturnal enuresis. A midline tuft of hair, an exaggerated dimple, or a birthmark in the area of the lumbosacral spine; a gait abnormality; absence of anal wink; or abnormal motor power, tone, reflexes, or sensation in the lower extremities suggests a neurogenic bladder. A palpably enlarged bladder or

kidney and a weak or dribbling urinary stream suggests urinary obstruction, such as may result from posterior urethral valves.

### **Laboratory and Imaging Studies**

A urinalysis is warranted to rule out urinary tract infection, diabetes mellitus, and a defect in the ability to concentrate urine. Ultrasound examination of the bladder (prevoid and postvoid) can be used to evaluate bladder dysfunction and functional bladder capacity.

### **Treatment**

One essential part of the treatment plan of every child with primary nocturnal enuresis should be compassion and support from both the family and physician. It is important to clarify to parents that the child is not at fault and to specify that punishment for bedwetting is inappropriate. The child and family can be reassured that in the absence of structural defect, primary nocturnal enuresis tends to resolve with time.

Simple behavioral strategies such as encouraging the child to urinate frequently during the daytime, emptying the bladder before bedtime, and limiting fluid and solute intake in the evening are often recommended. Caffeinated beverages should be avoided, particularly in the evening. Some authors recommend waking the child 1.5 to 2 hours after bedtime to go to the bathroom. Star charts and reward systems need to reinforce positive behavior. Behavioral therapy may increase the success rate of pharmacologic therapy or enuretic alarm therapy.

Desmopressin (DDAVP, 1-deamino-8-arginine vasopressin) is an analogue of vasopressin that has a profound antidiuretic activity without pressor activity. The medication acts on the V2 receptors of the renal tubules and increases the reabsorption of fluid from the renal tubules, thereby decreasing the amount of urine produced. The medication is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with nocturnal polyuria and normal bladder function. Desmopressin is available in a sublingual lyophilisate (melt) preparation,<sup>2</sup> as well as a tablet. The bioavailability of the lyophilisate (melt) preparation is approximately 60% greater than that of the tablet formulation. The recommended dose of desmopressin is 120 to 240 µg melt and 200 to 400 µg tablet. The former is usually given 30 minutes to 1 hour before bedtime, and the latter is usually given 1 hour before bedtime. Side effects are rare and include symptomatic hyponatremia with water intoxication. When desmopressin is prescribed, patients should be instructed to avoid high fluid intake in the evening.

Imipramine (Tofranil), a tricyclic agent with antimuscarinic property, may be helpful in children who have not responded to desmopressin alone. Presumably, the medication decreases the amount of time spent in rapid eye movement sleep, stimulates antidiuretic hormone secretion, and relaxes the detrusor muscle. The recommended starting dose is 25 mg for children 6 to 12 years of age and 50 mg for those older than 12 years, given 1 to 2 hours before bedtime. If necessary, the dose may be increased gradually to a maximum of 50 mg in children 6 to 12 years of age and 75 mg for those older than 12 years. However, potential side effects (anxiety, depression, dizziness, headache, drowsiness, lethargy, sleep disturbance, dry mouth, anorexia, vomiting, skin rashes) and serious adverse effects (hepatotoxicity, cardiotoxicity) with overdose limit their use.

Monotherapy with oxybutynin (Ditropan),<sup>1</sup> an anticholinergic and antispasmodic agent that decreases uninhibited bladder contraction, is not effective in treating monosymptomatic nocturnal enuresis. The medication can be added, however, as a second-line drug in the treatment of children with both diurnal and nocturnal enuresis. The dose is 5 mg administered 1 hour before bedtime.

Enuretic alarm is indicated as a first-line therapy for children with monosymptomatic nocturnal enuresis associated with a small bladder capacity or nocturnal detrusor overactivity.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

Randomized controlled trials have demonstrated that the enuretic alarm has greater efficacy than other forms of treatment. The enuretic alarm is triggered when a sensor in the sheets or night clothes gets wet; a bell or buzzer is thereby activated. Presumably, alarm therapy startles the child and improves arousal from sleep either by classical conditioning or avoidance conditioning. A disadvantage of alarm therapy is that it takes a couple of weeks to take effect. As such, alarms should be used for at least 6 weeks in children who do not respond before discontinuing their use. Because success depends on a cooperative, motivated child, conditioning therapy with an alarm device is generally used in children over 6 years of age.

It has been shown that combination of alarm and desmopressin works better than either treatment alone. Such treatment may be considered for children with refractory nocturnal enuresis.

When an anatomic abnormality or defect in urinary concentration ability is present, the underlying problem may require specific dietary, pharmacologic, or surgical treatment. Any underlying constipation should also be treated.

The newborn period is defined as birth through the 28th day of life. During this time, newborns primarily feed, grow, and sleep. Therefore adequate nutrition carries special significance during this phase of life. This chapter focuses on available options for newborn nutrition (e.g., breast milk and commercial formulas), information medical caregivers can use when counseling families, definitions of adequate quality and quantity of nutritional sources, and assessing for appropriate intake in terms of growth.

## Breast-feeding and Breast Milk

Breast-feeding is the nutritional source of choice as recommended by the American Academy of Pediatrics (AAP), the Canadian Pediatric Society, and the American Academy of Family Physicians. Caregivers should always respect the choice of the mother and support her during her bonding period with her newborn infant. However, because many misconceptions exist regarding breast-feeding, it is practical for caregivers to inquire about a mother's reasons if she chooses to use formula to feed her infant. She may have several concerns about breast-feeding including returning to work, the logistics of pumping, or her modesty, or she may consider breast-feeding to be "antiquated." Breast-feeding may be contrary to cultural and ethnic beliefs of the mother. For example, some Hispanic women are concerned that when breast-feeding they might inadvertently pass on negative emotions to their newborn. Because Somalian mothers attribute special powers to Western medicine and infant formulas, they often breast-feed but supplement with formula to ensure their infant gets everything that modern medicine can offer. With proper education and support, many mothers find breast-feeding to be a more reasonable option than they first thought.

Thanks to the efforts of several organizations promoting the health benefits of breast-feeding, even mothers who choose to formula feed recognize breast milk as the best nutritional option for their infant. But even after making the decision to breast-feed, some mothers continue to struggle with the actual undertaking of breast-feeding. There remains in our culture the inaccurate belief that something so "natural" must be easy to do. Many first-time mothers are easily frustrated and discouraged during the first few attempts at breast-feeding because they have unreasonable expectations based on the media and popular culture. With more and more women willing to try breast-feeding after delivery, adequate support and teaching should be provided by the entire medical team.

Thanks to multiple initiatives and ongoing education efforts, breast-feeding rates have been increasing in the US and are currently at their highest rates since World War II. In 2009, only 25% of infant were still breast-feeding at 1 year, but by 2015 the rate had increased to 36%. Healthy People 2030 has a goal of 54%. Similarly, rates of exclusive breast-feeding were approximately 16% in 2009, increased to 25% by 2015, and the current goal is 42%. While significant progress has been made, especially in the last 2 decades, there is still substantial room for further improvement. The biggest disparities in breast-feeding rates are among racial and ethnic minorities. Special attention should be made by medical teams to provide sufficient support and education to these women.

Breast milk is considered the ideal source of nutrition for all newborns, including premature infants, in a large part owing to its contents. There is a greater ratio of whey to casein in breast milk than in formula. Whey is associated with better absorption and digestion, as well as faster gastrointestinal transit times. There are also several specific proteins found only in breast milk, such as lactoferrin, lysozyme, and secretory immunoglobulin A, that aid in immune defense in the gut. Breast milk also contains long-chain polyunsaturated fatty acids (PUFAs) that aid in neural and visual development. Infants given formulas that contain long-chain PUFAs have serum concentrations that never match those of breast milk–fed infants, but there is also no known minimum amount needed to achieve benefit.

There is also a difference in the intestinal microflora seen in infants fed breast milk versus those fed formula. Larger percentages of *Lactobacillus* and *Bifidobacterium* species are found in infants fed breast milk, whereas *Bacteroides* spp and enterobacteria are in more abundance in formula-fed counterparts. Newer evidence

## NORMAL INFANT FEEDING

Method of

Amy Seery, MD

### CURRENT THERAPY

- Breast milk is considered the best nutritional source for all infants including preterm infants.
- Breast-feeding is strongly encouraged, but many mothers require support from a multidisciplinary medical team to achieve success.
- There are few absolute contraindications to breast-feeding but these include maternal HIV, infant galactosemia, herpetic lesions on the breast, maternal use of illicit drugs, and mothers undergoing some types of chemotherapy.
- Maternal medications should be individually reviewed for safety during breast-feeding.
- Newborns should be fed at least every 3 hours during the day and every 4 hours during the night.
- Breast-fed infants can go up to 10 days between stools. This is a normal stooling pattern so long as the infant shows no signs of distress or illness.

suggests this difference in the diversity of gut microflora accounts for the stronger immune systems seen in breast-fed infants.

Breast milk has the benefit of containing several nonnutritive substances that are advantageous for young infants including maternal antibodies, growth regulators, digestive enzymes, and hormones. Breast milk has been associated with a reduced risk for many chronic illnesses including asthma, food and environmental allergies, diabetes mellitus, eczema, cardiovascular disease, and obesity. There is a reduction in the number of short-term illnesses of childhood including acute respiratory and gastrointestinal illnesses, as well as otitis media.

Newer research shows an association between being fed breast milk and having higher IQ scores later in childhood.

The act of breast-feeding offers several benefits to the infant. There is a sense of security and closeness that comes from skin-to-skin contact and the resultant interaction between infant and mother. Nursing can also reduce the opportunities and risk for bottle-propping and overfeeding. Breast-feeding allows nutrition to be more immediately available with minimal preparation work compared to the mixing and warming of formula. Breast milk is a much cheaper alternative to supplemental formulas. Breast-feeding can also lead to health benefits for the mother such as decreased risk of ovarian and breast cancers, as well as diabetes mellitus type II.

There are very few contraindications to breast-feeding. Contraindications include maternal HIV, active herpetic lesions on the breast (herpetic lesions elsewhere are not a contraindication), maternal use of illicit drugs, women undergoing chemotherapy with antimetabolite agents, and mothers with active tuberculosis. Nearly all over-the-counter medications are safe to take during breast-feeding. Some prescription medications are contraindicated, although safe substitutes are usually available. Providers can use the online National Library of Medicine's Drugs and Lactation Database (LactMed) to check safety and provide up-to-date counseling. Infants with galactosemia should not be breast-fed or bottle fed with milk products.

## Infant Formulas

Commercially available infant formulas became widely used during World War II when there was a large influx of women into the national workforce. Since that time, infant formulas have been continuously improved upon and contain all the necessary energy and nutrient requirements for full-term infants up to the age of 6 months. According to the AAP there are three indications for the use of formulas:

- An alternative primary nutritional source for infants whose mothers choose not to or are unable to breast-feed
- A supplementary nutritional source for mothers with an inadequate supply of breast milk
- A nutritional source in infants with a medical condition in which breast-feeding is contraindicated (e.g., galactosemia)

Commercial formulas usually come in three distinct preparations, including ready-to-feed, concentrated liquid, and powder. All three preparations yield 20kcal per fluid ounce when prepared correctly, the same amount of energy per volume found in breast milk. Powder preparations are generally the least expensive. An advantage to formulas over breast-feeding is the ability to increase caloric density for an infant with increased metabolic needs (e.g., infants with congenital heart defects). Breast-feeding mothers have the option to breast pump and add a fortifier if needed to achieve similar increases in caloric density.

Formulas carry the risk of improper preparation, whether intentional or accidental. Caregivers might choose to dilute the formula secondary to financial pressures or to concentrate formula preparations in a desire to have a larger infant, because some cultures equate larger infant size and weight with better health. Either change can be dangerous to the infant. Diluting leads to an excess of free water with an insufficient solute load (e.g., hyponatremia) and concentrating can conversely lead to hypernatremia. Nevertheless, formulas remain an appropriate alternative when desired by the infant's mother or when medically indicated (Table 1).

**TABLE 1** Infant Formulas and their Indications

CLASS	BRAND NAMES	CALORIES (KCAL PER OZ)	CARBOHYDRATE SOURCE	PROTEIN SOURCE	INDICATIONS
Breast milk	—	20	Lactose	Human milk	Preferred for all infants
Term formula	Gerber Good Start Gentle	20	Lactose	Cow's milk	Appropriate for most infants
Term formula with DHA and ARA	Enfamil Premium Infant; Good Start Protect; Similac Advanced	20	Lactose	Cow's milk	Marketed to promote eye and brain development
Preterm formula	Enfamil Premature; Similac Special Care 24 with Iron	24	Lactose	Cow's milk	<34 wk gestational age Weight <1800 g
Enriched formula	Enfacare; Similac Neosure	22	Lactose	Cow's milk	34–36 wk gestational age Weight ≥1800 g
Soy formula	Enfamil Prosobee; Good Start Soy; Similac Isomil	20	Corn-based	Soy	Congenital lactase deficiency, galactosemia
Lactose-free formula	Similac Sensitive	20	Corn-based	Cow's milk	Congenital lactase deficiency, primary lactase deficiency, galactosemia
Hypoallergenic formula	Similac Alimentum; Enfamil Nutramigen; Enfamil Pregestimil	20	Corn or Sucrose	Hydrolyzed proteins	Milk protein allergy
Nonallergenic formula	Elecare; Neocate Infant; Nutramigen AA	20	Corn or Sucrose	Amino acids	Milk protein allergy
Antireflex formula	Enfamil AR; Similac Sensitive for Spit-Up	20	Lactose (thickened with rice starch)	Cow's milk	Gastroesophageal reflux

*Abbreviations:* ARA=arachidonic acid; DHA=docosahexaenoic acid.

Adapted from O'Connor NR. Infant formula. *Am Fam Physician* 2009;79:565–70.

**TABLE 2** Expected Growth Velocities during Infancy

AGE	WEIGHT GAIN (g/d)	LENGTH (cm/mo)	HEAD CIRCUMFERENCE (cm/wk)
0–3 mo	25–30	2.5	0.5
3–6 mo	15–20	2.5	0.5
6–12 mo	10	1.25	0.25

### Micronutrients

Both breast milk and formula contain most of the micronutrients needed by infants. Calcium and phosphorus are found in lower concentrations in breast milk but are more bioavailable than the minerals present in formulas. Therefore there is no difference in bone mineral concentrations in both sets of infants. Iron, zinc, and copper serum levels are sufficient during the first 6 months of life in breast-fed infants, although tissue stores are gradually depleted. After 6 months breast-feeding should be supplemented with complementary foods to prevent outcomes such as iron deficiency anemia.

Vitamin K, necessary to prevent hemorrhagic disease, is produced by the digestive actions of intestinal flora. For this reason, most infants at the time of birth are given a single intramuscular dose to provide adequate amounts until intestinal flora concentrations are more mature and dietary supplementation with solid food begins at 6 months.

Vitamin D needs historically have been achieved with adequate sunlight exposure. However, with appropriate use of sunscreens and sunlight avoidance, most infants are at risk for vitamin D deficiency. Vitamin D is not passed in sufficient quantities in breast milk, and the content in formulas is so low that the daily recommended amount of 400IU is only achieved when infants are consuming a volume typical of a 6-month old. Therefore supplementation should be recommended for all infants regardless of skin color and nutritional source to help prevent rickets. The recommendation is 400IU of vitamin D for all pediatric age groups beginning after the first 2 weeks of life.

Neither formula-fed nor breast-fed infants usually require supplementation with water. In fact, providing infants with excess free water can lead to hyponatremia, seizures, and death. If there is concern that the infant is constipated or overheated, caregivers can provide up to a tablespoon of water daily to infants younger than 4 months old.

### Defining Adequate Intake

To determine whether a newborn is receiving adequate nutrition, physicians should ask the caregiver how often feedings are occurring, for how long (for breast-fed infants), and how much is eaten (for formula-fed infants) and should assess the number of wet diapers and stools daily. Initially infants should consume 10 to 15 mL per feeding for the first 24 to 36 hours, gradually increasing to 30 to 45 mL by the fourth day of life. Breast-fed infants should feed 15 to 20 minutes each side. At the time of discharge to home, all newborns should be feeding 8 to 12 times a day, or every 2 to 3 hours. This interval can be increased to every 4 hours at night, and parents should be encouraged to wake any infants who sleep for longer than this duration. If an infant has lost more than 10% of his or her birth weight, the care team should consider delaying discharge to review the infant's nutritional status and feeding habits. Caregivers should be attentive to infant cues of hunger and satiety to provide an ideal feeding pattern for each infant.

Voiding and stooling patterns change with age and can also be influenced by the infant's diet. All newborns should have at least one wet diaper and one stool within the first 24 hours of life. If this does not occur, close observation and further workup are indicated to rule out structural or metabolic abnormalities. During the first week of life, infants usually void and stool with every feeding or even more often. Beyond the first week, infants

should have at least 4 to 6 voids daily regardless of diet. Formula-fed infants might have one stool every other day up to 2 to 3 stools daily. Because of the higher percentage of protein that is absorbed in breast milk, breast-fed infants can go up to 10 days between stools. Physicians should review with families the signs and symptoms (emesis, refusal to feed, lethargy, inconsolability, and abdominal distention) that indicate an infant with infrequent stooling should be medically evaluated. Breast-fed infants also have stools that are described as loose, yellow, and seedy. Caregivers should be educated that this is a normal stool color and consistency and is not considered diarrhea.

Medical providers can also calculate an infant's nutritional needs and compare to the actual intake. Nutritional needs are represented as kcal/kg per day (KKD). The following formula can be used:

$$KKD = \frac{\text{Volume in mL consumed in 24h}}{\text{Weight in kg}} \times \frac{20 \text{ kcal/oz}}{30}$$

During the first 3 months of life, infants should consume an intake that equals 90 to 135 kcal/kg per day. This intake goal should lead to a weight gain of approximately 25 to 30g daily. From 3 to 6 months of age, infants gain at a slightly slower rate of approximately 15 to 20g per day (Table 2). For example, a 2-month-old who weighs 6kg should consume between 810 mL to 1215 mL daily.

At subsequent visits an infant can be assessed for adequate growth using standardized, gender-specific growth curves. Attention should be paid to growth parameters including weight, length, head circumference, and weight-for-length. Weight-for-length charts are used during the first 2 years of life as a gross equivalent to body-mass-index charts used for children older than 2 years. For years, practices defined adequate weight gain using growth charts as designed by the National Center for Health Statistics (NCHS), a branch of the Centers for Disease Control and Prevention (CDC). These charts were last updated in 2000 and unfortunately still reflect means for a population with a predominance of formula-fed infants. The World Health Organization (WHO) has since completed the Multi-Centre Growth Reference Study to better establish growth norms for infants and children who are breast-fed throughout the first year of life. A provider who is uncertain whether an exclusively breast-fed infant is meeting minimum growth requirements should refer to these charts before automatically encouraging caregivers to begin formula supplementation. Growth failure is usually considered a weight less than the third percentile or a drop of two or more percentiles in a short time (Figures 1 to 8, available on Expert Consult).

Overfeeding of newborns is unfortunately common, although bottle-fed infants are at a greater risk compared with breast-fed infants. Several factors can contribute to overfeeding, including lack of caregiver experience and support, as well as cultural biases such as the desire to have a chubbier infant. Many caregivers are unable to recognize infant cues for hunger and satiety and misinterpret cries or other vocalizations as a request for food. Medical providers should teach families about the rooting and sucking reflex and explain that some forms of sucking provide the infant with a means for self-soothing and are not signals that the infant is hungry (nonnutritive vs nutritive sucking).

## Introduction of Complementary Foods

Both the WHO and AAP now generally recommend waiting until an infant is 6 months old before starting solid foods. Developmentally, infants should be able to maintain good head control with some truncal support. Preterm infants who still lack head and neck control are not safe to begin solid foods and should remain on their fortified formula and/or breastmilk as well as daily multivitamin with iron. The AAP encourages families to continue breast-feeding, in addition to the new solid foods, until infants are 1 year old. Some families may choose to initiate solids at 4 months old with the common explanation of “it helps babies sleep better.” There is no evidence to support this claim. Medical providers can best encourage families to introduce only cereal options at this stage if the infant has demonstrated appropriate developmental abilities. Families should not be encouraged to delay beyond 6 months of age but rather to initiate supplemental solids as many micronutrient stores (e.g., iron, zinc, copper) have become depleted. Only one new solid should be introduced every 3 to 5 days so infants can be monitored for adverse food reactions.

Either formula or breast milk should continue to be offered until 12 months old, at which time infants can be transitioned to whole-fat cow’s milk. Low-fat milk does not provide toddlers with sufficient lipid concentrations for adequate brain development or the required caloric density for general growth. Large quantities of fruit juices should be avoided throughout infancy and childhood because they provide little nutritional value.

## Summary

The majority of term infants are born ready and able to begin feeding, but it is up to providers to know available nutritional options, normal feeding patterns, and means for measuring adequate intake and growth. Providers and other members of the care team also need to be able to counsel caregivers about best practices when feeding infants. When infants are suspected to be overfed or underfed, it may take a multidisciplinary approach by physicians, nurses, dietitians, speech therapists, lactation counselors, and social workers to help patients and their families.

## OBESITY IN CHILDREN

Method of

Casey R. Johnson, MD, MS; and Seema Kumar, MD

## CURRENT DIAGNOSIS

- Body mass index (BMI) is calculated as weight in kilograms divided by height (or length) in meters squared (kg/m<sup>2</sup>). BMI is currently the standard measure for classifying the weight status of a child.
- A child ≥2 years of age is diagnosed as overweight if the BMI is ≥85th percentile and <95th percentile for age and sex, as obese if the BMI is ≥95th percentile, and as severely obese if the BMI is ≥120% of the 95th percentile or ≥35 kg/m<sup>2</sup> (whichever is lower).
- The Centers for Disease Control and Prevention (CDC) recommends using growth curves based on the World Health Organization (WHO) reference standards for infants and toddlers <2 years of age and using the CDC/National Center for Health Statistics growth reference standards for children ≥2 years of age.

## CURRENT THERAPY

- Lifestyle modifications including dietary changes, increased physical activity, and decreased sedentary time remain first-line for prevention and treatment of childhood obesity.
- Family-based lifestyle interventions and a multidisciplinary team approach are key components of effective management of childhood obesity.
- Pharmacotherapy should be considered for carefully selected children with obesity; however, there is limited data on long-term efficacy and safety of weight-loss medications in children.
- Bariatric surgery has been shown to result in significant weight loss and should be considered for children with severe obesity and those that have significant obesity-related comorbidities.

## Introduction

Childhood obesity has emerged as an important public health problem in the United States and across the globe. The increasing prevalence of childhood obesity, severe obesity, and weight-related comorbidities places great risk on affected individuals, societies, and healthcare infrastructures. Moreover, childhood obesity tracks closely with obesity in adulthood, especially those with severe obesity and/or a strong family history of obesity, a relationship that foreshadows bigger problems for future generations. Childhood obesity and evidence-based treatment guidelines are discussed in this chapter.

## Diagnosis

Childhood obesity is marked by excess accumulation of body fat. Body mass index (BMI) is considered the most practical method for evaluation of obesity. BMI is calculated from weight in kilograms and the square of the height (or length) in meters, as shown below:

$$\text{BMI} = \frac{\text{Weight}}{\text{Height}^2}$$

Normal growth and development during childhood results in dynamic changes in weight and height, which vary based on age and sex. Childhood growth parameters, including BMI, may then be plotted against growth curves created from standardized reference populations, normalized by age and sex. The World Health Organization (WHO) has developed growth standards for infants

and children up to 5 years of age, and the Centers for Disease Control and Prevention (CDC) has similarly published reference standards for children between ages 2 and 20 years. The CDC recommends using the WHO standards from infancy until a child's second birthday, and the CDC/National Center for Health Statistics standards for children 2 years of age and older.

Weight status categories for children are generally segregated by BMI percentile by age and sex. Weight status in childhood is categorized as follows: underweight, normal weight, overweight, obese, and severe obesity. Obesity can be further classified as follows: class I obesity, defined as BMI at or above the 95th percentile to less than 120% of the 95th percentile; class II obesity, defined as BMI  $\geq 120\%$  to less than 140% of the 95th percentile, or BMI  $\geq 35$  kg/m<sup>2</sup> and  $< 40$  kg/m<sup>2</sup>; and class III obesity, defined as BMI at or above 140% of the 95th percentile, or BMI  $\geq 40$  kg/m<sup>2</sup>.

### Epidemiology

The prevalence of obesity among children has more than tripled over the last four decades. However, it has stabilized in recent years (Figure 1A). The prevalence of severe obesity in childhood, on the other hand, continues to increase. According to the 2015 to 2016 National Health and Nutrition Examination Survey (NHANES), one-third of US children are overweight and one in five is obese. Overweight affects 26% of preschool aged children, 34% of school-aged children, and 40% of adolescents. Obesity and severe obesity affect 14% and 2% of preschool aged children, 19% and 5% of school-aged children, and 21% and 8% of adolescents, each, respectively (Figure 1B). Childhood obesity is more common among Black populations, Mexican Americans, and American Indians than in non-Hispanic White populations and Asians. Presence of parental obesity increases the risk of obesity in children. Additionally, higher prevalence of obesity is associated with lower socioeconomic status.

### Pathophysiology

Childhood obesity develops as a result of a complex interaction between genetic, metabolic, environmental, and behavioral factors. As such, our historical understanding of “weight equals calories in minus calories out” is a gross oversimplification of obesity and its pathophysiology. Environmental factors such as family socioeconomic status, wealth, and access to food; neighborhood safety and available community activities; and family dietary patterns are all critical components. Approximately 40% to 85% of variability in adipose tissue deposition may be contributed to heritable factors (polygenic and largely unidentified genetic changes). Having one obese parent increases the risk of childhood obesity by two- to threefold; having two obese parents increases that risk by up to 15-fold. Obesity can rarely ( $< 1\%$  of childhood obesity) result from single gene mutations (e.g., melanocortin 4 receptor deficiency, leptin deficiency, leptin receptor deficiency) and congenital syndromes (e.g., Prader-Willi, Bardet-Biedel, Cohen) (Table 1). As children age and gain more control over their surroundings, individual factors such as lifestyle and dietary choices may also play a role. A host of other etiologic factors include endocrine disorders, neurologic and hypothalamic disorders, and medications.

Environmental factors affecting childhood obesity are diverse and complex. Specific dietary factors that portend risk of childhood obesity include sugar-sweetened beverages, sweet snacks, fast foods, large portion sizes, and maladaptive coping strategies such as eating to suppress negative emotions. Adverse childhood events and emotion and psychological distress increase the risk of childhood obesity. Intrauterine growth restriction and birth size, as well as antibiotic use, may also be predictive factors. Children, adolescents, and adults are also now spending less time being physically active. Time is increasingly spent in sedentary activities such as use of electronic devices: cellular phones, television, tablets, and computers. Evidence suggests that shortened sleep duration and/or decreased quality of sleep also contribute to development of obesity. Certain epigenetic factors, affected by environment, also influence risk of obesity such as nutrition and microbiome.

### Clinical Manifestations and Associated Comorbidities

Obesity is categorized as a complex chronic disease by the American Medical Association. Obesity affects essentially every organ system, most notably, the endocrine, gastrointestinal, pulmonary, cardiovascular, musculoskeletal, and psychological systems. Importantly, comorbid conditions once thought to be “adult onset”—type 2 diabetes mellitus (T2DM), dyslipidemia, obstructive sleep apnea (OSA), steatohepatitis—are now commonly encountered in children with obesity.

#### Cardiometabolic and Cardiovascular

Children with obesity have increased risk of developing prediabetes and T2DM, an association that varies with age and ethnicity. Children with T2DM tend to have higher rates of poor response to metformin therapy and more rapid progression of complications of diabetes, compared with those who present with T2DM later in life. Children with obesity also have a high prevalence of cardiometabolic risk factors including hypertension (approximately 50% of obese children and adolescents) and associated echocardiographic left ventricular hypertrophy, low levels of high-density lipoprotein cholesterol, and elevated triglycerides. Obesity during childhood is associated with an increased risk for cardiovascular disease during adult life, even after adjusting for BMI during adulthood.

#### Endocrine

Children with obesity may experience accelerated linear growth and skeletal maturation. Postpubertal females with obesity are also at greater risk of developing hyperandrogenism and polycystic ovarian syndrome, commonly associated with menstrual irregularities, hirsutism, acne, and acanthosis nigricans.

#### Pulmonary

Obesity during childhood is a significant risk factor for OSA. The severity of OSA and its prevalence are directly related to the severity of obesity. Children with obesity are also at risk for alveolar hypoventilation syndrome, which can result in significant blood-oxygen desaturation and carbon dioxide retention. Childhood obesity is also associated with asthma.

#### Gastrointestinal

Childhood obesity is associated with a spectrum of liver abnormalities known as nonalcoholic fatty liver disease (NAFLD). This disease spectrum—progressing from nonalcoholic fatty liver to nonalcoholic steatohepatitis (NASH) to NASH cirrhosis—is the most common cause of liver disease in children in the United States. Children with obesity also are at increased risk for gastroesophageal reflux disease (GERD).

#### Musculoskeletal

Limited mobility, lower extremity joint pain and back pain, genu valgum, lower extremity malalignment, and fractures are more common among obese children than nonobese children. Obesity during childhood is also a predisposing factor to unilateral or bilateral slipped capital femoral epiphysis and tibia vara (Blount disease).

#### Psychosocial

Psychosocial consequences of childhood obesity are numerous and include poor self-esteem, depression, anxiety, alienation, distorted body image, and low self-reported quality of life. Psychosocial disturbances increase in prevalence and severity with age and are more common in females. Children with obesity are more likely to experience bullying and discrimination. Adult women who were obese during childhood years completed fewer years of advanced education and had greater rates of poverty and lower rates of marriage compared with normal-weight peers. Obesity has also been associated with disordered eating patterns. Overweight or obese adolescents are more likely to engage in self-induced vomiting or laxative use. Weight talk by family members

and healthcare providers, and especially weight teasing, are related to disordered eating patterns.

**Dermatologic**

Obesity is associated with several dermatologic conditions, including acanthosis nigricans, intertrigo, hidradenitis suppurativa, furunculosis, and stretch marks.

**Neurologic**

Idiopathic intracranial hypertension (pseudotumor cerebri) is rare in childhood but more prevalent among obese children. This risk is further increased among children with severe obesity. Symptoms include headache, vomiting, visual disturbances, and retroocular eye pain. Retinal examination is significant for papilledema.

**Clinical Evaluation of the Child With Obesity**

Initial evaluation of a pediatric patient with obesity should include a thorough history and physical examination. These components are generally sufficient to determine the cause of the obesity and help the clinician in selecting the children that need further evaluation with laboratory and radiologic testing.

Obtaining an effective history requires identifying factors contributing to obesity and screening for obesity-related comorbid conditions. Dietary history should detail eating habits including frequency, content, and location of meals and snacks. Identifying intake of both calorie-dense foods, such as fruit juices and

soda, as well as healthy foods such as fresh vegetables and fruits, is helpful with dietary recommendations and with motivational interviewing. Physical activity assessment should detail time spent in unstructured play, organized sports, school recess, physical education, and recreational screen time. Identifying interest in specific physical activities, regardless of current participation, can be incorporated into motivational interviewing techniques. Medical history should include height, weight, and BMI growth trajectories and use of medications that may cause weight gain such as steroids, antipsychotic drugs, and antiepileptic drugs. Identification of developmental delay during a careful developmental history may suggest genetic or chromosomal causes for obesity. A complete review of systems may be helpful in determining secondary causes of obesity (Table 1) and screening for obesity-related comorbidities such as OSA, musculoskeletal problems, and idiopathic intracranial hypertension. Psychosocial screening should evaluate for bullying, depression, disordered eating habits, and family support and other social support.

Physical examination should include accurate measurement of weight and height and evaluation for dysmorphic features that could represent monogenic or syndromal obesity. Children with obesity and short stature are more likely to have a genetic or syndromic form of obesity. Weight gain in a child with poor linear growth can be indicative of an endocrine cause for obesity such as Cushing syndrome. Physical examination should include evaluation for comorbid features of obesity. A few examples include skin examination for acanthosis nigricans, funduscopic examination to evaluate for papilledema, and musculoskeletal examination for bowing of the legs. Laboratory evaluation to identify comorbid conditions in children with obesity is recommended by several expert societies. These recommendations include obtaining fasting lipid profile for all children who are obese or overweight, and the frequency of follow-up testing should be every 1 to 3 years depending on the child's risk profile. Measurement of serum alanine aminotransferase (ALT) is recommended for screening for fatty liver disease in children who are obese with retesting every 2 to 3 years if initial ALT is normal. Screening for T2DM with fasting glucose or hemoglobin A1c is recommended in overweight or obese children with one or more risk factors for T2DM. These risk factors include family history of T2DM in a first- or second-degree relative; high-risk race/ethnicity (Native American, African American, Hispanic, Asian American, Pacific Islander); maternal history of diabetes or gestational diabetes mellitus during the child's gestation; small for gestational age; signs of insulin resistance on physical examination such as acanthosis nigricans; and conditions associated with insulin resistance (hypertension, polycystic ovary syndrome, dyslipidemia). Screening for T2DM is recommended starting at 10 years of age or sooner if onset of puberty occurs before age 10. Rescreening should occur every 1 to 3 years depending on the weight trajectory and risk factor profile.

Children in whom a genetic, syndromic, or endocrine cause of obesity is suspected need to undergo specific testing. Children with signs and symptoms of OSA should be evaluated with overnight polysomnography. Children with features suggestive of idiopathic intracranial hypertension require head imaging and referral to appropriate experts.

**Treatment: A Staged Approach to Prevention, Clinical Interventions, and Monitoring**

Managing childhood overweight and obesity is challenging but, when conducted properly, can be both effective and rewarding. A staged approach to weight management in children (Box 1) has been recommended by the Expert Committee on Assessment, Prevention, and Treatment of Child and Adolescent Overweight and Obesity. The four stages progress in a stepwise fashion and involve primary care providers and, subsequently, a multidisciplinary team—primary care providers, dietitians, behavior counselors, exercise specialists, and occasionally surgical specialists. The stages encompass primary and secondary prevention; clinical interventions such as lifestyle modifications, pharmacotherapy, and bariatric procedures; and ongoing monitoring.

**BOX 1** Staged Approach to Weight Management in Children and Adolescents as Recommended by the American Academy of Pediatrics

- Stage I (Prevention Plus) guidelines include five or more servings of fruits and vegetables per day, minimizing or eliminating consumption of sugar-containing beverages, limiting screen time to 2 hours (none for children <2 years old), and >1 hour of physical activity per day. These interventions can be implemented in a primary care office setting.
- Stage II (Structured Weight Management) includes stage I guidelines plus increased structure of meals and snacks with attention to energy density of foods. These interventions can be implemented in a primary care office with a dietitian.
- Stage III (Comprehensive Multidisciplinary Intervention) includes stage II guidelines with additional increased structured physical activity and dietary program. These interventions can be implemented in a primary care office with a multidisciplinary team and outside facilities for structured physical activity, or, alternatively, in a pediatric weight management center.
- Stage IV (Tertiary Care Intervention) includes stage III guidelines with use of medications, rigorously structured dietary regimens, or bariatric surgery in select adolescents. These interventions can be ideally implemented in a pediatric weight management center with a multidisciplinary team with expertise in pediatric obesity.

Adapted from Barlow SE and the Expert Committee. Expert committee recommendations regarding the prevention, assessment, and treatment of child and adolescent overweight and obesity: summary report. *Pediatrics* 120 (Suppl)2007:S164–S192, 2007.

## Lifestyle Interventions Weight Management Goals

The goals for weight management are dependent on the child's age and severity of obesity. In children with mild obesity that are continuing to grow, maintenance of weight or slower rate of weight gain compared with previous is sufficient as that itself will lead to a decrease in BMI percentile. On the other hand, weight loss is recommended for children with severe obesity. A weight loss of up to 1 lb per month is safe for children between 2 and 11 years of age with obesity and comorbidities. More weight loss (up to 1–2 pounds per week) is safe in adolescents with obesity and comorbidities, although a weight loss of 1 to 2 pounds per month is more realistic in this age group.

### Stage I

*Stage I (Prevention Plus)* focuses on prevention and encouraging healthy habits: emphasizing the importance of five or more servings of fruits and vegetables per day; minimizing (or eliminating) consumption of sugar-containing beverages; limiting screen time to less than 2 hours per day; and encouraging at least 1 hour of physical activity per day. This stage may be implemented in the outpatient setting by a primary care provider. Recommendations from this stage may be applied in well-child visits, regardless of weight status. Goals of treatment for children with obesity at this stage may include weight maintenance rather than weight loss, taking into account normal growth changes. Frequency of follow-up visits should be individualized for each child and family. The follow-up schedule should be guided by patient/family readiness to change and severity of obesity. Recognizing risk factors and protective factors in this stage and counseling appropriately is crucial. There may be financial, cultural, behavioral, or family barriers that can significantly impact treatment planning and follow through. Family involvement and participation in this stage

and subsequent stages are essential for effective implementation of dietary and lifestyle changes. Helping children and their parents to identify their own lifestyle or dietary goals empowers children to be involved in their management and can be very effective. Goals should be “SMART”: specific, measurable, attainable, realistic, and timely.

Dietary recommendations center on increasing consumption of low energy-density foods such as fruits and vegetables and decreasing high energy-density foods such as sugar-added food products and refined carbohydrates. The Dietary Guidelines for Americans suggest that half of each meal should comprise fruits and vegetables, with preference for whole fruits and dark green vegetables such as leafy greens and broccoli (<https://www.myplate.gov/>). Some weight management programs use a “traffic light” dietary format, labeling foods as red, yellow, or green on the basis of energy density (red foods indicate high calorie density, green foods indicate low calorie density). Children are encouraged to eat green foods frequently and red foods more sparingly, such as on special occasions.

Motivational interviewing is a counseling technique that may be helpful in this and subsequent stages. This nonjudgmental method helps people to resolve ambivalent feelings to find inner motivation to make lifestyle changes. The process involves reflective listening and helps children realize their own strengths, values, and motivation to change. This tool has been shown to be useful in treatment of childhood obesity.

### Stage II

If the child is being managed for obesity as indicated in *stage I (Prevention Plus)* and there is no improvement in BMI within 3 to 6 months, progression to *stage II (Structured Weight Management)* should be considered. *Stage II* includes physical activity of at least 1 hour per day; a more structured dietary approach focusing on low energy-dense foods, balanced diet, and structured meal times; and no more than 1 hour of screen time per day. At this stage, referral to a provider with additional training in nutrition or behavioral counseling such as a dietitian is warranted. Explicit behavior goals are set and eating and physical activity logs are encouraged in order to monitor diet and activity. Strategies used in previous clinic visits, such as motivational interviewing and family involvement, should be continued. Positive reinforcement techniques are recommended in order to achieve weight loss. Interventions should be tailored to the individual child and family. Monthly contact between the patient and providers is recommended in order to monitor progress and facilitate continued involvement of the family and child.

### Stage III

If improvements in BMI, or significant improvements in lifestyle habits, are not achieved after 3 to 6 months of stage II treatment, *stage III (Comprehensive Multidisciplinary Intervention)* should be considered. *Stage III* further increases the intensity of behavioral intervention by addition of more specialists and increase in frequency of the visits. The intervention is aimed at creating a negative energy balance and goal setting for diet and physical activity. This stage requires a multidisciplinary team with expertise in childhood obesity that includes a behavioral counselor (e.g., social worker, psychologist, trained nurse practitioner, or other mental health provider), registered dietitian, and exercise specialist, and a primary care provider who oversees the intervention and manages medical issues. This type of intervention may be implemented in a primary care office provided an appropriate multidisciplinary team and resources are available within the medical center or community, otherwise referral to a pediatric weight management center may be necessary. Primary care offices may require partnerships with community programming: public health programs, local schools, Head Start, Young Men's Christian Association, and Boys and Girls Club. Stage III requires more intensive follow-up, with frequent provider-patient contact. Weekly office visits for the first 8 to 12 weeks

are recommended, followed by monthly visits once the patient and family are able to take more responsibility for the treatment plan. Involvement of the parents and extended family is crucial for children younger than 12 years of age, though even in older children, parental involvement is helpful for improvement of the home environment.

#### Stage IV

Children with severe obesity that have attempted *stage III* recommendations and have not met their weight loss goals should be considered for *stage IV (Tertiary Care Intervention)*. Patients should be motivated and be able to understand the risks and benefits of intervention in this stage. *Stage IV* requires referral to a pediatric weight management center, where a multidisciplinary team with significant expertise in childhood obesity, including clinical and research protocols for assessment of outcomes and risks, help coordinate and individualize patient care. This stage builds on recommendations from *stage III* and also incorporates the use of meal replacements, low-energy diets, medications, and/or bariatric procedures.

The success of weight loss interventions in children is related to the intensity of interventions. Behavioral interventions of moderate or high intensity (defined as 26–75 hours and >75 hours of provider contact, respectively) have been shown to be effective in achieving weight loss. Interventions of moderate or high intensity often are not available or feasible in the majority of primary care settings.

#### Pharmacologic Therapy

Pharmacologic treatment options for children and adolescents with obesity are limited (Table 2). Several medications are currently being used off-label for pediatric obesity. Use of medications for weight loss in children should be done under the care of a multidisciplinary team, and regular monitoring for efficacy and side effects is essential. Some experts suggest consideration of pharmacotherapy in adolescents with BMI  $\geq$ 95th percentile and with at least one obesity-related comorbidity, or with BMI  $\geq$ 120% of the 95th percentile or BMI  $\geq$ 35 kg/m<sup>2</sup> (whichever is lower), irrespective of comorbidities. Experts emphasize that patients should have attempted lifestyle interventions prior to initiation of pharmacologic therapy. Continuation of pharmacotherapy is recommended only if the medication is felt to be effective, as demonstrated by  $\geq$ 5% BMI reduction from baseline within 12 weeks on the optimal dose, or if slowing down/arrest of weight gain is considered satisfactory due to linear growth in adolescence. Weight-loss medications should be discontinued in the presence of side effects that persist despite adjustment of the dose. Adolescence is defined as age 10 to 19 years by the World Health Organization and 11 to 21 years by the American Academy of Pediatrics. There is scarcity of data on the long-term safety or efficacy of weight-loss medications (orlistat or any of the other medications used off-label) in children and adolescents.

Orlistat (Xenical) is approved by the United States Food and Drug Administration (FDA) for treatment of obesity in children 12 years of age and older. It is a lipase inhibitor that, when taken at the recommended dose of 120 mg three times a day with meals, blocks absorption of about one-third of fat digested in a meal. Lower doses of 60 mg three times per day with meals are available over-the-counter (Alli).<sup>1</sup> Side effects include flatulence, oily spotting, fatty stools, diarrhea, and potential for micronutrient deficiencies. Moreover, long-term safety data are lacking. The efficacy of orlistat over placebo for treatment of childhood obesity is modest, decreasing BMI by less than 1 kg/m<sup>2</sup> after 1 year of therapy.

Phentermine (Adipex-P) is a sympathomimetic drug (class IV controlled substance) that is approved by the FDA for short-term use (up to 12 weeks) in adolescents 17 years of age and older. It is approved in adults for long-term treatment of obesity in combination with topiramate (Qsymia). Doses in adults

have ranged between 15 and 37.5 mg (phentermine) per day. One pediatric study found that the drug resulted in a 4.1% decrease in BMI at 6 months. Adverse effects noted in adults include insomnia, restlessness, euphoria, palpitations, hypertension, cardiac arrhythmias, headache, dizziness, visual disturbances, and ocular irritation. Adolescents should be screened for congenital heart disease and other cardiac pathology and also have baseline assessment of blood pressure and heart rate before initiation of this drug. Long-term safety data are lacking. Phentermine is contraindicated in patients with hyperthyroidism, glaucoma, cardiovascular disease, or history of drug abuse. Phentermine use is not recommended for treatment of childhood obesity in primary care due to its risk factor profile and lack of data on long-term use.

Liraglutide (Saxenda) is a glucagon-like 1 receptor (GLP-1) agonist that is FDA approved for weight management in children and adolescents 12 years and older. A recent randomized, double-blind, controlled trial in adolescents 12 to <18 years of age showed placebo-subtracted BMI reduction of  $-0.22$  kg/m<sup>2</sup> at 56 weeks; 43% of subjects achieved a BMI reduction of at least 5%. Adverse effects include nausea, vomiting, abdominal pain, diarrhea, and potential hypoglycemia. Long-term safety data are lacking. Exenatide (Bydureon, Byetta),<sup>1</sup> another GLP-1 agonist, has been used off-label for treatment of childhood obesity in small studies and the effect has been modest with a BMI reduction of 3.4% in one study at 3 months. Long-term safety data for use of GLP-1 agonists for weight loss in children are lacking. GLP-1 agonists may have a potential role in syndromic and hypothalamic obesity with hyperphagia. Both liraglutide and exenatide are contraindicated in patients with a personal or family history of medullary thyroid cancer or multiple endocrine neoplasia 2A or 2B.

Setmelanotide (Imcivree), a melanocortin 4 receptor agonist, has been recently approved for adults and children at age  $\geq$ 6 years with obesity due to genetically confirmed proopiomelanocortin (POMC), proprotein convertase subtilisin/kexin type 1 (PCSK1), or leptin receptor (LEPR) deficiency. In a single-arm, open-label, multicenter phase III trial, 80% (8/10) of participants with POMC deficiency and 45% (5/11) of participants with LEPR deficiency achieved at least 10% weight loss at approximately 1 year. Adverse events include injection site reaction, skin hyperpigmentation, nausea, vomiting, and skin discoloration.

Metformin (Glucophage, Glumetza, Riomet) is approved by the FDA for treatment of T2DM in children 10 years of age and older. Use of metformin for weight loss is considered off-label; however, it is the initial drug of choice for weight loss in adolescents with prediabetes,<sup>1</sup> metabolic syndrome,<sup>1</sup> polycystic ovary syndrome,<sup>1</sup> and insulin resistance.<sup>1</sup> Metformin may be helpful in children with weight gain secondary to treatment with antipsychotic drugs.<sup>1</sup> The dose may be gradually increased as tolerated to a maximum of 2000 mg/day. Improvements in BMI have been modest with a meta-analysis finding BMI z-score reduction of 0.10 and BMI reduction of 0.86 mg/kg<sup>2</sup>. Adverse effects include abdominal discomfort, diarrhea, flatulence, vitamin B2 deficiency, and lactic acidosis.

Topiramate (Topamax) is another medication that is used off-label for treatment of obesity in children. The weight-loss effect is likely mediated through modulation of various neurotransmitters. This drug is FDA approved for treatment of epilepsy in children aged 2 years and older and for migraine prophylaxis in children 12 years of age and older. Adverse effects include cognitive dysfunction, paresthesia, metabolic acidosis, kidney stones, and teratogenicity. Adolescents must be counseled against pregnancy because of decreased efficacy of oral contraceptives with treatment. Topiramate also has modest efficacy for treatment of obesity. In a small randomized placebo-controlled pilot clinical trial of 30 adolescents, 2% reduction in BMI was noted on topiramate 75 mg at 6 months.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Pharmacologic Agents Used as FDA-Approved and Off-Label Treatments for Childhood Obesity

DRUG NAME	MECHANISM OF ACTION	FDA INDICATION	SIDE EFFECTS	ADOLESCENT WEIGHT-LOSS OUTCOMES DATA
<b>FDA Approved</b>				
Orlistat (Xenical)	Pancreatic and gastric lipase inhibitor	Obesity $\geq 12$ years	Flatulence, diarrhea, oily spotting, fatty stools, micronutrient deficiencies	Weight loss of 2.6 kg more than placebo at 1 year. Placebo subtracted BMI reduction of $-0.7$ kg/m <sup>2</sup> at 1 year.
Phentermine (Adipex-P)	Sympathomimetic amine	Obesity $> 16$ years of age for short-term treatment	Dry mouth, insomnia, irritability increased heart rate, blood pressure, constipation, anxiety	BMI decreased by 4.1% at 6 months.
Liraglutide (Saxenda)	GLP-1 agonist	Obesity in $\geq 12$ years	Nausea, vomiting, abdominal pain, diarrhea, potential hypoglycemia	Placebo subtracted BMI reduction of $-0.22$ kg/m <sup>2</sup> at 56 weeks. BMI reduction of at least 5% was achieved by 43% of subjects.
Setmelanotide (Imcivree)	Melanocortin 4 receptor agonist	Obesity at age $\geq 6$ years due to genetically confirmed proopiomelanocortin (POMC), proprotein convertase subtilisin/kexin type 1 (PCSK1), or leptin receptor (LEPR) deficiency	Injection site reaction, skin hyperpigmentation, nausea, vomiting, skin discoloration	80% of participants with POMC deficiency and 45% of participants with LEPR deficiency achieved at least 10% weight loss at approximately 1 year.
<b>Not FDA Indicated for Obesity</b>				
Metformin (Glucophage)	Activation of protein kinase pathway	$\geq 10$ years of age for type 2 diabetes mellitus	Epigastric discomfort, diarrhea, flatulence	BMI z-score decreased by 0.10 and BMI 0.86.
Topiramate (Topamax)	Modulation of various neurotransmitters	Treatment of epilepsy $\geq 2$ years and migraines prevention $\geq 12$ years of age	Cognitive dysfunction, metabolic acidosis, kidney stones, teratogenicity	BMI decreased by 4.9% on topiramate 75 mg daily for at least 3 months.
Exenatide (Bydureon, Byetta)	GLP-1 agonist	Type 2 diabetes mellitus in adults	Bloating, nausea/vomiting, abdominal pain, elevation of pancreatic amylase and lipase	BMI decreased by 3.4% at 3 months

### Bariatric Procedures

Bariatric procedures, including bariatric surgery, should be considered for adolescents with severe obesity and, often, with significant health comorbidities (Table 3). Severe obesity in childhood is a unique subset which has outpaced less severe forms of childhood obesity in prevalence. Importantly, lifestyle modifications—a cornerstone of pediatric obesity therapy—have not demonstrated significant and lasting weight loss in children with severe obesity.

Eligibility criteria for bariatric surgery include the following:

1. BMI  $\geq 120\%$  of the 95th percentile for age and gender or BMI  $\geq 35$  kg/m<sup>2</sup>, whichever is lower, and a severe comorbidity having significant effects on health (e.g., moderate to severe OSA; apnea-hypopnea index  $> 15$ ), T2DM, idiopathic intracranial hypertension, or severe and progressive steatohepatitis

or

BMI  $\geq 140\%$  of the 95th percentile for age and gender or BMI  $\geq 40$  kg/m<sup>2</sup>, whichever is lower, with any obesity-related comorbidity or self-reported impaired quality of life;

2. History of previous sustained efforts to lose weight through changes in diet and physical activity;
3. Commitment from the patient and family to adhere to recommended pre- and postoperative treatments, including vitamin and mineral supplementation; and
4. Patient and family understanding of the risks and benefits of bariatric surgery.

**TABLE 3** Indications for Bariatric Surgery in Adolescents

WEIGHT CRITERIA	COMORBID CONDITIONS PRESENT
BMI $\geq 120\%$ to $< 140\%$ of the 95th percentile or BMI $\geq 35$ kg/m <sup>2</sup> and $< 40$ kg/m <sup>2</sup>	Moderate-severe obstructive sleep apnea, T2DM, idiopathic intracranial hypertension, NASH, Blount disease, slipped capital femoral epiphysis, hypertension, gastroesophageal reflux disease
BMI $\geq 140\%$ of the 95th percentile or BMI $\geq 40$ kg/m <sup>2</sup> .	None required, though commonly present

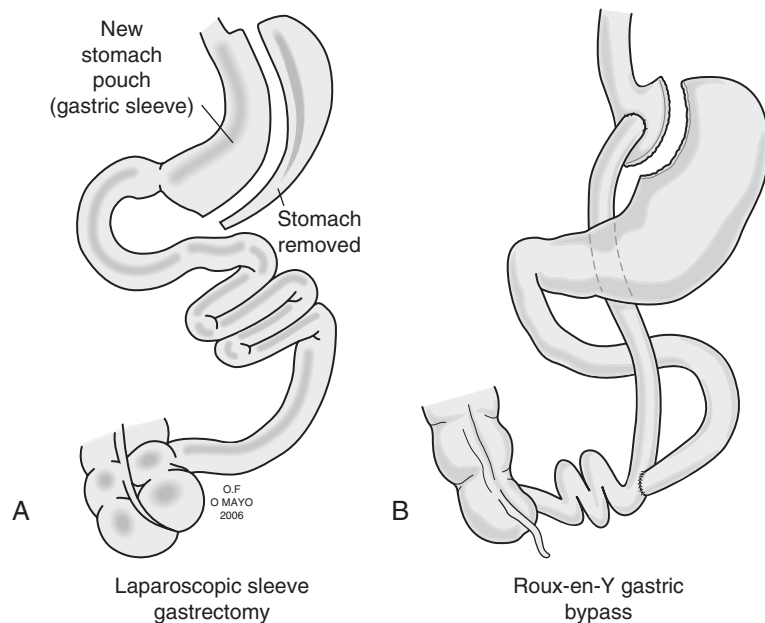

Adapted from Armstrong SC, Bolling CF, Michalsky MP, Reichard KW. Pediatric metabolic and bariatric surgery: evidence, barriers, and best practices. *Pediatrics* 144(6), 2019.

NASH, Nonalcoholic steatohepatitis; T2DM, type 2 diabetes mellitus.

The most recent expert guidelines do not recommend withholding surgery in those that have not completed puberty or physical maturity as determined by Tanner stage or skeletal maturation. Contraindications for bariatric surgery include the following:

1. Medically correctable cause of obesity;
2. An ongoing substance abuse problem (within the preceding year);

## Common bariatric procedures

**Figure 2** Bariatric surgical procedures commonly used for the surgical treatment of childhood obesity. (A) Laparoscopic sleeve gastrectomy. (B) Roux-en-Y gastric bypass.

3. A medical, psychiatric, psychosocial, or cognitive condition that prevents adherence to postoperative dietary and medication regimens or impairs decisional capacity;
4. Current or planned pregnancy within 12 to 18 months of the procedure; and
5. Inability on the part of the patient or parent to comprehend the risks and benefits of the surgical procedure.

### Types of Bariatric Procedures

The sleeve gastrectomy (SG; [Figure 2A](#)) is the most commonly performed procedure among adolescents with obesity. SG involves resecting the majority of the greater curvature of the stomach, leaving a tubular structure that serves as the new stomach. SG was initially performed as the first stage of a two stage procedure in high-risk adults with extreme obesity. The SG procedure is attractive during adolescence and particularly for adolescents with cognitive deficits. The procedure is less complex and can be converted to gastric bypass in the future if there is weight regain. The risk of micronutrient deficiencies is theoretically lower, as it is a purely restrictive procedure.

Roux-en-Y gastric bypass (RYGB; [Figure 2B](#)) was previously considered the gold standard of bariatric procedures among adolescents with severe obesity but is now performed less frequently than the SG. The surgery involves creation of a small proximal gastric pouch (<30 mL) and separation of the pouch from the distal stomach and anastomosis to a Roux-limb of small bowel that measures 75 to 150 cm in length. Though it is primarily considered a restrictive surgery, some degree of malabsorption does occur that leads to weight loss and places patients at risk for micronutrient deficiencies.

Both bariatric procedures have been shown to result in significant decreases in body weight and body mass index in the majority of adolescents undergoing those procedures. In the largest prospective study of bariatric surgery in adolescents (Teen-LABS), 26% reduction in BMI following SG and 28% reduction following RYGB was noted at 3 years. BMI reduction of 29.2% was noted at 5 years in 58 individuals undergoing RYGB. Both procedures have been shown to result in improvement of various

comorbid conditions including T2DM, prediabetes, hypertension, dyslipidemia, and renal disease.

Long-term adverse effects include deficiencies of iron, vitamin D, thiamine, and vitamin B12. Adolescents undergoing bariatric surgery need long-term monitoring, as long-term safety and efficacy data in this particular age group are limited.

### Conclusion

Childhood obesity presents a growing public health concern in the United States and globally. Weight-related comorbid conditions are common among children with obesity, conferring significant health risks, and such children should undergo routine clinical and laboratory screening. Treatment of obesity in childhood should follow a staged approach, focusing heavily on environment and lifestyle interventions. Children with severe obesity and those with weight-related comorbid conditions should be considered for pharmacotherapy and/or bariatric surgery. Bariatric surgery in adolescents has been associated with significant weight loss and improvement in weight-related comorbid conditions in the short and intermediate term.

## PARENTERAL FLUID THERAPY FOR INFANTS AND CHILDREN

Method of

Alan M. Hall, MD; Jimmy Chen, MD; Deval Patel, MD; and Michael L. Moritz, MD

### CURRENT DIAGNOSIS

- Maintenance intravenous fluids are used continuously to maintain extracellular volume and electrolyte homeostasis when enteral fluid (oral or via a feeding tube) intake is insufficient.
- Resuscitation intravenous fluids are used for the rapid restoration of intravascular volume.
- Replacement fluids are required to prevent hypovolemia and electrolyte abnormalities when continued excessive fluid losses are present.

### CURRENT THERAPY

- Intravenous fluids should be utilized only when enteral intake is inadequate and discontinued as soon as safely possible.
- Intravenous fluids should be individualized to each patient, with isotonic fluids recommended for the most acutely ill hospitalized patients when maintenance or resuscitation fluids are indicated.
- While a patient is receiving intravenous fluids, continuous reassessment is needed including clinical examination; assessment of vital signs, intake/output, and daily weights; and consideration of laboratory monitoring, especially sodium levels.

### Introduction

Intravenous fluid therapy is an integral component in the care of the acutely ill child. Intravenous fluids may be required as a bolus infusion for resuscitation, as a continuous infusion when sufficient fluids cannot be ingested orally, and to replace excessive ongoing losses from the gastrointestinal (GI) or urinary tract or from serous drains. The goal of fluid therapy is to provide sufficient fluids to maintain tissue perfusion and normal serum electrolytes. Acutely ill patients frequently have disorders that disrupt normal water and electrolyte homeostasis; therefore, choosing the appropriate volume and composition requires great care to prevent impairment in volume or electrolyte balance.

### Maintenance Intravenous Fluid Therapy

Maintenance intravenous fluids (MIVFs) are infused continuously to maintain extracellular volume and electrolyte homeostasis when enteral fluid (oral or via a feeding tube) intake is insufficient to meet daily requirements. Crystalloid intravenous fluids used for maintenance are categorized as isotonic (approximately equal to the plasma sodium concentration) or hypotonic (less than the plasma sodium concentration). [Table 1](#) shows the composition of commonly used intravenous fluids.

In 1957, Holliday and Segar proposed a theoretical approach to MIVF prescribing; they recommended that hypotonic MIVFs approximating the sodium and potassium concentration of breast milk or cow's milk could provide the water and electrolyte needs for acutely ill children. This led to widespread use of hypotonic MIVFs;

however, the first reports of the syndrome of antidiuretic hormone (SIADH) did not appear until after this publication. SIADH occurs when excess free water is retained, leading to hyponatremia secondary to the nonosmotic and nonhemodynamic triggered release of antidiuretic hormone (ADH). Virtually all acutely ill hospitalized children have a potential hemodynamic or nonhemodynamic stimulus for ADH production, placing them at risk for hyponatremia ([Figure 1](#)). The administration of hypotonic fluids increases their risk for developing hyponatremia, in particular from SIADH, which is the most common cause of hospital-acquired hyponatremia.

Multiple randomized controlled trials and meta-analyses have demonstrated a lower risk of hyponatremia when hospitalized children receive isotonic fluids compared with hypotonic fluids, with an approximate number needed to treat of 7.5. As a result, the American Academy of Pediatrics' Clinical Practice Guideline (AAP CPG) on MIVFs recommends isotonic MIVFs for most patients between 28 days and 18 years of age. In children younger than 28 days of age, the evidence is less clear on the choice between hypotonic and isotonic fluids. We tend to extrapolate the evidence from older children and use isotonic fluids in neonates given that they are also at risk for hyponatremia.

Isotonic fluids can be separated into balanced and unbalanced solutions. Balanced fluids include Ringer's lactate and Plasma-Lyte 148; they contain a buffer with chloride concentrations close to serum concentrations. A prime example of an unbalanced solution that contains significantly higher chloride concentrations compared with serum without an added buffer is 0.9% saline. Evidence is lacking on the choice between balanced and unbalanced solutions for maintenance in both children and adults. When MIVFs are used for short periods, which is typical for most pediatric patients, either a balanced solution or 0.9% saline is likely reasonable. If MIVFs are needed for long periods or at high doses, it is possible that 0.9% saline could cause a hyperchloremic metabolic acidosis. However, as detailed in the "Resuscitation Intravenous Fluid Therapy" section later in this chapter, the evidence regarding whether this could lead to adverse outcomes is equivocal. As a result, 0.9% saline or balanced solutions are both likely sensible options.

Although isotonic MIVFs are indicated for most, the choice of MIVF should be specifically tailored to each individual patient. Hypotonic fluids may be indicated in a subset of patients, including those with hypernatremia and a free water deficit or ongoing free water losses from a renal concentrating defect such as diabetes insipidus or voluminous watery diarrhea. Dextrose should be added to the MIVF for most children to prevent ketosis. Dextrose is rapidly metabolized upon infusion and does not contribute to the tonicity of the MIVF except in those with uncontrolled diabetes mellitus. There is little guiding evidence, but based on the AAP CPG, it is also recommended to add a potassium additive, typically 20 mEq/L, which can be in the form of potassium chloride. When MIVFs are used for only a short time, a potassium additive may not be needed except in patients with hypokalemia or risk factors for hypokalemia, including severe malnutrition and diuretic use. Hyperkalemia is a potentially serious complication of intravenous fluids, and potassium should be withheld from fluids if there is any concern for abnormal renal function or decreased or unknown urinary output.

The rate of infusion for MIVFs should be customized to each patient. There is no robust evidence to guide infusion rates, but this can be estimated by body surface area (1500 mL per 1.73 m<sup>2</sup> of body surface area per 24 hours) or weight (the Holliday-Segar formula). With the Holliday-Segar formula, fluids are calculated as follows:

- 100 mL/kg per 24 hours for the first 10 kg of body weight plus
- 50 mL/kg per 24 hours for weight between 10 and 20 kg plus
- 20 mL/kg per 24 hours for weight above 20 kg

This formula is estimated by what is known as the *4-2-1 rule*. It provides an estimate for the hourly MIVF infusion rate as follows:

- 4 mL/kg per hour for the first 10 kg of body weight
- 2 mL/kg per hour for weight between 10 and 20 kg

**TABLE 1** Composition of Commonly Used Intravenous Fluids

IV FLUID	SODIUM	CHLORIDE	POTASSIUM	CALCIUM	MAGNESIUM	BUFFER	OSMOLARITY (mOsm/L)
	mmol/L						
Human plasma	135–144	95–105	3.5–5.3	2.2–2.6	0.8–1.2	23–30 bicarbonate	308
<b>Isotonic/Near Isotonic Solutions</b>							
0.9% saline	154	154	0	0	0	0	308
Plasma-Lyte 148	140	98	5	0	1.5	27 acetate and 23 gluconate	294
Ringer's lactate	130	109	4	1.5	0	28 lactate	273
<b>Hypotonic Solutions</b>							
0.45% saline	77	77	0	0	0	0	154
0.2% saline	34	34	0	0	0	0	78

**Figure 1** Nonosmotic states of antidiuretic hormone (ADH) excess. (From Moritz ML, Ayus JC: Maintenance intravenous fluids in acutely ill patients, *N Engl J Med* 373:1350–1360, 2015. ©2015 Massachusetts Medical Society.)

- 1 mL/kg per hour for weight above 20 kg

MIVF infusion rates may need to be increased from these estimates in patients with polyuria from renal concentrating defects. Additionally, MIVFs may need to be avoided or used at lower rates of infusion in patients with volume overload states, including oliguric acute kidney injury, chronic kidney disease, cirrhosis, and congestive heart failure. Close monitoring with daily weights, frequent vital signs, strict measurements

of intake and output, and serial physical examinations are necessary while a patient is on an MIVF. Laboratory monitoring, specifically to follow sodium levels, should be considered for patients on MIVFs, especially in the initial 24 hours, when rates of hyponatremia are highest. Laboratory tests should also be checked if any neurologic symptoms develop, including unexplained nausea or vomiting, headache, confusion, or altered alertness.

### Resuscitation Intravenous Fluid Therapy

Volume depletion, commonly referred to as *dehydration*, occurs whenever water and salt losses exceed intake. Resuscitation intravenous fluids are used for the rapid restoration of intravascular volume to ensure cellular homeostasis and prevent end-organ dysfunction. Children are at risk for developing severe volume depletion when they are unable to keep up with fluid losses, such as from vomiting and diarrhea, traumatic injuries with significant blood loss, renal losses (e.g., hyperglycemia in diabetic ketoacidosis), cutaneous losses (e.g., burns), or third spacing (e.g., pancreatitis and sepsis). Rapid treatment can prevent the development of uncompensated shock while also decreasing morbidity and mortality.

The mainstay in the treatment of mild to moderate dehydration is oral rehydration therapy. However, patients presenting with severe dehydration or inadequate enteral intake should receive boluses of intravenous fluid. Because of their low cost and ready availability, isotonic crystalloids such as 0.9% saline, Ringer's lactate, or Plasma-Lyte 148 are preferred. Given the high risk of severe hyponatremia, hypotonic fluids should never be administered as boluses. Colloids, such as albumin, have not been shown to be superior to crystalloids in resuscitation.

Resuscitation with large amounts of 0.9% saline without a base equivalent may lead to hyperchloremic metabolic acidosis. Balanced or buffered solutions with lower chloride concentrations (e.g., Ringer's lactate or Plasma-Lyte 148), pose a lesser risk of causing a hyperchloremic metabolic acidosis. Since 2018, multiple large prospective controlled trials in adults comparing 0.9% saline to buffered solutions have shown no clear benefit in reducing mortality or acute kidney injury from buffered solutions. Balanced solutions have been associated with increased mortality in patients with traumatic brain injury. If a balanced solution is to be used, Plasma-Lyte 148 is preferred because Ringer's lactate is a near-isotonic solution and can contribute to a mild decrease in serum sodium.

The clinical signs of dehydration are a manifestation of extracellular volume depletion. Signs of extracellular volume depletion in children include elevated heart rate, delayed capillary refill, diminished tearing, dry mucous membranes, a sunken fontanel, poor skin turgor, decreased peripheral pulses, cool extremities, and ultimately a decrease in blood pressure when volume depletion is severe. Three factors determine the amount of extracellular volume depletion and therefore the severity of dehydration: (1) the fluid deficit, (2) the electrolyte deficit, and (3) the speed at which dehydration occurs. Given the same volume loss, hyponatremic dehydration is clinically more severe than hypernatremic dehydration because fluid shifts intracellularly in hyponatremic dehydration. This is the basis for classifying dehydration according to the serum sodium as hyponatremic, isonatremic, or hypernatremic.

To restore intravascular volume rapidly and provide adequate perfusion to vital organs, resuscitation fluid is given in rapid aliquots of 20 mL/kg followed by clinical reassessment. Patients with preexisting conditions, such as cardiac and renal disease, may require using smaller volumes of fluid (e.g., 5 to 10 mL/kg). In septic shock, up to 40 to 60 mL/kg may be given, with vasopressors quickly added if hemodynamics are not restored based on frequent clinical reassessments.

Potential harm is associated with excessive fluid resuscitation. Severe illness has been associated with damage to the glycocalyx, which lines the vascular endothelium. Damage to the glycocalyx can contribute to increased permeability of the endothelium and resultant increased risk of interstitial edema and fluid overload with intravenous fluid administration. Fluid overload has been associated with increased mortality, specifically in patients with acute kidney injury. Additionally, a large randomized controlled trial showed increased mortality when African children were given fluid boluses when they presented with a febrile illness and signs of shock.

To stay mindful of these potential adverse effects of resuscitation, an approach to fluid resuscitation with four phases has

been proposed in critical care settings. The first phase, rescue, is focused on correcting shock with rapid boluses. In the second phase, optimization, fluid is cautiously titrated to optimize tissue perfusion. The third phase includes stabilization with minimal fluid used only for maintenance, and the fourth phase is deescalation focused on mobilizing and removing any excess fluid.

The fluid deficit can be estimated by using the clinical signs listed [Table 2](#). As an example, a 10-kg boy presents with vomiting and diarrhea that has lasted for 3 days; he now weighs 9 kg. He is lethargic, tachycardic, and has a sunken fontanelle with cool extremities. Capillary refill is greater than 3 seconds. His clinical presentation and the amount of weight loss suggest at least 10% dehydration. The patient's calculated fluid deficit is as follows:

$$0.10 \times 10 \text{ kg} \times 1000 \text{ (mL/kg)} = 1000 \text{ mL (fluid deficit)}$$

Because the patient's pre-illness weight is known, an alternate method of calculation is to subtract his current weight from his pre-illness weight (10 kg to 9 kg) and multiply by 1000 (mL/kg), also resulting in 1000 mL of deficit. To start the resuscitation, a 20 mL/kg bolus of isotonic fluids (or 9 kg  $\times$  20 mL/kg = 180 mL) is then given over 30 minutes. If vital signs are restored to normal, a residual deficit of 820 mL will need to be replaced as oral or intravenous fluid therapy. If there is continued hemodynamic compromise after the initial bolus, additional boluses of 20 mL/kg are given.

### Replacement Intravenous Fluids

Replacement fluids are required to prevent hypovolemia and electrolyte abnormalities when continued excessive fluid losses are present. Common sources of fluid losses necessitating replacement include emesis, diarrhea, urine, and surgical drain outputs (chest tubes, nasogastric tubes, ileostomies, fistulas). If this fluid is not appropriately replaced, hypovolemia and significant electrolyte derangements can develop. Oral replacement of fluid is preferred when tolerated. Intravenous replacement of fluid is necessary when oral replacement cannot meet ongoing losses.

Before replacing ongoing losses, one must first restore extracellular volume with resuscitation fluids, as outlined previously. Once euvoolemia is restored, ongoing fluid losses must be closely replaced. It is important to note that this fluid replacement is in addition to the volume of required maintenance fluid. Replacement fluid therapy should be individually tailored for each patient, with inputs and outputs closely monitored. Existing guidelines recommend using 0.9% sodium chloride containing potassium as the initial fluid for replacement therapy. If fluid loss is ongoing and excessive, serial measurement of serum electrolytes is required to adjust the intravenous fluid prescription. The measurement of electrolyte concentrations may be helpful, as the electrolyte composition varies between sites of fluid loss. When measurement of electrolyte composition is not feasible, one must be familiar with the electrolyte contents of the fluid loss in varying disease processes in order to maintain the correct balance of electrolytes. The electrolyte composition of some of the common sites of fluid loss is shown in [Table 3](#).

In GI losses from infectious gastroenteritis, the electrolyte content varies based on the type of infection. A typical rotavirus enteritis can lead to a mean sodium loss of 50 mmol/L and up to 50 mmol/L of bicarbonate. Secretory diarrheal illnesses, such as cholera, can cause massive loss of fluid, with sodium losses as high as 140 mmol/L and bicarbonate losses several times that of other GI illnesses. If either hypernatremia or a metabolic acidosis is developing, a hypotonic replacement fluid or a buffered solution may be required. In the loss of other bodily fluids, such as emesis, a large amount of chloride is lost (90 to 150 mmol/L) instead of bicarbonate, and buffered solutions should not be used for replacement. Potassium and magnesium may also have to be replaced in diseases such as renal tubulopathies. In understanding the composition of the fluid lost, the appropriate type of intravenous fluid can be prescribed (see [Table 1](#)).

**TABLE 2** Clinical Signs to Estimate Dehydration

Older Child	3% (30 mL/kg)	6% (60 mL/kg)	9% (90 mL/kg)
<b>Infant</b>			
	5% (50 mL/kg)	10% (100 mL/kg)	15% (150 mL/kg)
Dehydration	Mild	Moderate	Severe
Skin turgor	Normal	Tenting	None
Skin (touch)	Normal	Dry	Clammy
Buccal mucosa/lips	Dry	Dry	Dry/cracked
Eyes	Normal	Slightly sunken	Sunken
Tears	Present	Decreased	None
Fontanelle	Flat	Soft	Sunken
Mental status	Alert	Alert/altered	Lethargic/obtunded
Pulse rate	Normal	Slightly increased	Increased
Pulse quality	Normal	Weak	Weak/very weak
Capillary refill	Normal	2–3 seconds	>3 seconds
Urine output	Normal/mild oliguria	Mild oliguria	Severe oliguria

**TABLE 3** Electrolyte Composition of Body Fluids

FLUID	Na <sup>+</sup> (mmol/L)	K <sup>+</sup> (mmol/L)	Cl <sup>-</sup> (mmol/L)	HCO <sub>3</sub> <sup>-</sup>
Gastric	20–60	14	140	60–80
Biliary drain	145	5	105	30
Pancreatic drain	125–138	8	56	85
Diarrhea/colostomy	30–140	30–70	—	20–80
Ileostomy	45–140	4–5	25–125	0–30

The management of ongoing fluid losses is a labor-intensive process that requires meticulous monitoring of the patient's total input and output. Close clinical assessment of the patient, daily weight measurements, and routine monitoring of electrolytes are necessary to ensure euvolemia and electrolyte homeostasis.

### Sodium Disorders

Disorders in serum sodium are the most frequent electrolyte abnormality in hospitalized patients and can occur on presentation or be hospital acquired. Hyponatremia and hypernatremia are both associated with potential neurologic and systemic complications and increased hospital morbidity and mortality. Careful fluid therapy is needed for both prevention and treatment.

#### Hyponatremia

Hyponatremia is defined as a serum sodium less than 135 mEq/L. The body's primary defense against developing hyponatremia is the kidney's ability to generate dilute urine and excrete free water. In most cases of hyponatremia there is a stimulus for ADH production that results in impaired free water excretion. There are numerous stimuli for ADH production (see [Figure 1](#)) that place virtually all hospitalized children at risk for hyponatremia. A particularly common cause of hyponatremia is SIADH. SIADH refers to euvolemic hyponatremia due to nonphysiologic stimuli for ADH production in the absence of renal or endocrine dysfunction. SIADH can be difficult to diagnose, as volume status is difficult to assess accurately and there are no specific biochemical tests

for diagnosing SIADH. Before SIADH can be diagnosed, diseases causing decreased effective circulating volume, renal impairment, adrenal insufficiency, and hypothyroidism must be excluded. The hallmarks of SIADH are (1) mild volume expansion with low to normal plasma concentrations of creatinine, urea, uric acid, and potassium; (2) impaired free water excretion with normal sodium excretion, which reflects sodium intake; and (3) hyponatremia that is relatively unresponsive to sodium administration in the absence of fluid restriction. The biochemical parameters most suggestive of SIADH in adults are a spot urine sodium concentration greater than 30 mEq/L, fractional excretion of sodium greater than 0.5%, fractional excretion of urea greater than 55%, fractional excretion of urate greater than 11%, and plasma uric acid less than 4 mg/dL. These parameters may not apply to young children.

The most serious complication of hyponatremia is hyponatremic encephalopathy, which is a medical emergency that can be fatal or can lead to irreversible brain injury if inadequately treated. The primary symptoms of hyponatremia are those of cerebral edema. The most consistent symptoms are nonspecific and can easily be overlooked: headache, nausea, vomiting, and generalized weakness. Advanced symptoms include seizures, respiratory arrest, noncardiogenic pulmonary edema, and decorticate posturing. Children are at particularly high risk for developing hyponatremic encephalopathy as they have a relatively larger brain-to-intracranial volume compared with adults. There is evidence to suggest that even mild and seemingly asymptomatic hyponatremia has deleterious consequences, being an independent risk factor for mortality.

Hyponatremic encephalopathy is a medical emergency that requires immediate therapy with 3% sodium chloride (3% NaCl, 513 mEq/L). The consensus treatment for hyponatremic encephalopathy is to give repeated intermittent boluses of 3% NaCl (2 mL/kg, maximum 150 mL) in order to raise the serum sodium acutely by approximately 5 mEq/L and decrease the risk of overcorrection. Fluid restriction is the cornerstone of treatment in asymptomatic hyponatremia. Isotonic saline is effective in treating hypovolemic hyponatremia, although it can aggravate hyponatremia due to SIADH. SIADH is usually of short duration and resolves with treatment of the underlying disorder or discontinuation of the offending medication. For more chronic forms of SIADH, therapies include oral sodium supplementation, oral urea (Ure-Na)<sup>32</sup>, or vasopressin V2-receptor antagonist.

Overcorrection of severe and chronic hyponatremia can result in brain injury from cerebral demyelination. Cerebral demyelination is primarily seen in chronically hyponatremic patients of greater than 48 hours' duration with a serum sodium of less than 115 mEq/L. Other risk factors that increase the likelihood of cerebral demyelination independent of the degree of hyponatremia or rate of correction are hypokalemia, thiazide diuretic use, severe liver disease, malnutrition, hypophosphatemia, and hypoxia. Excessive increases in serum sodium should be avoided under all circumstances, not just with hyponatremia. In patients with severe and chronic hyponatremia, the serum sodium should not be corrected by greater than 20 mEq/L in the first 48 hours of therapy.

### Hypernatremia

Hypernatremia is defined as a serum sodium >145 mEq/L. Hypernatremia occurs in children in the presence of restricted access to water, such as infants, debilitation by an acute or a chronic illness, neurologic impairment, or in the critically ill. Contributing factors for hypernatremia in the intensive care setting are excess sodium administration, renal concentrating defects, GI fluid losses, increased insensible water losses, restricted access to oral fluids, and dialysis-related complications.

If the thirst mechanism is intact and there is unrestricted access to free water, it is rare for someone to develop sustained hypernatremia from either excess sodium ingestion or a renal concentrating defect. The cause of hypernatremia is usually multifactorial. Measuring urine osmolality and electrolyte concentration can help to determine whether the renal concentrating ability is appropriate and to quantify the urinary free water losses. Less than maximally concentrated urine (<800 mOsm/kg) in the face of hypernatremia associated with signs of dehydration is a sign of a renal concentrating defect, as hypernatremia is a maximal stimulus for ADH release. A relatively new and useful clinical lab test for distinguishing central from nephrogenic diabetes insipidus is plasma copeptin testing. Copeptin, the C-terminal segment of the prehormone for arginine vasopressin, can be used as a surrogate marker of ADH as it is easier and more reliable to measure than ADH.

Hypernatremia results in an efflux of fluid from the intracellular space to the extracellular space to maintain osmotic equilibrium. This leads to transient cerebral dehydration with cell shrinkage. Children with hypernatremia are usually agitated and irritable but can progress to lethargy, listlessness, and coma. On neurologic examination they frequently have increased tone, nuchal rigidity, and brisk reflexes. Myoclonus, asterixis, and chorea can be present; tonic-clonic and absence seizures have been described.

The cornerstone of hypernatremia management is providing adequate free water to correct the serum sodium concentration but doing this at a rate that limits the risk of brain injury. Hypernatremia is frequently accompanied by volume depletion; if hemodynamic instability is present, fluid resuscitation with an isotonic solution should be instituted to establish more normal hemodynamics before slowly correcting the free-water deficit.

Following initial volume expansion, composition of parenteral fluid therapy largely depends on the etiology of the hypernatremia. Patients with sodium overload or a renal concentrating defect require a more hypotonic fluid than those with volume depletion and intact renal concentrating ability. Oral hydration should be instituted as soon as it can be safely tolerated. Plasma electrolytes should be checked frequently until adequate correction is achieved.

A simple way of estimating the minimum amount of fluid necessary to correct the serum sodium is by the following equation:

$$\text{Free water deficit (mL)} = 4 \text{ mL} \times \text{lean body weight (kg)} \times (\text{desired change in serum Na mEq/L})$$

The rate of correction of hypernatremia is largely dependent on the severity of the hypernatremia and the etiology. Due to the brain's relative inability to extrude unmeasured organic substances (idiogenic osmoles), rapid correction of hypernatremia can lead to cerebral edema. Although there are no definitive studies documenting the optimal rate of correction without causing cerebral edema to develop, empiric data have shown that a rate of correction of 0.5 mEq/h or 12 mEq/24 h is reasonable. Sodium chloride 0.45% with appropriate amounts of potassium is usually the most suitable composition of IVF to treat hypernatremia in children with hypovolemic hyponatremia and intact renal function.

## PEDIATRIC FAILURE TO THRIVE

Method of

Gretchen Homan, MD

### CURRENT DIAGNOSIS

- Pediatric failure to thrive (PFTT), also known as weight faltering, refers to failure to gain weight at an appropriate rate over time.
- History taking, physical examination, and growth chart data are used to identify PFTT.
- Weight below the fifth percentile with a decreasing trend over time indicates potential PFTT.
- Weight measurements declining across two major percentiles may indicate PFTT.
- Failure to gain or maintain weight is the earliest indication of PFTT, but length and head circumference may be impacted and should always be monitored.

## CURRENT THERAPY

- Successful treatment includes addressing all causes, including underlying medical problems.
- Hospitalization is generally not indicated, and serial clinic visits can be used to monitor weight gain and maintenance.
- Growth chart parameters can help set a goal weight. Daily weight gain goals can be identified to monitor treatment over weeks to months.
- The majority of patients respond to generalized techniques for increased calories combined with frequent outpatient monitoring of progress.
- Consulting with a dietitian or using detailed nutrition calculations can provide specific guidance for protein and calorie goals in complicated cases, and any contributing social determinants of health should be addressed by community resources..

In pediatric failure to thrive (PFTT), also known as weight faltering, the child fails to gain weight at an appropriate rate; this failure is documented over time. The concept has been recognized for over a century, but there is still no consensus on terminology or a definition. Historically, the terms *organic* and *nonorganic* were used to classify PFTT, and they were attributed to medical conditions and psychosocial causes, respectively. Insufficient usable nutrition is now regarded as the underlying cause of PFTT. It can be due to problems with calorie intake or absorption or both, and it is not unusual for patients to have more than one contributing factor. Approximately 80% of children with PFTT are diagnosed by age 18 months. For older children, the preferred term is *poor weight gain*.

### Epidemiology

In the United States, PFTT occurs in approximately 5% to 10% of children seen in primary care and in up to 5% of children admitted to the hospital. An estimated 20% to 30% of cases are undiagnosed. PFTT is a condition rather than a specific diagnosis, and imprecise diagnostic criteria complicate estimating its incidence and prevalence. Some children age 6 to 18 months show a decrease in their weight curves followed by weight maintenance on the new curve; although this occurs in approximately 25% of children, it is not considered weight faltering but a correction toward their genetic potential.

### Risk Factors

Risk factors for PFTT can be medical and/or psychosocial. In up to 80% of cases, no obvious medical etiology is identified. Any disease process has the potential to cause PFTT. Prenatal predisposing factors include exposure to toxins, intrauterine growth retardation, and poor maternal nutrition. Infants born prematurely are at high risk for PFTT. Premature infants need to catch up in growth over months to years and should not be expected to reach normal peer percentiles too quickly, as this could have negative implications for healthy weight in adult life. Any medical problem that interferes with or inhibits calorie intake and absorption of nutrients can cause PFTT, as can any condition that creates increased caloric demand. Leading medical causes include development delay, congenital anomalies such as cleft lip and/or palate, genetic conditions such as cystic fibrosis or celiac disease, and childhood cancers and related treatments.

Poverty is the most powerful psychosocial risk factor for PFTT, as it limits access to appropriate nutrition. Healthcare providers should be aware of “food deserts” in their communities as well as families within their practice that are food insecure. Children of families with increased life stresses, social isolation, poor parenting skills, or substance abuse are

at increased risk for PFTT. Personal nutritional beliefs and practices can also limit nutrition, leading to PFTT. Examples include prolonged exclusive breast feeding or avoidance of multiple food categories for cultural or religious reasons or real or perceived food allergy.

### Pathophysiology

Inadequate caloric intake, malabsorption, or increased metabolic demand, either as isolated entities or concurrently, can lead to PFTT. Caloric intake may be impaired by use of diluted formula, poor feeding habits, neglect, or mechanical feeding difficulties. Inadequate nutrient absorption can be caused by a range of diseases or conditions that affect the gastrointestinal tract, including celiac disease, cystic fibrosis and other pancreatic diseases, milk protein allergy, inborn errors of metabolism, and chronic infections. Increased energy needs and potential caloric deficit leading to PFTT can occur in children with chronic infections, congenital heart or lung disease, hyperthyroidism, malignancy, renal failure, inflammatory conditions, and HIV.

### Prevention

Prevention of PFTT begins with prenatal care and maternal health, especially limiting potential exposure to toxins, optimizing maternal nutrition, and conducting routine pregnancy screenings. Being aware of potential genetic conditions facilitates planning appropriate support for the family. State-mandated newborn screening tests provide opportunities for early intervention in patients at risk for PFTT. Routine well-child visits in the first 2 years of life provide surveillance for growth and anticipatory guidance regarding nutrition to support development. Connecting families with appropriate community resources can help provide high-risk children and families with access to nutritional resources. Supporting overall good health with patient education and general preventive services, including oral health and immunization, is essential to reducing the risk of FTT.

### Clinical Manifestations

PFTT is defined by problems with weight as a documented trend over time. The Centers for Disease Control and Prevention (CDC) recommend that the World Health Organization growth charts be used to document growth for children under age 2 years and that the CDC growth charts be used for children ages 2 years and older. The majority of PFTT patients show at least one of three characteristics: weight below the 5th percentiles for age and sex, weight drop of two major percentiles, or weight less than the 80th percentile of ideal body weight. Some infants may benefit from a PFTT evaluation when their daily weight gain is less than expected for age and sex but does not yet meet these criteria. If weight faltering persists, length and then head circumference are impacted, and these indicate severe PFTT.

Patients with PFTT can generally be diagnosed as outpatients. Laboratory evaluation or imaging is not generally required and is low yield in the absence of specific findings. Detailed history taking and physical examination, along with the growth chart information, are sufficient to identify PFTT. If the history or physical exam is concerning, initial laboratory work-up may include a complete blood count with differential, iron studies, lead level, chemistry panel, urine analysis, stool studies, or testing for immune deficiency. A delay in development coupled with weight faltering noted on the growth chart comprise the clinical presentation of severe or prolonged PFTT. The aim of the physical examination is to identify any underlying or contributing medical condition that could impair nutrition and/or increase metabolic demands. The clinician should observe for any dysmorphic features and look for signs of abuse or neglect. Signs of malnutrition may become evident when PFTT is allowed to persist. The most severely affected children show edema, wasting, hepatomegaly, rash, or skin and hair changes.

**Differential Diagnosis**

Prematurely born infants, infants with intrauterine growth retardation, and small for gestation age infants may be mistaken for patients with PFTT. These infants and children may meet the diagnostic criteria for delay on standard growth charts (values less than the 5th percentile) for age and sex. Ongoing monitoring for underlying medical conditions, regular developmental assessments, and evaluation of the social support network for each patient can provide reassurance that the child does not have PFTT and is expected to “catch up” in growth parameters within 18 to 36 months.

Genetic short stature and constitutional growth delay should be ruled out by reviewing the midparental height and growth patterns for delays. Radiologic testing for bone age may be helpful when confirming constitutional growth delay. Children with autism may have behaviorally restricted diets combined with medical complexities that predispose them to malnutrition and thus should be monitored carefully.

**Therapy**

PFTT can have one or multiple causes or complicating factors. Each issue should be addressed in the context of the overall health of the child and family. Any underlying medical condition must be diagnosed and treated. Children with a history of choking, signs of aspiration, or oral motor dysfunction may benefit from a swallow study and speech therapist evaluation and treatment program. Hospitalization is rarely indicated but may be helpful if there are complicating medical or social problems or if outpatient treatment has failed. Outpatient therapy is centered on increasing calorie intake with appropriate food options (Table 1). Equations can be used to calculate estimated calorie and protein needs by age and sex for both normal and catch-up growth. To simplify this process, a generalized list of targets is provided in Table 2. When available, a dietitian can define the required protein and calorie goals for catch-up growth initially and over the remaining treatment period. Alternatively, the primary care physician can use the growth chart to determine the desired weight goal for age and plan for a daily weight gain goal over weeks or months. The techniques described in Table 1 can be used to initiate treatment. Frequent visits are necessary. At each visit, the child’s measurements should be done on the same well-calibrated scale to

provide reliable data for clinical decision making about appropriate weight gain and maintenance. Patients who are unable to grow with these interventions may benefit from either short-term nasogastric tube feedings or more long-term gastric tube feedings.

**Monitoring**

Children with PFTT may require more frequent monitoring than the scheduled routine well-child visits. Young infants can be seen weekly or monthly and older patients every 2 to 4 months. At these visits, patients should be weighed and measured, infants in only a dry diaper and older children in light clothing without shoes, by trained staff using routinely calibrated devices and standardized techniques to ensure the most accurate measurements. The clinician should review the patient’s growth charts, diet and activity history, any changes in the social and medical history, and perform a physical examination. Recent acute illness may slow or reverse growth progress and should be addressed. It may take months for malnourished patients to show and maintain growth recovery. Patients who were born prematurely or with intrauterine growth retardation may require years to catch up. Depending on the underlying cause of PFTT, relapse is possible.

**Complications**

Weight loss or deceleration is the earliest clinical indicator for PFTT; if allowed to persist, height and length can be affected. Eventually, head size and brain growth can be impaired. At this level

**TABLE 2** Estimated Calorie Needs by Age

AGE	KCAL/KG/DAY
Preterm infant	115–130; up to 150 for very low birth weight infants
Full-term infant	<ul style="list-style-type: none"> <li>• 104–107</li> <li>• 0–2 months</li> <li>• 95</li> <li>• 3 months</li> <li>• 82</li> <li>• 4–35 months</li> </ul>
Toddler	70–80

Add 5–20 kcal/kg/day for catch-up growth, depending on tolerance and desired rate of recovery.

**TABLE 1** Techniques to Increase Calories

AGE	CALORIE SOURCE ADJUSTMENT	FEEDING TECHNIQUE
Infant – breast fed	<ul style="list-style-type: none"> <li>• Increase feeds up to 12 in 24 hours</li> <li>• Pump after feeds and use expressed breast milk (EBM) to supplement nursing; add formula powder to expressed breast milk</li> </ul>	<ul style="list-style-type: none"> <li>• Evaluate and ensure proper latch/position</li> <li>• Feed both breasts with each feeding</li> <li>• Work to keep baby awake for complete feeding</li> <li>• Do not allow feeds to persist beyond 30 minutes total</li> </ul>
Infant – formula fed	<ul style="list-style-type: none"> <li>• Increase calorie concentration by mixing formula powder with less water, from 19/20 to 24/26 kcal; monitor for tolerance</li> <li>• Evaluate feeding volume and frequency to avoid over- or underfeeding; rule of thumb feeds average 1 oz/h (e.g., 3 oz/3 h)</li> <li>• Formula powder may be added to foods</li> </ul>	<ul style="list-style-type: none"> <li>• Evaluate for intolerance and change formula if needed; consider predigested proteins</li> <li>• Use proper bottle nipple speed</li> <li>• Avoid bottle propping</li> </ul>
Toddler	<ul style="list-style-type: none"> <li>• Use high-calorie foods and offer proteins such as cheese, peanut butter, avocados, high-fat yogurts, oils, and heavy creams</li> <li>• Encourage a variety of healthy foods such as fruits, vegetables, proteins, and grains</li> <li>• Consider supplement drinks or shake powders to mix 1–2 times/day</li> </ul>	<ul style="list-style-type: none"> <li>• Structured mealtimes for 20–30 minutes in a high chair with adult supervision and without distractions (e.g., television, other children)</li> <li>• Evaluate toddler’s ability to self-feed effectively; intervene and teach if needed</li> <li>• Aim for 3 meals with 3 snacks daily</li> <li>• Minimize fruit juices</li> <li>• Offer water with meals and offer foods before milk or supplement drinks</li> <li>• Avoid low nutrition foods such as sweets and fried foods</li> </ul>

of severity, PFTT puts cognitive development and achievement of milestones in jeopardy. Immune system function may be impaired during a malnourished state, thus putting affected patients at risk for infections. Social and emotional health may also be impacted. Research is ongoing to understand the long-term effects of PFTT.

**PEDIATRIC SLEEP DISORDERS**

Method of

**Julie M. Baughn, MD**

**CURRENT DIAGNOSIS**

- Sleep disorders are common in children.
- Evaluation of pediatric sleep disorders in children begins with a thorough sleep history.
- Overnight polysomnography is most commonly used to evaluate for sleep-disordered breathing
- Other diagnostic tools include the multiple sleep latency test (MSLT), oximetry, sleep logs, and actigraphy.
- Common sleep disorders in children include obstructive sleep apnea, insomnia, restless legs syndrome, and delayed sleep phase syndrome.

**CURRENT THERAPY**

- For most children tonsillectomy and adenoidectomy are an effective treatment for obstructive sleep apnea.
- Behavioral therapy is essential to treating insomnia.
- Only in select circumstances are medications used to treat children with sleep disorders.

**Introduction**

Pediatric sleep medicine has grown as the importance of sleep in the developing child has been recognized along with the impact that insufficient or disrupted sleep can have on cognitive development and behavior. The American Academy of Sleep Medicine (AASM) and the American Academy of Pediatrics (AAP) have

recently published guidelines and practice parameters addressing several aspects of pediatric sleep medicine. Pediatric sleep disorders have unique societal impact; both the child's and the family's sleep can be affected when a disorder is present. The aim of this chapter is to offer a practical approach to the diagnosis and treatment of the most common pediatric sleep disorders, discuss diagnostic tools available, and discuss recommended treatment.

**Developmental Aspects of Sleep**

Pediatric sleep disorders also have the unique challenge of dealing with sleep issues that are subject to change based on the child's developmental age. The amount of sleep required by age has been described in a recent AASM consensus statement (Table 1). The sleep architecture of the child characteristically changes as he or she develops. The portion of rapid eye movement (REM) sleep declines from 50% at birth to 25% to 30% in adolescence. The proportion of slow-wave sleep is highest in early childhood and continues to decline throughout life. The pattern of sleep and sleep requirement also change. Neonates may not develop a regular sleep-wake pattern until about 3 months of age. Most infants are capable of sleeping through the night by about 6 months of age, but many may continue to awaken. Naps are typically given up somewhere between 3 and 5 years of age. Most adolescents, due to many societal and social constraints, do not get a requisite 8 to 10 hours of sleep at night.

**Clinical Approach**

**Taking a Sleep History**

There are several key elements to obtaining a sleep history in children. The mnemonic BEARS (Bedtime problems, Excessive daytime sleepiness, Awakenings during the night, Regularity and duration of sleep, and Sleep-disordered breathing) has been offered as a practical starting point for obtaining a history, tailoring questions to both parent and child where appropriate (Table 2).

The primary sleep complaint should be obtained in the child's or parent's own words. Once the primary complaint is detailed, the presence/absence of snoring, the presence of restlessness at sleep initiation and during sleep, and the child's sleep-wake patterns during school should be gathered. The presence or absence of a bedtime routine and the details of that routine should be noted. A child's sleep environment should be carefully queried. A child who shares his or her bedroom, sleeps in his or her parents' bed, or ends up sleeping on a couch in front of the television may lead to specific sleep complaints. A history of whether there is more than one household involved (i.e., shared custody) is particularly important.

Sleepiness in children can be a particularly challenging symptom to evaluate. It is normal physiologically for children to nap until age 5. Other clues to daytime sleepiness that can be obtained in children include behavior issues, hyperactivity,

**TABLE 1** Sleep Requirements in Children by Age

AGE	AVERAGE SLEEP DURATION IN 24 HOURS (OVERNIGHT AND NAPS)
Infants (4 to 12 months)	12 to 16 hours
Children (1-2 years)	11-14 hours
Children (3-5 years)	10-13 hours Most give up naps between 3 and 5 years
Children (6-12 years)	9-12 hours
Teenagers (> 12 years13-18 years)	9 hours8-10 hours

**TABLE 2** BEARS Mnemonic: A Screening Tool for Sleep Disorders in Children

	<b>PRESCHOOL (2–5 YEARS)</b>	<b>SCHOOL-AGE (6–12 YEARS)</b>	<b>ADOLESCENT (13–18 YEARS)</b>
Bedtime problems	Does your child have any problems going to bed? Falling asleep?	Does your child have any problems at bedtime? (P) Do you have any problems going to bed? (C)	Do you have any problems falling asleep at bedtime? (C)
Excessive daytime sleepiness	Does your child seem overly tired or sleepy during the day? Does your child still take naps?	Does your child have difficulty waking in the morning, seem sleepy during the day, or take naps? (P) Do you feel tired a lot? (C)	Do you feel sleepy a lot during the day? In school? While driving? (C)
Awakenings during the night	Does your child wake up a lot at night?	Does your child seem to wake up a lot at night? Any sleepwalking or nightmares? (P) Do you wake up a lot at night? Have trouble getting back to sleep? (C)	Do you wake up a lot at night? Have trouble getting back to sleep? (C)
Regularity and duration of sleep	Does your child have a regular bedtime and wake time? What are they?	What time does your child go to bed and get up on school days? Weekends? Do you think your child is getting enough sleep? (P)	What time do you usually go to bed on school nights? Weekends? How much sleep do you usually get? (C)
Sleep-disordered breathing	Does your child snore a lot or have difficulty breathing at night?	Does your child have loud or nightly snoring or any breathing difficulties at night? (P)	Does your teenager snore loudly or nightly? (P)

Abbreviations: C = child; P = parent.

From Owens JA, Dalzell V: Use of the “BEARS” sleep screening tool in a pediatric residents’ continuity clinic: A pilot study. *Sleep Med* 2005;6:63–69.

**TABLE 3** Principles of Sleep Hygiene in Children

The child’s bedroom should be dark and quiet. Bedtime routines should be strictly enforced. Routines should be relaxing and only 20 to 30 minutes in length. The time of morning awakening should be firmly and consistently structured. Bedroom temperatures should be kept comfortably cool (< 75 °F). Environmental noise should be minimized as much as possible. Background music and/or white noise may inhibit extraneous noise. Children should not go to bed hungry and may have a snack before bedtime. Excessive fluids before bedtime may result in bladder distention and arousal and disrupt sleep. Children should learn to fall asleep alone (i.e., without their parents’ presence in the room). Vigorous activity should be avoided before bedtime. A bath is often a stimulating activity for children. If bedtime struggles are present after a child’s bath, it may be moved to the morning or separated from the child’s bedtime by at least 2 hours. Methylxanthine-containing beverages and food (e.g., caffeinated beverages/colas, tea, chocolate) should be avoided several hours before bedtime. Parents should read labels on all over-the-counter and prescription medications. Some may contain alcohol or caffeine and may disrupt sleep. Naps should be developmentally appropriate. Brief naps may be refreshing, but prolonged naps or napping too frequently may result in significant accumulation of sleep during the day and make it more difficult to fall asleep at night.

Modified from Sheldon SH, Ferber R, Kryger M (eds): *Principles and Practice of Pediatric Sleep Medicine*. Philadelphia: Elsevier Saunders, 2005.

excessive napping, or napping after age 5 years (intentionally or unintentionally). School-age children often display symptoms of behavioral problems or inattentiveness rather than sleepiness. Sleep-wake patterns on school days, weekends, and vacations

need to be detailed. Often the child’s most natural sleep pattern will emerge over the summer months.

Determining the child’s sleep hygiene or good sleep practices is important in diagnosing and treating sleep disorders. Principles of good sleep hygiene are listed in [Table 3](#).

#### Past Medical History/Family History

A history of prematurity, trisomy 21, velopharyngeal cleft palate repair, or hypotonia is each associated with an increased risk of sleep-disordered breathing. A past history of adenotonsillectomy for snoring is important information to obtain. Chronic nasal obstruction can cause maxillary hypoplasia. Arnold-Chiari malformation, myelomeningocele, or a brainstem lesion can predispose to central sleep apnea due to impaired central respiratory drive. Chronic health issues can also be associated with sleep disruption and consequently with behavioral problems associated with sleep.

A family history of obstructive sleep apnea (OSA), insomnia, or restless legs syndrome (RLS) is important; a family history of RLS can be used to support a diagnosis of RLS in the child. In particular, questioning the mother if she had symptoms of RLS during any of her pregnancies can be helpful because this is a common time for RLS to present or worsen. Morning or evening preferences (i.e., “night-owl” or “lark” tendencies) can also have a familial element. In addition, sleepwalking can be found to occur in families.

#### Focused Physical Examination

The physical examination in a child presenting with a sleep complaint should include a general assessment. Presence/absence of sleepiness, fatigue, and irritability/hyperactivity are all important. Height, weight, and body mass index (BMI) should be recorded. Children with OSA can have poor growth and even failure to thrive. Obesity is a risk factor for OSA. Special attention to a child’s craniofacial features is important because these may make a child more at risk for sleep-disordered breathing.

Assessment of tonsil size, oropharyngeal crowding (using the Mallampati or Friedman classification systems can be useful), and presence of maxillary/mandibular hypoplasia can all offer clues to an airway that may predispose to OSA. The practitioner should evaluate for evidence of nasal obstruction by noting mouth breathing and signs of allergy (i.e., allergic shiners, nasal crease).

### Diagnostic Tools

#### Polysomnography

The AASM has published practice parameters on both the respiratory and nonrespiratory indications for polysomnography (PSG) in pediatric patients. In this chapter, a sleep study or PSG will refer only to an in-laboratory attended study, because home monitoring currently has not been sufficiently evaluated in the pediatric population. PSG in children entails spending the night at a sleep center. A parent or caregiver must also spend the night. During the night, the child's sleep characteristics, respiratory function, and movement are analyzed. This is done by the following measures: electroencephalography (EEG), electromyography (EMG) of chin and limbs, airflow by thermistor and nasal pressure, end-tidal or transcutaneous carbon dioxide measurements, and induction plethysmography to measure respiratory effort. Scoring of a PSG performed on a child is done using pediatric scoring rules set forth by the AASM.

The most common indication for a sleep study in children is OSA. PSG can be used to both diagnose OSA and treat sleep apnea with continuous positive airway pressure (CPAP). PSG can also be used to evaluate for elevated periodic limb movements of sleep, and in rare cases to characterize abnormal nocturnal behavior such as evaluation of parasomnias or nocturnal seizures.

#### Overnight Oximetry

The gold standard for diagnosis of pediatric OSA is PSG. Overnight oximetry has been suggested as an alternative screening tool for pediatric sleep-disordered OSA. Although an abnormal oximetry will suggest OSA, a normal oximetry does not rule out OSA. Children can have sleep apnea that is severe and still maintain normal oxygenation. In a study by Brouillette and colleagues (2000), when a positive oximetry graph was present (defined by three or more desaturation clusters and at least three desaturations < 90%) in a referred population, the positive predictive value for OSA on PSG was 97%. A negative or inconclusive oximetry by this definition did not rule out OSA and there was still a 47% chance OSA was present on PSG.

#### Sleep Logs/Actigraphy

Sleep logs can be effective in demonstrating a child's sleep-wake patterns. Actigraphy is often done in conjunction with a sleep log. Actigraphy is a portable wristband that measures movement. The absence of movement over a certain time period is used as a surrogate marker of sleep, and the presence of movement over a certain time period is used as a surrogate for wakefulness. Some devices also measure ambient light exposure. Used in conjunction with actigraphy sleep logs can be extremely helpful in demonstrating discrepancies between perceived and actual sleep, and are helpful in demonstrating insufficient sleep and circadian rhythm disorders. Those that measure light as well can aid in uncovering sleep hygiene issues.

#### Multiple Sleep Latency Test

The multiple sleep latency test (MSLT) is a daytime study used to objectively measure sleepiness. It is often used to aid in the diagnosis of narcolepsy or hypersomnia. It is a set of four to five scheduled naps that typically occur the day after an

overnight sleep study. Often 2 weeks of actigraphy are done before the MSLT to determine sleep-wake patterns.

### Common Pediatric Sleep Diagnoses and Treatment Obstructive Sleep Apnea

#### Epidemiology

Up to one-fifth of children can have intermittent snoring. Prevalence rates of OSA range from 1.2% to 5.7%. OSA is most common in children 2 to 8 years of age corresponding to the peak age of adenotonsillar hypertrophy. Due to the rise in childhood obesity there is now a corresponding rise in older children diagnosed with OSA.

#### Pathophysiology

The pharynx has many roles, including swallowing, speaking, and maintaining airway patency. Pharyngeal size is determined by the bones and soft tissue. The soft tissue is affected by the size of the tonsils and adenoids, as well as adipose tissue. Airway patency is maintained during wakefulness; a small airway can become vulnerable during sleep resulting in partial or total closure of the airway, hypoxemia, hypercapnia, and an arousal that results in opening of the airway and termination of the obstructive event. This leads to sleep disruption and daytime consequences. OSA in children likely results from a combination of narrowing of the upper airway, abnormal upper airway tone, and genetic factors.

#### Clinical Manifestation

OSA in adults is typically associated with daytime sleepiness. Associations have been made with hypertension, stroke, and metabolic syndrome. In children, OSA may not present with daytime sleepiness. Children may present with daytime inattention and/or neurocognitive and behavioral issues. Symptoms include snoring with or without apneic pauses or gasps. Restless sleep or secondary enuresis may also be noted. Parents may comment on increased work of breathing while sleeping. Other associations include poor growth, obesity, hypertension, and systemic inflammation.

#### Diagnosis

The gold standard for diagnosis of pediatric OSA is an in-laboratory attended PSG by an accredited sleep laboratory. History and physical examination lack sensitivity and specificity in predicting which children with snoring have OSA. However, a history of loud snoring, tonsillar hypertrophy, and abnormal oximetry is strongly suggestive of the diagnosis of OSA (see above). History alone cannot distinguish children with OSA from those with primary snoring. Criteria for the diagnosis of OSA in children are met when there is one or more apnea or hypopnea events per hour identified using scoring criteria by the AASM.

#### Differential Diagnosis

Other forms of sleep-disordered breathing are not as common as OSA. Sleep-related hypoventilation can occur in patients with neuromuscular weakness. Central hypoventilation syndromes are rare, but should be considered in children with persistent gas exchange abnormalities without additional explanation. Sleep-related hypoxemia can be present in pediatric patients with chronic lung disease. Central sleep apnea should be thought of in patients with brainstem abnormalities or Arnold-Chiari malformation. Sleep-related seizures may be difficult to differentiate from OSA in infants and an extended EEG montage may be necessary during their sleep study. Normal breathing patterns of infants and children should also be identified; brief (less than 10 seconds), central respiratory pauses that are self-resolving (and without significant desaturation) are common in normal children in either REM sleep or post-arousal/post-sigh.

### Treatment

Treatment of OSA in most children is adenotonsillectomy. Recent guidelines from the AAP recommend an overnight sleep study in children where the practitioner had a clinical suspicion of OSA before adenotonsillectomy. Children with mild OSA preoperative can be monitored clinically postoperatively. Children with moderate to severe OSA, as well as children with craniofacial abnormalities, neurologic disorders, and obesity, should have a follow-up PSG to demonstrate resolution of OSA after surgery. Recent randomized controlled trials have shown that some children may outgrow their OSA, particularly if it is mild. Children who are not candidates for adenotonsillectomy may be treated with CPAP and use may have an impact on neurobehavioral outcomes. Treatment with CPAP therapy in children requires close follow-up because pressure needs may change with growth. In certain children, treatment with intranasal corticosteroids and/or montelukast may be considered with close follow-up.

### Difficulty with Sleep Initiation and Night Wakings

#### Epidemiology

Bedtime problems and night wakings occur in up to 30% of children.

#### Clinical Manifestations

The diagnosis of insomnia includes difficulty going to sleep and/or staying asleep, the complaint that sleep is not of good quality, and the report of poor daytime functioning. The sleep complaints of infants and young children are often in the words of their parent or caregiver.

In preschool-age children both bedtime problems and night wakings are common and characterized by two types of behavioral insomnia of childhood: sleep-onset association type and limit-setting type. The definition of the *sleep-onset association type*, as defined in the ICSD-3, includes the following: sleep initiation is an extended process, associations are demanding, if the associations are not present sleep onset is delayed, and awakenings require caregiver intervention. The *limit-setting type* involves difficulty initiating or maintaining sleep, there is bedtime stalling or refusal, and the caregiver does not set sufficient and appropriate limits around this behavior. Children with frequent and prolonged night wakings have the sleep-onset association type. They often require an intervention by the caretaker to reinitiate sleep. Both problems can be present at once. Children who have difficulty going to sleep and provide resistance to bedtime have the limit-setting type. Parents of these children may complain of daytime behavioral issues due to the parent's inability to set limits during the day as well.

#### Diagnosis

Diagnosis is made from the history in the majority of cases. An overnight sleep study may be indicated in cases where another sleep disorder is suspected.

#### Differential Diagnosis

The differential diagnosis of insomnia or behavioral insomnia of childhood includes sleep disorders such as OSA, RLS, or nocturnal seizures. These disorders can prompt nocturnal awakenings or make sleep initiation difficult. If there is clinical suspicion of one of these disorders, an overnight sleep study may be indicated.

#### Treatment

Behavioral interventions have been shown to be effective in treating all forms of insomnia. In older children, primary and secondary insomnia can be effectively treated with cognitive-behavioral therapy. This often includes stimulus control and sleep restriction. Stimulus control includes maintaining a

regular sleep-wake pattern and using the bed and bedroom only for sleeping. It involves getting out of bed if sleep is not initiated within about 20 minutes. Sleep restriction includes minimizing the time in bed to be only sleeping. It often includes delaying bedtime to the child's actual sleep onset, and then over time gradually advancing the bedtime. Sleep hygiene should be effectively addressed, including development of a relaxing bedtime routine, maintaining a regular sleep-wake pattern, and eliminating electronic use before bedtime.

There are several treatments of behavioral insomnia of childhood sleep-onset association type. No one treatment has been found to be superior. The goal of all of these methods is for the child to fall asleep in his or her crib or bed on the child's own. These include extinction (i.e., "cry it out"), which is often not palatable to caregivers. There is the graduated extinction method, which has parents ignoring crying or protests for specified periods of increasingly longer intervals. Some prefer an even more gradual approach of sitting next to the child's bed in a chair and over several days to weeks moving that chair across the room and out of the room. A consistent bedtime routine should also be implemented. Use of a transitional object can be helpful. Treatment of the limit-setting type includes firm limit setting. Positive reinforcement and limiting negative reinforcement should be used. The use of a reward system can be helpful. Effectively addressing behavioral treatment of sleep issues can be challenging for the primary care provider because of time constraints.

### Restless Legs Syndrome/Willis Ekblom Disease

#### Epidemiology

Prevalence rates for pediatric RLS/WED have ranged from 1% to 6%.

#### Risk Factors

Risk factors include a family history and a history of anemia or iron deficiency. Attention-deficit/hyperactivity disorder (ADHD) is associated with RLS.

#### Pathophysiology

Decreased dopamine has been suggested in the pathophysiology of RLS/WED. Iron is a cofactor in the synthesis of dopamine and treatment of iron deficiency or low ferritin, if present, may improve symptoms.

#### Diagnosis

Diagnosis of pediatric RLS/WED is a clinical diagnosis. It is made using the adult criteria set forth in the ICSD-3 but with some modification for children due to developmental issues. It consists of the child reporting an urge to move the legs, usually accompanied by an uncomfortable sensation; this urge or sensation worsens during rest or inactivity; the sensations are improved or resolved by movement; the sensations are present or worsen in the evening or night. If a child cannot express a description in his or her own words, diagnosis can be made using two out of the following three criteria: a sleep disturbance for age, a family history of RLS, and a periodic limb movement index on PSG of > 5 per hour. Because of this last criterion, a sleep study can be helpful in children to make this diagnosis. There can be an association with sleep initiation and maintenance difficulties.

#### Differential Diagnosis

Differential diagnosis of RLS should include insomnia, sleep-disordered breathing, or neurologic or musculoskeletal etiologies for the discomfort.

#### Treatment

Nonpharmacologic treatment of RLS includes good sleep hygiene, moderate exercise a few hours before bedtime, and

avoidance of substances that are associated with worsening of RLS symptoms, including caffeine, alcohol, antihistamines, and antiemetics. A serum ferritin should be drawn in all children with RLS and if  $< 50$  ng/mL, treatment with 6 mg/kg/day of oral elemental iron should be considered. Oral iron absorption is enhanced by vitamin C and impaired by calcium. Gastrointestinal upset and constipation can be common side effects. Compliance can be difficult. A serum ferritin should be rechecked at 3 months to evaluate therapy. Referral to a sleep medicine specialist should be made if lifestyle and oral iron therapy have been unsuccessful. There are no FDA-approved medications for the treatment of RLS in children. Dopamine agonists, gabapentin (Neurontin),<sup>1</sup> clonazepam (Klonopin),<sup>1</sup> and clonidine (Catapres)<sup>1</sup> have been used to treat pediatric RLS.

### Delayed Sleep Phase Syndrome

#### Epidemiology

Delayed sleep phase syndrome (DSPS) occurs most commonly in adolescents and young adults.

#### Clinical Manifestations

Symptoms usually present in adolescents but can occur in younger children. Adolescents with DSPS consistently have sleep onset at a later time, typically after midnight. They have difficulty initiating sleep earlier. They do not have difficulty maintaining sleep. They have difficulty waking in the morning unless able to sleep until their preferred time, which is typically after 10 AM. They may have sleepiness during the daytime if forced to rise early (i.e., for school); however, during long vacations or summer breaks when allowed to sleep to preferred wake time they feel refreshed. Children who already have a preferred evening preference may find this exacerbated in adolescence. Poor school performance can be present.

#### Diagnosis

Diagnosis is made from history; actigraphy and sleep logs are also useful. An overnight sleep study may be indicated if another sleep disorder is suspected (e.g., OSA).

#### Differential Diagnosis

The differential diagnosis includes insomnia, poor sleep hygiene, insufficient sleep, mood disorder, OSA, and RLS.

#### Treatment

Treatment is typically behavioral and includes good sleep hygiene. Typically either the patient's sleep-wake schedule is advanced (if there is less than 3 hours between actual and desired bedtime) by 15 minutes every 2 to 3 days until the goal bedtime is achieved. Rise time is advanced as well and if set at the desired wake time initially it should facilitate the advancement of the bedtime by increasing sleep drive. If the desired bedtime of the adolescent is greater than 3 hours from the current bedtime, phase delay can be considered. Bedtime is delayed by 2 to 3 hours each day until the target bedtime is reached. Timing of this therapy should be considered, because it will interfere with school or other daytime activities. Parental or caregiver support is necessary, as well as commitment by the adolescent.

Once the new pattern is established weekends must not differ from weekdays by more than 1 to 2 hours. This is particularly important for the rise time. Relapse is common if strict sleep-wake patterns are not adhered to, a problem common on vacations.

Both bright light exposure and melatonin have been used to help reset the circadian rhythm. Exposure to bright light in the

morning is encouraged and can be as simple as increasing sun exposure in the morning. Light boxes using 2500 to 10,000 lux can be used in the morning for 20 to 30 minutes. Exposure to light in the evening should be limited. A small dose of melatonin<sup>7</sup> (0.5 mg) can be used in the early evening (about 5 hours before desired bedtime) to attempt to physiologically advance sleep onset. If the timing is not optimal for both light and melatonin, the phase delay can be worsened; consultation with a sleep physician should be considered.

### Parasomnias

Parasomnias can occur out of both non-REM (NREM) and REM sleep. Those occurring out of NREM sleep include sleepwalking, sleep terrors, and confusional arousals. They typically occur in the first one-third of the night, when NREM-3 sleep is most prevalent, and are not recalled the next day. They can be part of normal development, but depending on their nature, they can be distressing to caregiver and child. Parasomnias occurring out of REM sleep include nightmares and REM-sleep behavior disorder (RBD). Nightmares are commonly recalled and have been associated with anxiety in children. Nightmares typically peak in the school-age child. RBD is rare in children but has been reported; it involves the loss of atonia that occurs in REM sleep and consequently dreams are "acted out."

#### Risk Factors

Poor sleep hygiene, insufficient sleep, irregular sleep-wake patterns, and a positive family history are all risk factors. Sleep disruption from sleep-disordered breathing or periodic limb movements of sleep can exacerbate parasomnias.

#### Differential Diagnosis

The differential diagnosis should include nocturnal seizures. In addition, if another sleep disorder is present, parasomnias can be exacerbated.

#### Treatment

Safety is most important in children with parasomnias, and it is important that the child's sleep environment is kept clear of things that could cause injury. Door alarms can be effective. The child should not be awakened during the episode. The event should not be referred to the next morning because this can cause distress for the child. Maintaining good sleep hygiene and regular sleep-wake patterns is important. If the events occur at a predictable time each night, the caregiver can do planned awakenings 30 minutes before the event typically occurs for several weeks. This may abolish the episodes. It can also have the effect of pushing the episode to later in the night. Pharmacologic treatment with a small dose of a benzodiazepine (e.g., 0.5 mg of clonazepam [Klonopin]<sup>1</sup> at bedtime) may be indicated in severe cases with the drug tapered slowly after episodes are suppressed.

### Hypersomnias

A full discussion of primary hypersomnias (including narcolepsy) in children is beyond the scope of this chapter. Consideration for a primary hypersomnia should be made in a child who is sleepy after common causes of sleepiness such as insufficient sleep and obstructive sleep apnea have been ruled out. Symptoms of narcolepsy include disrupted nocturnal sleep, hallucinations on going to sleep or waking up, and sleep paralysis. Daytime sleepiness is present with "sleep attacks" both during quiet activities and while active. Cataplexy may also be present and is defined by loss of muscle tone without

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

loss of consciousness. It should be noted that onset of narcolepsy is often in adolescence or as a young adult. Diagnosis is often delayed because the symptoms are attributed to other conditions. Treatment of pediatric hypersomnia is done under the supervision of a sleep specialist and often involves use of stimulants.

## RESUSCITATION OF THE NEWBORN

Method of

David S. Gregory, MD

### CURRENT DIAGNOSIS

- The transition from intrauterine to extrauterine life at birth requires effective breathing by the infant to expand the lungs and oxygenate the blood. All newborn infants are at risk for delays in this process, prompting a need for resuscitation.
- The fetal and newborn response to hypoxia is to develop apnea. If primary apnea is diagnosed, it can be corrected by gentle stimulation and oxygen delivery. If hypoxia persists, secondary apnea will occur. It is not readily apparent whether a newborn has primary or secondary apnea, and the approach to resuscitation therefore requires that any apneic event be treated using the same sequence of interventions.
- The initial steps of newborn resuscitation include drying the infant, providing warmth, using gentle stimulation, and clearing the airway if needed. Infants who do not respond to these interventions need more assistance. Establishment of effective ventilation spontaneously by the newborn or with assistance by positive-pressure ventilation is the most important step in newborn resuscitation.
- Reassessment of the infant’s heart rate, respiratory effort, pulse oximeter reading or color, and tone every 30 seconds during resuscitation is crucial to determine the next appropriate intervention. Apgar scoring should *not* be used to guide newborn resuscitation. Electrocardiographic (ECG) monitoring is the best method for assessing heart rate. Pulse oximetry in the delivery room should be used to guide oxygen therapy. Temperature of the infant should be monitored.
- If application of positive-pressure ventilation does not improve the infant’s heart rate, chest compressions or drug therapy, or both, may be required. A team approach is needed to coordinate these interventions, and ongoing reassessment is necessary to determine cardiorespiratory and hemodynamic status. Subsequent assessment and treatment should be performed in an intensive care setting.

### CURRENT THERAPY

- Term gestation infants who are breathing and crying with good muscle tone do not need newborn resuscitation.
- Most newborns do not require immediate cord clamping and can be monitored during skin-to-skin contact with their mothers.
- Initial resuscitation includes drying the infant, providing warmth, giving gentle stimulation, and clearing the mouth and nose, if needed.
- If the infant is apneic, breathing slowly, or gasping, positive-pressure ventilation (PPV) with a mask and bag should be administered. A rise in heart rate is the best indicator of effective ventilation and response to resuscitation.
- When oxygen therapy is needed during resuscitation, pulse oximetry should be used to guide oxygen concentration.
- If the heart rate does not improve with ventilation efforts, endotracheal intubation should be considered.
- When the infant’s heart rate drops below 60 beats/min, chest compressions should be initiated using the two-thumb technique. Heart rate should be monitored using ECG.
- If the heart rate remains less than 60 beats/min despite PPV and chest compressions, IV epinephrine (Adrenalin) may be given using an umbilical venous catheter or via intraosseous catheter.
- Infants who do not improve with epinephrine and have a history consistent with blood loss may improve with fluid expansion.
- Reassessment of the newborn every 30 seconds during resuscitation is required to adjust therapy as indicated. The best indicator of successful resuscitation is an increase in heart rate.

The changes that occur in the transition from fetus to newborn are unmatched in any other time of life. Most newborns manage to make this transition on their own, but about 10% require some assistance. Approximately 1% of newborns require extensive resuscitative measures to survive. The approach to resuscitation in infants is similar to that in adults, consisting of evaluation and intervention when needed for the infant's airway, breathing, and circulation. Every birth should be attended by personnel trained in neonatal resuscitation. Specific training and certification are offered by the American Academy of Pediatrics/American Heart Association's Neonatal Resuscitation Provider (NRP) course. This chapter has been updated based on the American Heart Association 2020 Guidelines and the 8th edition of the NRP June 2021 (Box 1). Ongoing training and a team-based approach are vital components of newborn resuscitation.

### Transition From Fetal to Extrauterine Life

The environment of the fetus differs greatly from that of the infant after birth. The fetus depends on receiving oxygen and nutrients from the mother through the placental circulation. The fetus experiences relative hypoxia and almost constant body temperature in the amniotic fluid. The fetal lungs are filled with fluid and do not participate in the exchange of oxygen and carbon dioxide. Several adaptations in the fetus permit survival in this environment.

Oxygenated blood from the mother enters the fetus by means of the placenta through the umbilical vein. Most of this oxygenated blood bypasses the liver through the ductus venosus and enters the inferior vena cava. On entering the right atrium, this oxygenated blood is directed toward the patent foramen ovale into

the left atrium, bypassing the fetal lungs. Fetal blood also passes through the right atrium into the right ventricle and then into the pulmonary artery. The vascular resistance and blood pressure of the pulmonary vessels in the fetal lung are higher than in the aorta and systemic circulation; most of the blood is therefore shunted away from the lungs through the ductus arteriosus into the ascending aorta. Only a small amount of fetal blood passes through the lungs to the left atrium and then to the left ventricle. The umbilical arteries branch off from the internal iliac arteries and return fetal blood to the placenta. The functional organ for gas exchange of oxygen and carbon dioxide in the fetus is the placenta.

At birth, the newborn is no longer connected to the placenta, and the lungs become the only source of oxygen. The first breaths of the infant cause the fluid in the lung alveoli to be replaced with air. The umbilical arteries and veins constrict at birth and are eventually clamped. This increases the vascular resistance and blood pressure of the systemic circulation. As the oxygen level in the alveoli increases, the blood vessels in the lung start to relax, decreasing pulmonary vascular resistance. Blood in the pulmonary artery travels toward the lung and away from the ductus arteriosus because the blood pressure in the systemic circulation is higher than that in the pulmonary circulation. Increased blood flow to the lungs allows the oxygen from the alveoli to enter the infant's blood, increasing the PO<sub>2</sub>. Oxygenated blood enters the left heart through the pulmonary vein and is delivered to the rest of the infant's tissues through the aorta.

Although the initial steps in this transition occur within a few minutes of birth, the entire process may not be completed for several hours to days. The ductus venosus, foramen ovale, and ductus arteriosus remain potentially patent and do not completely involute for days or weeks. Changes in the infant's systemic and pulmonary pressures can result in blood flow through these channels in the infant.

Transition can be prevented or delayed in several circumstances. The infant may not breathe adequately, in which case the lung fluid is not forced out of the alveoli. Material such as meconium may block air from entering the alveoli. If the lungs do not fill with air, hypoxia will quickly develop. Systemic hypotension caused by excessive blood loss, poor cardiac function, or bradycardia prevents the change in the direction of blood flow that is necessary to promote blood flow into the lungs. Failure of the lungs to expand or hypoxia can prevent relaxation of the pulmonary blood vessels, resulting in a high pulmonary vascular resistance. This leads to decreased blood flow to the lungs and worsening of hypoxia.

### Risk Factors for Newborn Resuscitation

A number of prenatal and intrapartum factors are associated with a higher chance that the infant will have a delay in transition and require resuscitation (Table 1). A recent multicenter review of risk factors for resuscitation at gestation age 34 weeks or greater found that the following risk factors were significantly associated with a need for advanced resuscitation: 34 to 37 weeks gestation, intrauterine growth retardation (IUGR), gestational diabetes, meconium-stained amniotic fluid, vacuum or forceps assisted delivery, clinical chorioamnionitis, fetal bradycardia, placenta abruption, general anesthesia, and emergency cesarean section. In preparation for labor and delivery, staff should ask the following questions: (1) What is the expected gestational age of the infant? (2) Is the amniotic fluid clear? (3) Are there additional risk factors? and (4) What is the umbilical cord management plan? However, some infants *with no risk factors* need resuscitation; therefore preparations for neonatal resuscitation should be made during all deliveries.

### Reaction to Hypoxia and Asphyxia

Normally at birth, the newborn makes vigorous efforts to breathe. The process of leaving the warm, dark, and liquid environment in utero is replaced by cold air, dryness, and bright lights. Drying the infant with towels and wiping the mouth and nose are

#### BOX 1 Summary of Key Points for Newborn Resuscitation Based on Neonatal Resuscitation Program, 8th Edition

1. Individual providers and neonatal resuscitative teams should train, prepare, brief and check equipment as a team prior to resuscitative efforts.
2. Vigorous newborn infants—whether term or preterm—do not require immediate cord clamping with resuscitative efforts, but rather can be evaluated and monitored while providing skin-to-skin contact with their mother and 30 seconds of delayed cord clamping.
3. Ventilation of a newborn's lungs is the priority when support is required.
4. Routine intubation and tracheal suctioning is not recommended for infants born in meconium stained amniotic fluid (including those who may be nonvigorous).
5. Effective ventilation and proper response to resuscitative efforts is first indicated by a rise in newborn heart rate.
6. After initial use of room air for ventilation efforts in term infants, pulse oximetry monitoring guides oxygen concentration adjustment to meet goals at specific minute-based intervals after birth.
7. In cases of insufficient heart rate response to ventilation of a newborn's lungs (including corrective steps, such as endotracheal intubation), chest compressions are indicated.
8. Electrocardiographic monitoring is necessary to assess the heart rate response to chest compressions and medication.
9. When chest compressions do not result in an adequate increase in heart rate, epinephrine, preferably via the intravenous route, is indicated.
10. Infants with history or examination consistent with blood loss, and having poor response to epinephrine, may require volume expansion.
11. Following effective resuscitation, if no heart rate is attained by 20 minutes, cessation of resuscitative efforts should be discussed with team and family.

all the assistance that most newborns require. The end result of any mechanism that delays transition is a period of hypoxia for the fetus or newborn infant. Laboratory studies have shown that the first sign of oxygen deprivation in the newborn is a change in the breathing pattern. After an initial period of rapid breathing attempts, cessation of breathing occurs. This is called *primary apnea*. Stimulation by drying the infant or slapping the feet can cause breathing to resume. If hypoxia continues after primary apnea has occurred, the infant will make attempts at gasping and then stop breathing. This is called *secondary apnea*. Stimulation does not affect secondary apnea. Assisted ventilation is necessary to provide breaths to the newborn to reverse the hypoxia. The infant's heart rate starts to decrease when primary apnea occurs. The heart rate increases with stimulation if the infant has primary apnea, and blood pressure is maintained. With continued hypoxia, the heart rate continues to drop, and hypotension develops. If assisted ventilation is not adequate to increase the infant's heart rate, chest compressions will be required.

When a newborn becomes apneic, it is not readily apparent whether the infant has primary or secondary apnea. The approach to resuscitation therefore requires that any apneic event in a newborn be treated using the same sequence of interventions. If the apneic infant responds to simple stimulation, the diagnosis is primary apnea, and no further intervention is required. If the infant does not improve with stimulation, secondary apnea has occurred, and more intensive intervention is needed.

Unlike adults, the progression from primary apnea to secondary apnea in newborns results in the cessation of respiratory activity before the onset of cardiac failure. For this reason, neonatal resuscitation should begin with PPV rather than with chest compressions. Delays in initiating adequate ventilation in newly born infants increase the risk of death.

### Preparation for Newborn Resuscitation

The neonatal resuscitation team, prior to resuscitative efforts, should attempt to perform a team brief and check all necessary

equipment. The team brief should include answers to questions that should be asked of the delivery team to clarify neonatal needs, including gestational age, amniotic fluid color and clarity, known risk factors for cardiopulmonary dysfunction (such as congenital heart disease) or infection (such as chorioamnionitis), and any concern for delayed cord clamping. The team brief allows the neonatal team to refocus and organize their team response, while checking all equipment ensures that needed instruments, devices, and medications are at their disposal for the resuscitative efforts.

### Sequence of Newborn Resuscitation

#### Initial Steps and Basic Resuscitation

Resuscitation of the newborn starts with the rapid assessment of three characteristics: Is the infant at term gestation, does the infant have good tone, and is the infant crying and breathing? The answers to these questions will affect the approach to care. Resuscitation when fluid is meconium stained is discussed later in this chapter. The information presented here refers to term infants with clear amniotic fluid. More information regarding the care of premature infants is discussed in a later section.

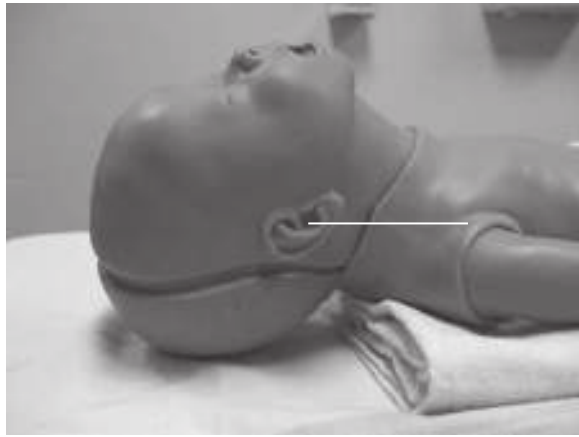

The infant at term who is crying and breathing with good muscle tone does not need resuscitation and should not be separated from the mother. Current evidence suggests cord clamping should be delayed for at least 30 seconds for most vigorous term and preterm infants unless there is evidence of placental abruption or bleeding. The baby should be dried, placed skin-to-skin with the mother, and covered with dry linen to maintain temperature. Ongoing observation for breathing, activity, and color should continue while the infant is with the mother. If the infant is not term, is not crying and breathing, or does not have good muscle tone, newborn resuscitation should begin with the initial steps: providing warmth, drying and stimulating the infant, then positioning and clearing (if needed) the airway,

The newborn should be placed under a radiant warmer to prevent heat loss and allow easy observation. Although warm blankets or towels can be used to dry the infant, they should not be left in place to cover the infant. Drying the infant, slapping the feet, and rubbing the back are appropriate forms of stimulation. More forceful methods of stimulation can harm the infant. Primary apnea, if present, will respond to stimulation in less than 30 seconds. Prolonged apnea will require positive-pressure ventilation (PPV).

The newborn should be placed on the back with the neck slightly extended in the "sniffing" position (Figure 1). This facilitates air entry into the lungs by lining up the posterior pharynx, larynx, and trachea. Hyperextension or hyperflexion of the neck can obstruct air entry into the lungs.

If the newborn is crying vigorously, secretions can be removed by wiping the nose and the mouth with a towel. Routine suctioning should be avoided. Gentle suctioning of the mouth and nose with a bulb syringe or suction catheter is *only* indicated when there is obvious obstruction to spontaneous breathing or when there is a need for positive-pressure ventilation. Deep or vigorous suctioning can be detrimental to the infant because of stimulation of the vagus nerve, causing bradycardia or apnea. The mouth should be suctioned before the nose to prevent aspiration if the infant gasps during suctioning.

Evaluating the infant's response to resuscitation is essential. The Apgar score is a traditional method for evaluating newborn status at 1 and 5 minutes after delivery. However, effective resuscitation demands that evaluation of the newborn's status not be delayed until 1 minute of age, and Apgar scores therefore should *not* be used to guide resuscitative efforts. Within 30 seconds of delivery, the infant's need for PPV must be assessed. Establishment of effective ventilation spontaneously by the newborn or with assistance by PPV is the most important step in newborn resuscitation. The respiratory status, heart rate, and color or oximetry reading should be determined. The chest wall should move with each breath, and the newborn should be breathing spontaneously. Although heart rate can be assessed by feeling for a pulse at the base of the umbilical cord, this method can be unreliable. Auscultation with

**Figure 1** The sniffing position. Positioning the infant on the back with the neck slightly extended brings the posterior pharynx, larynx, and trachea in line (*white line*) to facilitate air entry into the lungs.

**Figure 2** Self-inflating bag with infant mask and reservoir. This type of device is available in most delivery rooms.

a stethoscope is the preferred method during initial resuscitation. The heart rate should be greater than 100 beats/min. Placement of 3-lead ECG (electrocardiograph) as soon as possible to monitor the infant's heart rate during resuscitation may be beneficial. Monitoring of heart rate using ECG is more reliable than palpation and auscultation and is faster than using the pulse oximeter. Peripheral cyanosis (i.e., blueness of the hands and feet) is acceptable in the initial period after delivery. Central cyanosis in which the lips and trunk are blue indicates hypoxemia and the need for more resuscitation efforts. Pulse oximetry should be used to confirm the perception of central cyanosis. A pulse oximeter can provide continuous assessment of the oxygen saturation and is the optimal method for monitoring the infant's state of oxygenation. The oximeter probe should be placed on the newborn's right wrist or hand to detect preductal saturation. Temperature should be monitored during newborn resuscitation. The normal range is an axillary temperature of 36.5°C to 37.5°C. The initial steps of stabilization, reassessment, and establishing ventilation should be completed within the first minute of life (the "Golden Minute").

#### Respiratory Support and Positive-Pressure Ventilation

If the infant is breathing with a heart rate higher than 100 beats/min but has central cyanosis, free-flowing oxygen delivery is indicated. This can be administered with a facemask or by holding oxygen tubing or a flow-inflating bag and mask close to the infant's face. *A self-inflating bag and mask cannot be used to give free-flowing oxygen.* If the newborn is apneic, not breathing effectively, or has a heart rate less than 100 beats/min, PPV using a self-inflating bag, flow-inflating (or anesthesia) bag, or a T-piece resuscitator is required. Use of a flow-inflating bag requires a compressed gas source and considerable practice to be used effectively. A T-piece resuscitator needs special equipment and a compressed gas source. Most delivery rooms are equipped with self-inflating bags (Figure 2) because they are easy to use and can be fitted with a pressure-release valve to decrease overinflation. A reservoir must be used with a self-inflating bag to provide 100% oxygen. For free-flow oxygen or PPV, the flow meter on the oxygen source should be set to 10 liters/minute.

PPV should begin using room air for term newborns. The facemask should cover the infant's nose, mouth, and tip of chin, but not the eyes (Figure 3). Multiple sizes should be available. A tight seal between the infant's skin and the facemask is needed, but excessive pressure can bruise the face. The mask can be held in place using the thumb and index finger in a C-shaped position on top of the mask, with the remaining fingers in an E-shaped position below the infant's chin (Figure 4). Inspiratory pressures of 20 to 25 cm H<sub>2</sub>O are usually needed when squeezing the bag to make the infant's chest rise; peak inspiratory pressures in a term newborn of 30 cm H<sub>2</sub>O may be required. A pressure gauge can be connected to the self-inflating bag for monitoring inspiratory

**Figure 3** Facemask. Choose a size that covers the infant's mouth and nose.

**Figure 4** Facemask placement. The thumb and index finger are held in a C-shaped position on top of the mask, and the remaining fingers are held in an E-type position under the chin.

pressure. The heart rate and color of the infant should rapidly improve if enough pressure is being given. An assistant can also use a stethoscope to listen to breath sounds for air movement. Breaths should be given at a rate of 40 to 60 breaths/min.

Traditionally, 100% oxygen has been used in newborn resuscitation. However, several randomized, controlled studies enrolling term and near-term infants have shown that room air can be used initially with oxygen as a backup if room air fails. A meta-analysis of these trials showed a benefit for the use of room air. Providing oxygen at concentrations between room air and 100%

**TABLE 2** Titrated Oxygen Saturations After Birth

1 minute	60–65%
2 minutes	65–70%
3 minutes	70–75%
4 minutes	75–80%
5 minutes	80–85%
10 minutes	85–95%

requires the use of compressed air, oxygen, and blenders by experienced personnel. A pulse oximeter with a probe designed for use in newborns can be used to guide oxygen administration during newborn resuscitation. It will take 1 to 2 minutes to apply the pulse oximeter probe to the infant's right palm or wrist (preductal site) and get a consistent reading. Pulse oximetry often displays lower-than-actual heart rate readings during the first 2 minutes of life. The pulse oximeter may not function during states of very poor cardiac output or perfusion. In these situations, observation for central cyanosis will be necessary. The infant's oxygen saturation may remain in the 70% to 80% range for several minutes after birth. Oxygen may be titrated to the interquartile range of preductal saturations measured in healthy babies following vaginal birth at sea level (Table 2). If blended oxygen is not available, room air should be used for resuscitation. If the infant's heart rate does not respond to positive pressure ventilation with room air after 90 seconds, 100% oxygen should then be used.

After 30 seconds of PPV, the infant should be reevaluated. Once PPV is started, an electronic cardiac monitor (ECG) is the preferred method to measure heart rate. Ventilation with a bag and mask can be stopped when the newborn has a heart rate higher than 100 beats/min, spontaneous breathing, improved color, and good muscle tone. Supplemental oxygen should still be given to the infant. If the newborn is not improving, use the acronym MR SOPA to correct the technique of PPV: M = mask adjustment to check seal, R = reposition head in sniffing position, S = suction mouth and nose, O = open mouth with infant's jaw lifted forward, P = increase pressure up to 30 to 40 cm H<sub>2</sub>O, and A = consider using an alternative airway such as endotracheal (ET) intubation.

ET intubation is a technical skill that must be learned and practiced to maintain competency. Effective ventilation can be given with a bag and mask approach to most newborns. This skill is easily mastered and maintained. If an infant is responding well to bag and mask ventilation, it can be continued for longer periods; however, some air may escape into the esophagus and into the stomach. This may cause gastric distention, which can prevent full expansion of the lungs and cause vomiting and aspiration. An orogastric tube can be placed in the stomach and left open to air to vent any air introduced into the infant's stomach during bag and mask ventilation.

### Chest Compressions

Before beginning chest compressions, intubation is strongly recommended to provide effective ventilation. After 30 seconds of effective PPV, the heart rate should be assessed. If the heart rate dips below 60 beats/min, chest compressions are needed to support the circulation. The two-thumb technique (Figure 5) is recommended. The two-thumb technique generates higher blood pressure and coronary perfusion with less rescuer fatigue. It can also be continued with the rescuer at the head of the bed if access to the abdomen is needed. If chest compressions are required, 100% oxygen should be given by PPV. Two people are required to give PPV and chest compressions effectively. To coordinate the breaths and chest compressions, three compressions are given followed by one breath, and this sequence is repeated to give the infant 90 compressions and 30 breaths/min. The thumbs are placed on the lower third of the infant's sternum but above the xyphoid process. The sternum is depressed to a depth of one third of the infant's

**Figure 5** Two-thumb technique. The hands encircle the torso, and the thumbs are placed on top of the lower sternum above the xyphoid process and below a line drawn between the nipples (white line).

anteroposterior chest diameter. The purpose of chest compressions is to squeeze the heart between the sternum and the spine, forcing blood in and out of the heart and to the body. The direction of the compressions should be perpendicular to the chest surface, and the thumbs should not be lifted off of the chest after the correct placement is obtained. Incorrect methods during chest compressions can cause rib fracture and liver laceration.

After 60 seconds of chest compressions, the infant's heart rate, breathing, pulse oximeter reading or color, and tone are reassessed. If the heart rate is higher than 60 beats/min, chest compressions can be stopped, although PPV may still be needed. If the heart rate is not improving, the following problems must be considered: ventilation is not adequate, 100% oxygen concentration is not being given, or the compressions may not be deep enough or well-coordinated with the breaths. If the arrest is suspected to be of primary cardiac etiology, a compression ratio of 15 compressions to 2 breaths may be more effective.

### Medications for Newborn Resuscitation

If the newborn heart rate remains below 60 beats/min despite 30 seconds of effective PPV and 60 seconds of chest compressions, epinephrine (Adrenalin) can be used to stimulate the newborn heart. Fewer than 2 of 1000 infants will require this step in resuscitation. *IV administration of epinephrine is preferred.*

In the delivery room, a catheter can be quickly inserted into the umbilical vein for intravenous access. A 3.5 or 5F catheter pre-filled with saline and connected to a 3-way stopcock is inserted about 2 to 4 cm into the umbilical vein using sterile technique. After blood is aspirated, insertion of the catheter is stopped, and the epinephrine is given rapidly, followed by a 3 mL saline flush. The concentration of epinephrine used in neonatal resuscitation is 1:10,000 (0.1 mg/mL). The intravenous dose is 0.01 to 0.03 mg/kg (0.1–0.3 mL/kg) (Table 3). The 8th edition of NRP recommends an initial dose of epinephrine as 0.02 mg/kg (0.2 mL/kg). The intraosseous route can be used if needed. A dose of epinephrine may be considered through the ET tube during the umbilical vein catheterization process but there is no evidence of benefit. The ET dose of epinephrine is 0.05 to 0.1 mg/kg (0.5–1 mL/kg).<sup>1</sup> The 8th edition of NRP recommends giving 0.1 mg/kg (1 mL/kg) via the ET tube if needed while establishing vascular access. *These higher doses are for ET use only.* Because lung absorption of epinephrine varies, the intravenous route using the umbilical vein or intraosseous catheter is preferred.

During umbilical vein cannulation, PPV and chest compressions are continued. More personnel will be needed to place the catheter and draw up the medications and saline flushes. After an intravenous dose of epinephrine, the infant's heart rate, respirations,

\*8th edition Neonatal Resuscitation Program (NRP) 2021

color or oximeter reading, and tone are reevaluated. The heart rate should increase to more than 60 beats/min. If the heart rate does not respond, the dose of epinephrine can be repeated every 3 to 5 minutes. The effectiveness of ventilation and compressions should be reassessed. If the infant appears pale, has delayed capillary refill, or has decreased pulses, shock may be present. Infant blood loss might have occurred during delivery from placental problems or other sources. Administration of an isotonic crystalloid solution such as normal saline or type O negative blood at 10 mL/kg over 5 to 10 minutes can improve circulation. Ringer's lactate is no longer recommended for newborns. Volume expansion should be used cautiously because there is evidence from animal studies for poorer outcomes when it is used in the absence of hypovolemia. Rapid infusion of large volumes has been associated with intraventricular hemorrhage in premature infants.

Hypoglycemia is common in newborns who have required resuscitation. Blood from the infant's heel or the umbilical vein can be tested at the bedside and intravenous 10% dextrose (2–5 mL/kg) given for low blood glucose. No specific glucose level has been associated with a poorer outcome. There is no evidence that use of sodium bicarbonate benefits the neonate, and its use during resuscitation in the delivery room is not recommended.

After resuscitation, newborns should be monitored in an intensive care setting. These infants are at risk for several complications, such as infection, metabolic abnormalities, and seizures. Infants of 36 weeks' gestation or older with moderate to severe hypoxic-ischemic encephalopathy may benefit from induced hypothermia under clearly defined protocols.

### Special Considerations

Some newborns do not respond to resuscitation because of specific problems. Infants with upper airway obstruction from micrognathia can be helped by a nasopharyngeal airway and placement of the infant in the prone position. Choanal atresia can be treated by placing an oral airway. Absence of breath sounds on one side of the chest can indicate a pneumothorax, requiring needle aspiration of the chest. An infant with a scaphoid abdomen and decreased breath sounds may have a diaphragmatic hernia. These infants should be intubated, and PPV by mask and bag should not be used. If the mother has received narcotics shortly before the delivery, the narcotic may be the cause of respiratory depression in the infant. These infants need PPV and respiratory support. Naloxone is no longer recommended as part of initial resuscitative efforts in the delivery room. Heart rate and oxygenation should be supported by PPV.

### Endotracheal Intubation

During neonatal resuscitation, endotracheal intubation may be indicated in the following circumstances: cases in which bag and mask ventilation is ineffective or prolonged, in which chest compressions are performed, and in special situations such as congenital diaphragmatic hernia or extremely low birth weight infants.

Intubation of the newborn requires preparation that can be performed while the infant is being ventilated by bag and mask. The ET tube should not be placed unless the glottis is visualized by direct laryngoscopy. To ensure that the tube is in the trachea, a carbon dioxide (CO<sub>2</sub>) detector should be used. Listening for equal breath sounds and looking for vapor condensation in the ET tube during exhalation can help, but an increase in the infant's heart rate or a positive detection of CO<sub>2</sub> is most reliable. It should be noted that poor or absent pulmonary blood flow may result in the absence of CO<sub>2</sub> detection despite tube placement in the trachea. The best indicator for effective ventilation is an increase in the newborn's heart rate.

Intubation should be performed as quickly as possible, with a goal of 30 seconds from insertion of the laryngoscope to the connection of the ET tube to the resuscitation bag. Complications of intubation include worsening of hypoxia and bradycardia, pneumothorax, contusions, perforation of the trachea or esophagus, and infection. After the infant has been intubated, deterioration in the infant's status should prompt an organized sequence to assess the adequacy of ventilation using the mnemonic DOPE:

- **Dislodged (D):** Is the tube in the right bronchus or out of the trachea?
- **Obstructed (O):** Is the tube obstructed by secretions or blood?
- **Pneumothorax (P)**
- **Esophagus (E):** Is the tube in the esophagus?

An alternative to intubation for infants  $\geq 34$  weeks gestation and  $\geq 2000$  grams is placement of a laryngeal mask airway. This type of airway does not require laryngoscopy. A soft inflatable mask that is attached to a flexible airway tube is placed in the hypopharynx such that the air in the tube is directed into the larynx and away from the esophagus. However, this type of airway cannot be used to suction the trachea nor to give endotracheal drugs. Its use has not been evaluated during chest compressions. For infants who require an alternative airway, cardiac monitoring (ECG) is recommended to assess the heart rate and whether chest compressions are needed or not.

### Premature Infants

Infants born before 37 weeks' gestation are at increased risk for complications and the need for resuscitation. Premature lungs may lack surfactant, making ventilation difficult. Very-low-birth-weight (less than 1500 g) infants will need additional warming techniques such as prewarming the delivery room, covering the baby in plastic wrapping, and placing the baby under a radiant warmer and/or an exothermic mattress; however, iatrogenic hyperthermia (axillary temperature  $>38^{\circ}\text{C}$ ) should be avoided. Immature brain development may decrease the drive to breathe. Weak muscles make respiratory efforts less effective. Thin skin and decreased subcutaneous fat make temperature regulation a challenge. Premature infants often have infections such as pneumonia or sepsis. The blood vessels in their brains are fragile and can easily bleed during periods of blood

pressure variation. The lower birth weights of premature newborns also require smaller sizes of equipment for resuscitation such as face-masks, suction catheters, endotracheal tubes, and umbilical catheters. Initial oxygen concentrations between room air and 30% should be used to protect premature infants <35 weeks gestation from oxygen toxicity. The use of continuous positive airway pressure (CPAP) in premature infants who are breathing spontaneously but with difficulty following birth may reduce the need for intubation, mechanical ventilation, and surfactant use. If PPV is needed, it is preferable to use a device that can deliver positive end expiratory pressure (PEEP). More than one person trained in newborn resuscitation should be present at the delivery of a high-risk premature infant.

### Meconium Staining of the Amniotic Fluid

Meconium is formed in the newborn gastrointestinal system during gestation. Intrauterine stress can cause release of meconium into the amniotic fluid. Aspiration of meconium-stained amniotic fluid into the lungs can result in severe pneumonitis and lung injury. The approach to resuscitation for an infant born in meconium-stained amniotic fluid (MSAF) has been revised. There is no evidence that the consistency of meconium-stained fluid (i.e., thick or thin) has an effect on the outcome of the newborn.

### Crying and Vigorous Infant

If the newborn born in MSAF has normal respiratory effort and muscle tone with a heart rate higher than 100 beats/min, routine care including delayed cord clamping and skin to skin time with the mother is appropriate. Secretions can be wiped from the baby's mouth and nose. *Gentle* mouth and nose suctioning can be performed using a bulb syringe or suction catheter *only if needed*. Deep and prolonged suctioning should be avoided. ET intubation is not required for vigorous infants with meconium-stained amniotic fluid.

### Nonvigorous Infant

Routine endotracheal intubation and tracheal suctioning is no longer recommended for nonvigorous newborns born in MSAF; however, the resuscitation team should include someone skilled in endotracheal intubation. If the newborn is gasping or apneic and has poor muscle tone, the initial steps of routine resuscitation should be started: provide warmth, dry the infant, position the airway, and clear the mouth and nose. Tactile stimulation should be limited to drying the infant and rubbing the back and soles of the feet. If there is visible fluid obstructing the airway or a concern about obstructed breathing, the mouth and nose may be suctioned. If there is no response, PPV should be started using a bag and mask. Suction may also be considered if there is evidence of airway obstruction during PPV. If bag and mask ventilation is not effective, intubation should be performed. There is no evidence that suctioning the trachea of nonvigorous newborns born in MSAF prevents morbidity or mortality. It is possible that the main cause of meconium aspiration into the lungs is caused by intrauterine fetal gasping.

### Newborn Resuscitation Outside of the Delivery Room

Resuscitation of infants born at home, in an emergency room, in an ambulance, or otherwise outside of a delivery room setting should proceed according to the same principles as in the delivery room. Providing warmth with stimulation and wiping the airway are usually adequate measures. Establishing effective ventilation using a bag and mask is the most important step if the infant fails to breathe on its own. Emergency providers should be familiar with resuscitation of the newborn, and basic equipment (Table 4) should be available.

### Withholding and Withdrawing Newborn Resuscitation

Newborns should be offered resuscitation at delivery except in extreme circumstances. Newborn resuscitation should not be used if the infant has a condition that is incompatible with survival, such as a confirmed gestational age of less than 22 completed weeks, birth weight less than 400g, or congenital anomalies associated with certain death or extreme morbidity.

In most situations, initial resuscitation can provide time to observe the infant's response to interventions and to discuss the infant's condition with the parents. Techniques for

Ventilation	Face masks (premature, newborn, and infant sizes) Self-inflating bag (450–750 mL) with oxygen reservoir and manometer Oxygen source Orogastric tubes (8, 10F) Carbon dioxide (CO <sub>2</sub> ) indicator Chest tubes (8 and 10F)
Circulation	Umbilical catheters (3.5 and 5F) Umbilical catheter tray (sterile scissors, scalpel, forceps, umbilical tape) Three-way stopcock Syringes (1, 3, 5, 10 mL) Normal saline Epinephrine 1:10,000 10% Dextrose

obstetric dating of pregnancies are accurate only to  $\pm 1$  to 2 weeks, and estimates of fetal weight are accurate only to  $\pm 100$  to 200 g. Care must be taken before deciding to withhold resuscitation from a newborn. Ongoing conversation between parents and medical caregivers allows mutual decision making. Withdrawal of care is indicated if continued support is futile. After 20 minutes of asystole (heart rate of 0), newborns are very unlikely to survive, at which point cessation of resuscitative efforts may be considered, based upon patient specific factors.

## URINARY TRACT INFECTIONS IN INFANTS AND CHILDREN

Method of

Ellen R. Wald, MD

The urinary tract is the most common site for serious bacterial infections in infants and young children. Urinary tract infections (UTIs) are more common than bacterial meningitis, bacterial pneumonia, and bacteremia.

Infection of the urinary tract may involve only the bladder, or only the kidney, or both. In general, infections of the bladder (cystitis), while causing substantial morbidity, are not regarded as serious bacterial infections. In contrast, infections that involve the kidney (pyelonephritis) can cause acute morbidity and lead to scarring with rare consequences of hypertension, preeclampsia, and chronic renal disease.

### Diagnosis

The diagnosis of UTI may be suggested by certain signs and symptoms, but culture of the urine is the gold standard. Because culture results are not available for at least 24 hours, there has been considerable interest in evaluating tests that may predict the results of urine culture, so that appropriate therapy can be initiated at the first encounter with the symptomatic patient. The tests that have received the most attention are urine microscopy for white blood cells and bacteria and biochemical analysis of leukocyte esterase and nitrite, which can be assessed rapidly by dipstick.

Several studies have concluded that both the presence of any bacteria on Gram staining of an uncentrifuged urine sample and dipstick analysis for leukocyte esterase perform similarly in children from birth through 12 years of age and are helpful in identifying individuals with UTI. Other recent studies done involving young infants (<2 months of age) and older infants (<12 months and 1–24 months) concluded that a hemocytometer white blood cell count of 10 or more cells/ $\mu\text{L}$  provides the most valuable cutoff point for identifying infants for whom urine culture is warranted.

The definition of a positive urine culture depends on the method used to collect the specimen. This variable definition reflects the fact that urine that has passed through the urethra may be contaminated by bacteria present in the distal urethra. If the urine is obtained by the clean-catch method, a positive culture is defined as equal to or greater than  $10^5$  colony-forming units (CFU)/mL. If the specimen is obtained by catheterization of the urethra, a positive culture is defined as equal to or greater than  $5 \times 10^4$  CFU/mL. Finally, if a urine culture is obtained by suprapubic aspiration, a method that bypasses the potential source of contamination, a positive culture is defined as recovery of any bacteria from the urine. A sample of urine obtained by suprapubic aspiration is easiest to interpret. Use of point of care ultrasound can ensure a positive aspirate, and topical anesthetic, applied to the suprapubic area, can reduce discomfort of the procedure.

### Imaging

Imaging studies have been the standard of care for young children with a first UTI for the past decade. Commonly, a renal ultrasound study is performed to evaluate the gross anatomy of the urinary tract (size and shape of the kidneys, duplication or dilatation of the ureters). A voiding cystourethrogram (VCUG) is done to determine whether vesicoureteral reflux is present. This practice has rested on the assumption that continuous prophylactic antimicrobial therapy is effective in reducing the incidence of reinfection of the kidney and renal scarring that may occur in children with vesicoureteral reflux. The 2016 reaffirmation of the 2011 guideline on diagnosis and management of urinary tract infection in infants and children 2–24 months of age issued by the American Academy of Pediatrics recommend postponing performance of the VCUG until the second infection (unless there is a major abnormality of the renal ultrasound).

### Treatment

In general, there are many choices for the antibiotic treatment of UTIs in children. If a child is toxic in appearance or vomiting (thereby precluding oral antimicrobials), admission to the hospital for parenteral therapy is appropriate. Many would recommend a third-generation cephalosporin, such as ceftriaxone (Rocephin) 50 mg/kg/d given once daily or ceftazidime (Fortaz) 50 mg/kg/dose every 8 hours, until the emesis has resolved and the patient can be treated orally. Otherwise, children, even those with presumed pyelonephritis, do well on oral therapy.

For the child who is to receive oral therapy, the choices are amoxicillin potassium clavulanate (Augmentin) 30 mg/kg/dose given every 12 hours<sup>3</sup>; a second- or third-generation cephalosporin such as cefuroxime (Ceftin) 50 mg/kg/dose twice daily,<sup>3</sup> cefpodoxime (Vantin)<sup>1</sup> 5 mg/kg/dose given twice daily, cefdinir (Omnicef)<sup>1</sup> 7 mg/kg/dose given twice daily, or cefixime (Suprax) 10 mg/kg/dose once daily<sup>3</sup>; or sulfamethoxazole-trimethoprim (Bactrim) 6 mg/kg/day of trimethoprim given once daily. There has been a tendency during the past several years for the prevalence of antimicrobial resistance to increase. The overall resistance to antibiotics varies geographically, and it is essential for the practitioner to be familiar with local antibiotic resistance patterns. In patients with suspected acute pyelonephritis, amoxicillin (Amoxil), cephalexin (Keflex), and sulfamethoxazole-trimethoprim should be avoided as presumptive therapy because of the potentially high rate of antibiotic resistance.

The optimal duration of therapy for children with UTI has been somewhat controversial. If the diagnosis of pyelonephritis is known or suspected, 10 days of treatment is conventional. Shorter courses of therapy have been successful in adult women with infection of the lower urinary tract. A recent meta-analysis conducted by the Cochrane Database of Systematic Reviews evaluated 10 trials (652 children) with lower-tract UTI. There was no significant difference in frequency of positive urine cultures between short-term (2–4 days) and standard (7–14 days) duration of oral antibiotic therapy for cystitis in children, either early after treatment or at 1 to 15 months after treatment. Furthermore, there was no difference between groups in the development of resistant organisms at the end of treatment or in the incidence of recurrent UTIs. Accordingly, in cases in which the diagnosis of cystitis is assured, 4 days of antimicrobial therapy is sufficient.

### Voiding Dysfunction

Voiding dysfunction is a broad term indicating a voiding pattern that is abnormal for the child's age. This is a condition that should be considered in all children who are diagnosed as having a UTI after toilet training has been accomplished. Constipation plays a significant role in some children with voiding dysfunction, and attention to this comorbidity often results in resolution of recurrent UTIs.

### Prophylaxis

For children who are thought to be at very high risk for recurrent UTIs and potential scarring, prophylactic treatment with sulfamethoxazole-trimethoprim or nitrofurantoin (Macrochantin) should be considered. These groups include children with high degrees of vesicoureteral reflux (grades 4 and 5), those with frequent and closely spaced UTIs without reflux, and, occasionally, those who have urologic abnormalities.

The RIVUR study, Randomized Intervention for Children with Vesicoureteral Reflux (VUR), was undertaken in 2007 to determine whether antimicrobial prophylaxis with SMX-TMP is effective in preventing recurrent UTI in infants and children with reflux of any grade. The study showed a modest benefit of prophylaxis with regard to febrile episodes of UTI with an approximately 50% reduction; however, there was no difference in scarring. There is no question of the biologic plausibility of

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

prophylactic antimicrobial therapy in preventing recurrent UTI; however, adverse effects, emergence of antimicrobial resistance, and difficulties with long-term adherence to prophylactic strategies present barriers to effectiveness. The choice as to whether to prescribe antibiotic prophylaxis is an opportunity for shared decision making with the family.

# Physical and Chemical Injuries

## BURNS

Method of

Allyson M. Briggs, MD; and Bradley E. Barth, MD

### CURRENT DIAGNOSIS

- Perform primary and secondary survey to assess for concomitant injuries.
- Calculate percentage of burns—use a diagram.
- Chemical burns—be aware of treatment difference based on the substance involved.
- Ocular injury—assess for injury and consult ophthalmology.
- Carbon monoxide—check CO-oximetry on burn patients from enclosed fires or with prolonged smoke exposure.

### CURRENT THERAPY

- The first, immediate treatment is to stop the burning.
- Use cool water irrigation (NOT ice or ice water); avoid hypothermia.
- Perform standard airway, breathing, and circulation (ABC) resuscitation.
- Calculate resuscitation fluids on the basis of surface area of deep partial and deeper burns—do not include superficial burns.
- Update tetanus vaccination if needed.
- Consult poison control center for chemical injuries.
- Hyperoxia is the treatment of choice for carbon monoxide exposure.
- Hydroxocobalamin (CYANOKIT) is the treatment of choice for cyanide exposure.
- Develop transfer relationship with burn center.

### Epidemiology

Annually in the United States there are nearly 500,000 burns that are significant enough to require emergency treatment with 40,000 hospital admissions. The vast majority of the injuries that require admission are treated at a specialized burn center. Fire and fire-related inhalations injuries are responsible for nearly 3300 deaths. Worldwide incidence of burn death from all causes of burns is difficult to estimate due to a lack of centralized reporting, but 180,000 deaths occur annually from fire alone, with 95% of these occurring in low- and middle-income countries.

### Risk Factors

Burns are distributed across the spectrum of age, although their types and mechanisms vary. Overall, burn injury tends to be more common in males. Males tend to get burned by flames, while females are more likely to sustain scald or heat contact wounds. Older and pediatric patients are more likely to sustain injury due to inability to get away from heat sources or flame. Use of alcohol and other substances is associated with increased risk of burn injury. Burns tend to have higher incidence in lower

socioeconomic groups and are much more common in countries with lower incomes.

### Prevention

Public safety initiatives have decreased the risk of burn injury in the developed world. Patient visits provided opportunities for educational interventions, especially if a patient is seen for a minor burn. Campaigns to decrease hot water heater temperatures in homes have helped reduce scald injuries. Safety plugs for electrical outlets decrease the risk of electrical injury in children. Smoke detectors and planned and practiced escape routes increase the likelihood of escaping from structure fires. Reminders to check smoke detectors and to change the batteries with the seasonal clock change ensure that devices are functional. Child-resistant lighters and safety matches increase fire safety, especially when stored out of reach of children. Keeping screens or safety devices around fireplaces and fire pits may decrease injuries as well. Avoiding activities with potential fuel sources and flames, especially while intoxicated, will also decrease fire injuries.

### Pathophysiology

The injuries that result from burns are due to a combination of immediate tissue injury and resulting inflammation. This includes the activation of an inflammatory cascade, immediate and delayed cellular and humoral effects, and the delayed effects of changes in gene expression induced by the earlier injuries. The immediate injury is classically divided into three zones. The most severely injured is the central zone of necrosis; this area is surrounded by the zone of stasis, which is surrounded by the zone of hyperemia (Figure 1). The zone of necrosis is composed of coagulated tissue that will progress to rapid cell death and eschar formation. The outer zone of hyperemia has increased blood flow and minimal tissue damage and will almost certainly heal. The middle zone of stasis is the region where blood flow has ceased within the capillary bed. Depending on subsequent actions over the next 24 to 48 hours, this area either will worsen to necrotic tissue or may reepithelialize to healing. The immediate postinjury efforts are focused on salvaging this area.

### Burning Tissue

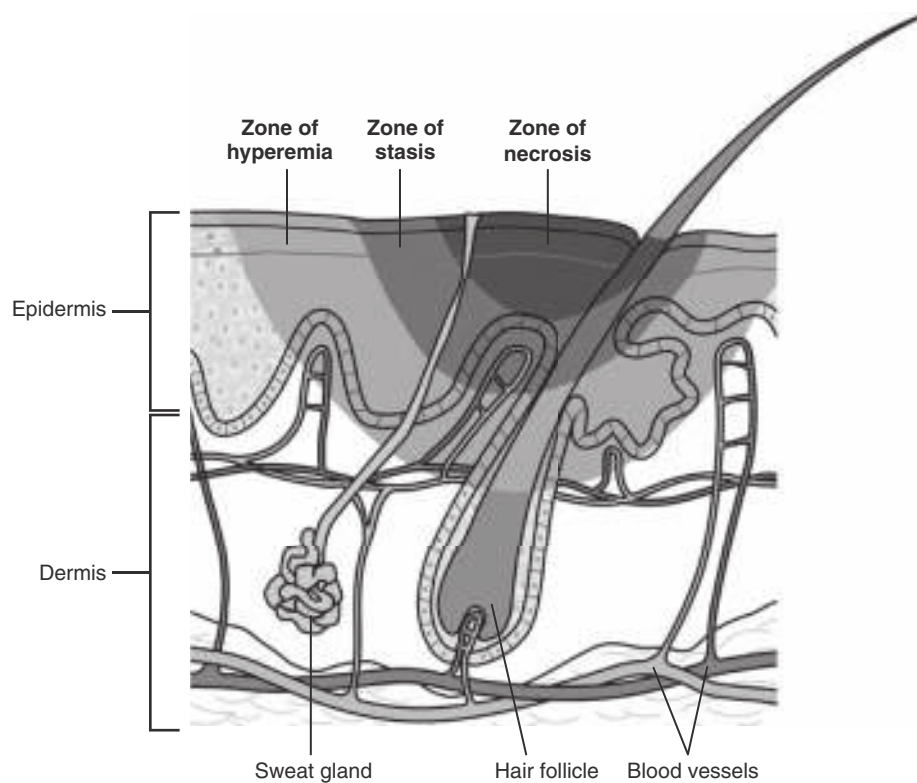

As heat transfers to tissue, damage begins to occur as cellular temperature rises above 44°C. Once the internal cellular temperature reaches 60°C, the cell will die. Generally, once the heat source is removed from the skin, the tissue temperature rapidly returns to normal, but the tissue injury does not stop at that point. Within seconds of the injury, arterioles begin to spasm, and red blood cells aggregate within the tissues. Histologic changes are visible within 15 minutes, and tissue edema begins. Tissue edema typically peaks 6 to 12 hours postinjury.

It is much easier for a burn injury to penetrate through the dermal layers in thin skin than in thick skin, leading to more severe injury in the former with a similar degree of heat transfer. These injuries pose a particular risk in infants and children as well as the elderly.

Shortly after the burning stops, processes of both inflammation and healing begin. There is a complex interplay of inflammatory mediators, immune cell action, and changes in gene expression that will continue over the following weeks to months and will play a role in how the wound heals.

### Clinical Manifestations

Descriptions of burns are based on the depth of the injury and the extent of coverage. They are divided into superficial partial,

**Figure 1** Burn injury.

**TABLE 1** Types of Burns

DEPTH	ANATOMY	APPEARANCE	SENSATION	TIME	TREATMENT
Superficial	Epidermis only	Pink or red and dry, blanches	Painful	Days	Topical
Superficial partial thickness	Epidermis and upper papillary dermis	Pink, clear blisters, moist surface, blanches	Painful	14–21 days	Debride and topical medication
Deep partial thickness	Epidermis, papillary dermis, and lower reticular dermis	Pink or red, moist surface, blisters, may be hemorrhagic, does not blanch	Painful, may have decreased sensation	Weeks or may progress to full thickness	Debride, topical medication, possible surgery
Full thickness	Epidermis, dermis, and into underlying tissue	White or brown, dry, leathery, does not blanch	Insensate	Weeks, and heals by contraction and scarring	Surgical

which is further characterized as superficial partial or deep partial, and full thickness (Table 1). Superficial burns involve the epidermis alone. These injuries are typically painful and erythematous, and they will heal without scarring. These injuries are not included in calculations of the percentage total body surface area (TBSA) burned. Superficial partial thickness burns involve the entire epidermis and extend down to the papillary region of the upper dermis. These injuries are painful, erythematous, and moist, and they form blisters. Deep partial thickness burns involve the entire epidermis and extend deeper into the lower reticular dermis. These wounds are typically painful and whitish, and they have less weeping and blanching than superficial partial thickness wounds. These may have less pain than expected depending on the extent of damage to nerve endings in the skin. Full-thickness burns extend through the epidermis and entire dermis and destroy nerves and other deep structures. These wounds are insensate, stiff, white or tan in color, and they do not blanch. Wounds of this depth cannot heal spontaneously and will have significant scarring and contracture if not surgically managed.

Areas of burn that have extensive or circumferential deep partial thickness or full-thickness burns are at risk for development

of restrictive eschars. Eschars can restrict circulation, leading to compartment syndrome in extremities and can decrease respiration if on the chest or neck. Ideally, burn patients can reach burn centers before these complications arise, but an escharotomy could be required urgently in some cases.

Inhalation injury is a source of significant morbidity in burn patients. The initial injury may not seem particularly severe, but edema can develop rapidly in the airway, which makes delayed airway management perilous. Early intubation may be necessary.

### Special Situations

#### Ocular Injuries

Patients with any signs of burns to the face, complaints of eye pain, or inability to communicate should undergo eye examinations with fluorescein staining. If corneal burns are identified, appropriate antibiotic ointment should be started, and consultation with an eye specialist should be obtained.

#### Nonaccidental Trauma

Clinicians should have a high index of suspicion for nonaccidental trauma (NAT) in burns occurring in pediatric patients. NAT has been shown to be present in up to 25% of pediatric burn

cases. Burns caused by NAT are more likely to occur in males and children with developmental delays and may result in a delay in seeking care. Other concerning findings are burns that have clear lines of demarcation (e.g., cigarette burns, dunking, radiator, grill, curling iron), that are symmetric on both extremities, or spare the flexor creases with deep surrounding burns. If NAT is suspected, it must be reported, and the child must be kept in a safe place until authorities have cleared the child to go home.

### Chemical Burns

The risk and degree of injury caused by chemical burns vary greatly, depending on the substance involved as well as on the concentration of the material and the duration of exposure. The Centers for Disease Control and Prevention has a website that provides information on treatment for chemical injuries: <https://emergency.cdc.gov/chemical/mmg.asp>. General precautions for chemical burns are to decontaminate as quickly as possible while avoiding rescuer contamination or injury. For dry or powdered chemicals, remove as much chemical as possible while it is still in the dry form by brushing or other mechanical removal. After mechanical removal, or for liquid contamination, dilute the chemical and continue the removal process by using water. Water should be used via copious, high-flow, low-pressure irrigation for at least 20 minutes. If feasible, check the pH of the contaminated area and continue irrigation until it returns to normal. In most cases, removal and irrigation are more important to neutralizing the chemical because using neutralizing agents can make the injury worse. Evaluate the patient for possible inhalation or ocular injury as well. Ocular chemical exposures should be irrigated with water or lactated Ringer's solution, starting as early as possible after exposure, until a normal pH is obtained. There are important exceptions to typical management, some of which are listed in Table 2.

### Electrical Injuries

Injuries with electrical sources vary based on the type of circuit (alternating vs. direct current), amperage, voltage, tissue resistance, duration of exposure, and path of current through the body. High voltage ( $\geq 1000\text{V}$ ) tends to cause more thermal tissue injury and often causes concomitant traumatic injuries. Depending on the path of electricity, there may be significant internal injuries beneath normal-appearing skin, especially in high-voltage cases. Significant injuries should be treated more like crush injuries, as the extent of the internal injuries is difficult to assess. Cutaneous burns due to electrical injury can be treated similarly to thermal burns. During the initial evaluation of

electrical injury, patients should undergo assessment for other injuries, electrocardiography, and cardiac monitoring. In patients with injury from high-voltage sources, obtaining serum levels of electrolytes, renal function studies, creatine kinase, troponin, and coagulation studies should be considered.

Special circumstances include multivictim injuries and oral commissure burns. In cases of multiple victims of a lightning strike, a reverse triage process occurs whereby care is provided first to the patients who appear to be in cardiac arrest, as cardiopulmonary resuscitation and defibrillation may save their lives if applied early enough. Oral commissure burns occur most often in young children who have chewed through electrical cords. Caregivers should be warned about delayed bleeding from the labial artery that can occur during wound healing. Due to risk of scar contracture and concern for aesthetic outcomes, these patients should be referred to a plastic or oral surgeon.

### Therapy and Treatment

#### First Aid and Office Management

The initial management for burn injuries consists of stopping further injury by removing the heat source and providing cooling. Remove the patient from the burning area in the event of flame injury. If the patient's clothing is on fire, it is important to stop the burning and remove hot clothing as quickly as possible. Hot liquid or scald injuries especially require prompt removal of overlying clothing, as the clothing will trap the heat, which can continue the tissue damage. After the heat source is removed, copious cool water should be used to irrigate the injured area, and any constricting jewelry should be removed immediately. The ideal temperature for cool water irrigation is not clear, but it is likely between  $15^{\circ}\text{C}$  and  $25^{\circ}\text{C}$  ( $59^{\circ}\text{F}$ – $77^{\circ}\text{F}$ ); colder temperatures can be damaging. The cooling irrigation should be continued for 20 minutes. Early wound cooling decreases the temperature of the injured area quickly to halt the burning process, but irrigation has been shown to be beneficial even after the wound has returned to a normal temperature. Cooling the wound is thought to be effective up to 3 hours after the injury. It is unclear why cool water irrigation improves burn outcomes; heat removal and edema prevention play a role, but it may also lead to alterations in gene expression that decrease injury and improve healing. After cooling the injured area, the initial treatment is to cover the wounds with a clean, thin cloth or sterile sheets while the patient awaits further care. Ensure that the patient's tetanus vaccination is up to date. Check

**TABLE 2** Chemical Burns\*

CHEMICAL	TREATMENT	SPECIAL NOTES
Dry chemical	Brush or remove as much chemical as possible, then copious irrigation	Obtain material safety data sheet information on exposure
Liquid chemical	Copious irrigation	
Ocular injury	Copious irrigation with lactated Ringer's solution, measure pH early and repeat frequently	
Elemental metals (e.g., sodium, magnesium)	Cover with mineral oil if available, physically remove as soon as possible, irrigate with water if no other options	Water causes an intense exothermic reaction, but tissue damage occurs with continued contact
Strong alkalis (pH 10–12; e.g., lye, bleach, cement [calcium oxide], ammonia)	Copious irrigation, continue until pH normalizes but at least 1 hour; may require 12 or more hours	Current recommendations are not to try to neutralize, but research is continuing
Petroleum	Irrigation, mild soap solution	May be seen in vehicle trauma patients
Hydrofluoric acid	Irrigation, topical calcium gluconate (Calgonate) <sup>1</sup> mixed with water-based lubricant (e.g., K-Y jelly), intradermal or intravenous calcium gluconate <sup>1</sup>	Associated with pain out of proportion to appearance, fluoride ion can cause hypocalcemia and death
Phenol	Polyethylene glycol (PEG) (Miralex) <sup>1</sup> stops phenol burn more quickly than water; if PEG is not available, use high-flow, low-pressure, copious irrigation	

\*Consider contacting a burn center or poison control center for assistance with chemical injury treatment.

<sup>1</sup>Not FDA approved for this indication.

the patient's temperature and provide warm blankets or a warm air environment to avoid hypothermia.

Superficial burns or superficial partial thickness burns can generally be treated on an outpatient basis, with important exceptions: >10% TBSA, extremes of age, circumferential injury, or burns on the head, face, or genital areas. Debride any ruptured blister tissue. Clean the wounds with mild soap and water or dilute antiseptic solutions and dress the wound. Topical bacitracin or triple-antibiotic ointment with an occlusive dressing is often used. Silver sulfadiazine cream 1% (Silvadene) is now generally discouraged as it may delay healing and can lead to pigmented scarring. Wound dressings may include topical antibiotic cream or ointment, silver impregnated nylon, bismuth tribromophenate and petrolatum impregnated gauze (Xeroform), or various specialized products to form occlusive dressings (including polyurethane films and foams, hydrocolloid, hydrogel, alginate, and chitin in various forms). The management of intact blisters is controversial; however, if a blister appears fragile or likely to rupture, unroof and debride the wound before dressing the wound. If the blister is in thicker skin or appears stable, most recommendations are to aspirate the blister fluid and dress the wound.

Burns are painful injuries and often require early, aggressive pain control, such as with nonsteroidal antiinflammatory drugs (NSAIDs), opioid medications, and acetaminophen. It is important to remember to provide additional analgesia as needed for dressing changes and wound care. Pruritus and neuropathic pain may occur as the wound heals. These are often treated with adjunct pain medications such as gabapentin (Neurontin),<sup>1</sup> and diphenhydramine (Benadryl).<sup>1</sup>

Deep partial thickness or deeper wounds usually require some form of surgical management and should be referred for specialized care. Early surgical management has been demonstrated to be beneficial. Prophylactic antibiotics should not be used for burn management, as they have been shown to be harmful. If burns have not healed within 2 weeks, they should be referred to a specialist.

### Initial Hospital Management

For patients with more severe injuries, follow the traditional algorithm of assessing and stabilizing the respiratory and circulatory system first, then proceeding with a complete history and physical examination, including comorbid conditions, allergies, medications, and other past medical history. If possible, identify the mechanisms and circumstances surrounding the injury, including agents involved, duration of exposure, and situation, including possibility of inhalation injury or enclosed space involvement. Assess whether there are chemical or electrical burns and any associated trauma. The social history may play an important role in disposition and management decisions.

### Management of Inhalation Injury

Patients who were in an enclosed space or structure fire or who were otherwise exposed to high levels of smoke or toxins should be assessed for carbon monoxide and cyanide injuries. Lactate, troponin, and carboxyhemoglobin levels should be checked in patients at risk for carbon monoxide or cyanide exposure. Patients at risk for cyanide exposure with decreased level of consciousness, hypotension, or a lactate level greater than 9 should receive 5 g (or 70 mg/kg to a maximum of 5 g) of hydroxocobalamin (Cyanokit) intravenously. If the patient is in cardiac arrest or does not improve with the initial dose, a total of 10 g should be given.

A patient with carbon monoxide exposure should have a carboxyhemoglobin level obtained and be placed on 100% oxygen as soon as possible, typically delivered via a nonrebreather face mask. Carbon monoxide binds tightly to hemoglobin, and by increasing the oxygen concentration in the lungs and blood, the half-life of carboxyhemoglobin is greatly reduced. With oxygen levels typically delivered by nonrebreather face mask, the half-life of carboxyhemoglobin is 74 minutes. After 6 hours on 100%

oxygen, if the patient is asymptomatic, treatment can be stopped. It is unnecessary to use arterial blood or to repeat carboxyhemoglobin levels. Patients with carbon monoxide poisoning may experience delayed neurologic sequelae. Hyperbaric oxygen therapy may reduce the risk of delayed neurologic sequelae in appropriately selected patients. Although controversial, this therapy is thought to be most helpful if it occurs within 12 hours after the end of the patient's exposure, but patients may benefit up to 24 hours after exposure. If possible, consult with a physician capable of providing hyperbaric oxygen therapy or with a poison control center for patients with carboxyhemoglobin levels greater than 10, symptoms consistent with carbon monoxide exposure, or pregnant patients (Box 1).

Patients with inhalation injuries can develop rapidly progressing airway swelling. The initial evaluation of burn patients should include assessment for perioral injury, singed facial or nasal hair, and soot or swelling in the oral or hypopharyngeal cavities. These findings, extensive neck burns, other indications of airway swelling, or difficulty breathing should prompt early placement of a definitive airway. Delay may make placement of an endotracheal tube difficult or impossible.

### Burn Management

After evaluation and stabilization of the respiratory and circulatory status of the patient, and after stabilizing acute traumatic injuries, the next step is to evaluate the extent of the burn injuries. Removing the heat source and cooling the injured areas remain a priority. Burned areas can be cooled with cool water irrigation or saline-soaked gauze. Because patients with extensive wounds can be at risk of developing hypothermia during this phase, it is important to raise the ambient temperature in the resuscitation room or use warm blankets to maintain normothermia. The extent of the burns should be determined. The "rule of nines" diagram is an accepted mechanism for approximating the percentage of TBSA burned in adults, but it tends to overestimate. Because children have a proportionally larger head and torso, diagrams have been adapted for use in pediatric populations. The Lund-Browder chart can be utilized with patients of all ages (Figure 2). It can also be useful to diagram the areas of burn by estimated depth. For determination of burn severity, calculation of transfer criteria, and fluid resuscitation, only the areas of deep partial thickness and deeper burns are added together to determine TBSA. Use of a diagram is recommended because TBSA is frequently overestimated when providers estimate the extent of burned areas. Overestimating TBSA burned leads to excessive fluid administration and the complications that accompany fluid overload.

### Fluid Resuscitation and Monitoring

Critically ill burn patients should be monitored in an intensive care setting while awaiting transfer to a burn center. In addition to monitoring respiratory and circulatory status, a Foley catheter should be placed to monitor urinary output and for intermittent assessment of bladder pressure to evaluate for the development of intraabdominal compartment syndrome.

#### BOX 1 Symptoms of Carbon Monoxide Exposure\*

- Headache
- Dizziness
- Nausea
- Vomiting
- Confusion
- Fatigue
- Chest pain
- Shortness of breath
- Loss of consciousness

\*It is important to note that carboxyhemoglobin levels do not correlate well with symptoms or with severity of exposure. Arterial blood gas samples are not superior to venous blood samples.

<sup>1</sup>Not FDA approved for this indication.

**Figure 2** Lund-Browder classification of burn size.

Because burned tissue increases insensible fluid losses, burn victims have increased fluid requirements. Various formulas are available for calculating approximate fluid requirements, but all require careful monitoring of the results and progress of fluid resuscitation. Patients who receive more than 250 mL/kg in the first 24 hours are at increased risk of developing fluid-related complications. The American Burn Association Consensus Statement formula is used to guide initial fluid management. The starting fluid requirements are 2 to 4 mL/kg of lactated Ringer's solution per TBSA percent value, with half given in the first 8 hours and the rest over the next 16 hours (Box 2). Urine output should be monitored hourly and maintained between 0.5 and 1 mL/kg/h. If a patient's urine output is greater than 1 mL/kg/h, the rate of fluid administration should be decreased by 20% and continued to be monitored hourly. If the urine output

is less than 0.5 mL/kg/h, the rate of fluid administration should be increased by 20% and continued to be monitored.

Unfortunately, ensuring adequate urine output does not necessarily guarantee adequate fluid resuscitation. In addition to using urine output as an indicator of resuscitation adequacy, other modes of monitoring can be used to help guide fluid resuscitation (hemodynamic monitoring, echocardiography, gastric tonometry, or other devices). Whether they lead to any increased improvement or survivability is not clear, however.

#### Burn Center Referral Criteria and Transfer

It is important to identify the regional burn referral center and to establish a line of communication with it before a burn patient is encountered in order to know of the center's suggested criteria

**BOX 2** Fluid Administration and Calculation

80-kg male patient with a burn of 35% TBSA full-thickness and partial thickness burns:  
 $80 \text{ kg} \times 35 \times 3 \text{ mL/kg} = 8400 \text{ mL}$  in first 24 hours  
 $8400 \text{ mL}/24 \text{ hours} \div 2 = 4200 \text{ mL}$  in first 8 hours, 4200 mL in next 16 hours  
 Initial rate of 525 mL/h over first 8 hours, then switching to a rate of 265 mL/h over next 16 hours  
 Expected urine output is 0.5–1 mL/kg/h  
 $80 \text{ kg} \times 0.5 \text{ mL/kg/h} = 40 \text{ mL/h}$   
 $80 \text{ kg} \times 1 \text{ mL/kg/h} = 80 \text{ mL/h}$   
 So, for our 80-kg patient, we would expect 40–80 mL of urine every hour. In hours 1 and 2 of resuscitation, the patient has 65 mL of urine per hour. In hour 3 of resuscitation, the patient has 90 mL of urine per hour. We would then decrease the fluid administration rate by 20%, or  $525 \text{ mL/h} - (0.20 \times 525) = 420 \text{ mL/h}$   
 Thus, the rate of administration of lactated Ringer's solution would change from 525 mL/h to 420 mL/h and continue to be monitored and recorded hourly, with continued adjustments based on hourly urine output.

TBSA, Total body surface area.

**BOX 3** Burn Center Referral Criteria

Partial thickness burns greater than 10% TBSA  
 Full-thickness burns  
 Burns to high-risk areas, such as the face, hands, feet, genitals, perineum, or major joints  
 Circumferential burns  
 Electrical burns, including lightning strikes  
 Chemical burns  
 Inhalation injury  
 Preexisting conditions known to impair healing and increase risk of mortality  
 Burns in combination with traumatic injury (e.g., fracture, traumatic brain injury) whereby the burn is the leading risk for patient mortality  
 Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention  
 Burns in a setting unequipped (personnel, equipment, or unit) to care for critically ill children

TBSA, Total body surface area.

Available from <https://ameriburn.org/public-resources/burn-center-referral-criteria/>. Accessed May 1, 2021.

for transfer (Box 3). Burn centers typically manage more than 200 burn patients annually and have specially trained physicians, nurses, and ancillary personnel who are focused on treating burn patients. Severely burned patients who are treated at specialized centers have better outcomes. It is recommended that hospitals and clinics have agreements with burn centers for the management of complicated patients and patients who meet criteria for burn center transfer.

In general, the following criteria are recommended for transfer to a burn center: burns greater than 10% of TBSA; inhalation injury; burns with significant associated mechanical injury; burns of the face, hands, feet, perineum, or genitalia or across major joints; full-thickness burns of any size; and circumferential burns. Burns that warrant a discussion with a burn center for possible transfer or outpatient follow-up include burns in children; patients with comorbid conditions that will impact healing; and patients with special social, emotional, psychological, or rehabilitative needs.

**Complications**

Pain management for burns may require multiple modalities because the type of pain varies, depending on where the patient is in the cycle of treatment and healing. There are four types of pain that need to be treated during the care of a burn patient: background pain, breakthrough pain, procedural pain, and long-term pain. Background pain is present from the onset of the injury, and the pain is typically intensified during procedures. There will also be episodes of breakthrough pain. Depending on the severity of the injury, initial pain and background pain may be treated with multimodal therapy including acetaminophen, NSAIDs (e.g., ibuprofen, naproxen sodium), or opioids. Low-dose ketamine (Ketalar)<sup>1</sup> is increasingly used in addition to opioids for background and breakthrough pain. Procedural pain may require bolus dosing of opioids or other adjunctive medications such as ketamine (0.1–0.2 mg/kg IV). Long-term pain may respond to medications such as gabapentin (Neurontin),<sup>1</sup> clonidine (Catapres),<sup>1</sup> or others.

Psychosocial recovery from burns is impacted by the preexisting conditions and the resilience of the patient. Preexisting mental health, substance abuse, and other medical and psychosocial issues complicate the patient's recovery from burns. Risk factors for burn injury include poverty, a history of abuse or neglect, substance abuse, serious mental illness, and risk for suicide or assault. Psychiatric recovery is negatively affected by posttraumatic stress disorder, depression, learning disorders, substance abuse, stigma, and disability. Individual resilience, social support, and education or occupation also impact patient outcomes.

The patient's age and stage of life at the time of injury impact recovery as well. Younger victims have a longer remaining lifespan to live with persistent scarring and disfigurement. Pediatric patients often have fewer comorbid medical conditions, which can speed their recovery and limit disability, and they tend to heal more quickly. However, their injuries may have a significant impact on their body image development, self-confidence, and interpersonal relationship building. The family may be of assistance in recovery from the injury, but family members, too, may experience stress and psychological concerns related to the child's injury. Adults and older patients have to deal with the impact of the injury on their identity and their ability to return to their preinjury roles.

Some patients and caregivers may develop posttraumatic stress disorder related to the injury or to postinjury treatment. It is thought that early multidisciplinary interventions may decrease this risk, but the research is unclear. Some patients will require long-term, continued outpatient treatment.

Hypertrophic scarring is the most common complication related to healing of burn wounds, but scar contracture and pruritus are common complications as well. It is thought that hypertrophic scarring may be decreased with early, appropriate surgical repair, but it still can occur. The development of hypertrophic scarring is multifactorial; it is likely a result of a complex interplay of humoral and cellular immunity causing an inappropriate response to healing tissue. Multiple host and injury factors contribute, but protracted healing of a partial thickness injury is a common theme. There are some experimental therapies for manipulating different components of the host response, but none has clearly proven to be beneficial.

Scar contracture results from tissue loss at the time of injury and tissue-healing properties. Burn injuries are more complicated than other traumatic wounds because the destroyed tissue is surrounded by profoundly damaged tissue. As a result of this tissue injury, there is increased collagen deposition resulting from changes in inflammation, proliferation, and remodeling at the cellular and extracellular matrix levels. Hypertrophic scars tend to form within the first month after injury and may improve over the first 6 months but then tend not to show significant changes after that time. Burn treatment and scar prevention consist of tissue replacement, tissue rehabilitation, and tension release. Early and existing scars are often treated with compression garments and silicone sheets. It is thought that these may alter and improve

<sup>1</sup>Not FDA approved for this indication.

remodeling of the extracellular matrix and thereby improve scarring. In some cases, surgical release of tension may be necessary.

## DISTURBANCES DUE TO COLD\*

Method of

Jerrold B. Leikin, MD; Scott Leikin, DO; Frederick Korley, MD; and Ernest Wang, MD

### CURRENT DIAGNOSIS

- Accidental hypothermia may be classified as mild, moderate, or severe.
- The temperature measured should be core body temperature.
- The method of rewarming depends on the severity of the temperature drop.
- Complications of rewarming include arrhythmias, rewarming-related hypotension, core temperature after drop, and rhabdomyolysis.
- Patients can be declared dead only after they are warm.

### CURRENT THERAPY

#### Mild Hypothermia: 32.2°C to 35°C (90°F to 95°F)

- Begin passive external rewarming; remove wet clothing.
- Ambient temperature should exceed 21°C (70°F).
- Cover the patient with insulating material.

#### Moderate Hypothermia: 28°C to 32.2°C (82.4°F to 90°F)

- Begin active external rewarming; use radiant heat.
- Use thermal mattresses and electric heating blankets.
- Use forced-air heating blankets.
- Perform active core rewarming; use warmed humidified oxygen.
- Give warmed intravenous saline solution.
- Give bladder, colonic, and gastric irrigation.
- Start pleural cavity lavage.
- Avoid alcohol, caffeine, and nicotine (tobacco).

#### Severe Hypothermia: Less than 28°C (82.4°F)

- Begin aggressive active core rewarming; use warmed, humidified oxygen.
- Give warmed intravenous saline solution.
- Give bladder, colonic, and gastric irrigation.
- Begin pleural cavity lavage.
- Perform peritoneal lavage or dialysis.
- Perform extracorporeal warming or heated cardiopulmonary bypass.

#### Frostnip

- Begin gentle rewarming, generally in a water bath of 104°F to 108°F (40°C to 42°C).
- It is usually self-resolving.

#### Frostbite

- Immerse in warm (not hot) water.
- Débride broken vesicles.
- Do not débride hemorrhagic or intact blisters.
- Apply topical aloe vera<sup>7</sup> or antibiotic ointment.
- Use nonsteroidal antiinflammatory drugs (NSAIDs) for pain.
- Update tetanus status.
- Do not rub or massage the affected area.
- Do not use a heating pad or heat lamp; affected areas can be easily burned.
- Avoid alcohol and tobacco products.

#### Chilblain

- Rewarm gently.
- Nifedipine (Procardia)<sup>1</sup> may be useful.

#### Trench foot

- Dry the foot.
- Rewarm gently.
- Use NSAIDs for pain.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

## Accidental Systemic Hypothermia

Hypothermia is classically defined as a reduction in the body's core temperature below 95°F (35°C). Most reported cases of hypothermia are caused by environmental exposure to low ambient temperatures (accidental hypothermia). Other causes of hypothermia include sepsis, severe hypothyroidism (myxedema coma), acute spinal cord injury, diabetic ketoacidosis, multisystem trauma, and prolonged cardiac arrest. Episodic hypothermia can be encountered in patients with advanced secondary progressive multiple sclerosis, subarachnoid hemorrhage, HIV-1 infections, and brain contusion. Shapiro syndrome is episodic hypothermia associated with hyperhidrosis caused by agenesis or lesions of the corpus callosum.

## Epidemiology

Risk factors for developing hypothermia include extremes of age (older adults might not be able to remove themselves from cold environments, and young children lose heat more rapidly because of their increased total body surface area), major trauma, homelessness, psychiatric illness, and drug and alcohol abuse (Box 1). Cold-related deaths also are reported in military combatants and outdoor winter sports participants. Several drugs and chemicals can predispose to hypothermia (Box 2). Alcohol is the most common intoxicant associated with hypothermia because of its ability to cause cutaneous vasodilation, impair shivering, and impair adaptive behavior.

Between 1999 and 2011 in the United States, 16,911 deaths (an average of 1301 per year) were attributed to exposure to low environmental temperatures. In 2002, of the 646 hypothermia-related deaths reported, 66% occurred in male patients, 52% occurred in patients who were 65 years of age or younger, 45% occurred among white male patients, and 14% occurred among black male patients. The state of Alaska (age-adjusted mortality of 2 deaths per 100,000), followed by Montana and New Mexico, had the largest overall age-adjusted death rates from hypothermia from 1999 to 2015. The incidence of accidental hypothermia in Europe and New Zealand ranges from 0.13 to 6.9 cases per 100,000 annually. The lowest recorded core temperature in a pediatric survivor of accidental hypothermia is 57.9°F (14.4°C), and the lowest temperature in an adult survivor is 56.7°F (13.7°C).

## Pathophysiology

The normal range of human core temperature is 97.5°F to 99.5°F (36.4°C to 37.5°C). Humans are thus warm-blooded and are normally able to maintain their body temperature by heat-generating mechanisms and heat-conserving behavior. These compensatory responses, however, can be overwhelmed under extreme environmental conditions, leading to hypothermia.

The anterior hypothalamus coordinates nonshivering heat conservation and dissipation mechanisms, and the posterior hypothalamus coordinates shivering thermogenesis. Heat loss usually occurs by four mechanisms: About 55% to 65% of heat is lost by radiation, 25% to 30% by evaporation from the skin and respiratory tract, and 10% to 15% by conduction and convection. The amount of heat lost via conduction is markedly increased in cold-water immersion (by about 32-fold). Each organ system is affected uniquely by hypothermia.

## Skin

Cutaneous blood flow is regulated by the individual's thermoregulatory needs, modulated by neural control through the arteriovenous anastomoses located in the extremities. Sympathetic tone is increased, which leads to arteriovenous constriction, which is maximum at 59°F (15°C). Cold-induced dermal vasodilation can occur at 50°F (10°C).

## Cardiovascular System

One of the initial heat-conserving mechanisms is peripheral vasoconstriction to decrease blood flow to the skin. There are also initial increases in heart rate and blood pressure caused by a catecholamine surge. At core temperatures below 82.4°F (28°C),

## BOX 1 Factors Predisposing to Hypothermia or Frostbite

### Physiologic

#### Decreased heat production

- Age extremes (infants, older adults)
- Dehydration or malnutrition
- Diaphoresis or hyperhidrosis
- Endocrinologic insufficiency
- Hypoxia
- Insufficient fuel
- Overexertion
- Physical conditioning
- Prior cold injury
- Trauma (multisystem or extremity)

#### Increased heat loss

- Burns
- Dermatologic malfunction
- Cold infusions
- Emergency resuscitation
- Poor acclimatization or conditioning
- Shock
- Vascular diseases

#### Impaired thermoregulation

- Central nervous system trauma or disease
- Metabolic disorders
- Pharmacologic or toxicologic agents
- Sepsis
- Spinal cord injury

#### Psychological

- Fatigue
- Fear or panic
- Hunger
- Intense concentration on tasks
- Intoxicants
- Mental status or attitude
- Peer pressure

#### Environmental

- Altitude with or without associated conditions
- Ambient temperature or humidity
- Duration of exposure
- Heat loss (conductive, evaporative, radiative, convective)
- Quantity of exposed surface area
- Wind chill factor

#### Mechanical

- Constricting or wet clothing or boots
- Inadequate insulation
- Immobility or cramped positioning

bradycardia can result from a decrease in spontaneous depolarization of the pacemaker cell firing. The myocardium also becomes irritable, predisposing it to bradyarrhythmia and hypotension. Cardiac output decreases to approximately 45% at 77°F (25°C).

Atrial arrhythmias can occur with a slow ventricular response, and they can precede ventricular arrhythmias and asystole at core temperatures below 77°F (25°C). Moderate hypothermia (82.4°F or 28°C) does not significantly alter ventricular conduction but can result in prolongation of repolarization, leading to arrhythmia. The characteristic Osborn or J waves (a hump seen at the QRS-ST junction) may be seen on an electrocardiogram (ECG) at core temperatures below 89.6°F (32°C). The development of the Osborn wave appears to be related to lower blood pH, low serum bicarbonate, and higher serum creatinine levels. Orthostasis also commonly occurs. Risk factors for development of cardiac arrest include core temperature less than 82.4°F (28°C), ventricular arrhythmia development, and systolic blood pressure less than 90 mm Hg.

### Renal System

Renal blood flow is affected by peripheral vasoconstriction, causing the glomerular filtration rate to fall and contributing to metabolic acidosis. Antidiuretic hormone activity is usually inhibited. This can result in intravascular volume depletion, subsequent vasodilation, increased renal blood flow, and, ultimately, acute renal failure. Urinary output can increase threefold, and this may be accentuated with concomitant ethanol use.

### Respiratory System

At core temperatures below 82.4°F (28°C), minute ventilation, tidal volume, respiratory rate, and thoracic elasticity all are reduced; bronchorrhea can occur with a loss of cough and gag reflexes, leading to an increased risk for aspiration. Carbon dioxide production drops by one-half for every 14°F (8°C) drop in temperature, and oxygen consumption is reduced by 75% at 72°F (22°C). Apnea can then result.

### Central Nervous System

Cerebral metabolism is depressed 6% to 7% per 1°C decrease in core temperature. Cerebrovascular autoregulation remains intact until below 77°F (25°C), which helps maintain cortical blood flow. Electroencephalographic activity is clearly not prognostic, but it is abnormal below 92°F (33°C); burst suppression can occur at 71.6°F (22°C), and it silences at around 66.2°F to 68°F (19°C to 20°C). Most patients are unconscious at a core temperature of 82.4°F to 86°F (28°C to 30°C).

### Coagulation

Because of depression of enzymatic activity of the activated clotting factors, clotting time (particularly partial thromboplastin time [PTT]) is prolonged. At 84°F (29°C), a 50% increase of PTT can be expected. Thrombocytopenia also commonly occurs as a result of bone marrow suppression along with splenic and hepatic platelet sequestration, which can be exacerbated by cryoglobulinemia.

### Clinical Presentation

Accidental hypothermia is classified as mild at body temperatures of 90°F to 95°F (32.2°C to 35°C), moderate at body temperatures of 82.4°F to 90°F (28°C to 32.2°C), or severe at body temperatures less than 82.4°F (28°C).

In general, a patient's symptoms depend on the severity of the temperature drop. Patients with mild hypothermia can develop vigorous shivering and cold diuresis. Those with moderate hypothermia can have a paradoxical decrease in shivering, slurred speech, hyporeflexia, and confusion. They are also at risk for intravascular thrombosis. Splanchnic vasoconstriction, gastric erosions, hepatic necrosis, and pancreatitis can occur. Prominent laboratory abnormalities include leukopenia (from splenic sequestration), thrombocytopenia (during rewarming), hypoglycemia, respiratory or metabolic acidosis, and hyperkalemia. In pregnant patients, fetal bradycardia can occur in response to maternal hypothermia, but long-term sequelae are unknown. It should be noted that hypothermia (core temperature below 96.5°F or 35.8°C) portends a poorer prognosis (a longer period of intubation, longer intensive care unit stay, and approximately double the risk of mortality) in patients with COVID-19 infections.

During severe hypothermia, shivering gives way to rigor, minute ventilation decreases, and heart rate and cardiac output decrease. Cardiac instability can be seen at this stage and can manifest in the form of arrhythmias, heart blocks, and eventually asystole. Neurologically, the patient's mental status declines. The patient might attempt to undress (paradoxical undressing) and might respond only to painful stimuli, have decreased gag reflexes, and eventually become apneic. Generally, at about 68°F (20°C), patients become totally neurologically unresponsive, lose corneal and ocular reflexes, and can have a flat electroencephalogram (EEG).

### Emergency Department Evaluation

Typically, the source of hypothermia is revealed from the patient's history; however, it is very important to rule out secondary causes of hypothermia, such as sepsis, hypothyroidism, central nervous system lesions, and hypoglycemia, among others. All patients arriving in the emergency department with hypothermia need a complete evaluation to rule out traumatic injuries and drug or toxin ingestion or overdose.

As in all resuscitation, attention should be paid to the ABCs (airway, breathing, and circulation). The mean decrease of vital signs associated with a 1°C drop in core temperature in moderate to severe hypothermia is estimated to be 0.5 breaths per minute (respiratory rate), 2.5 beats per minute (heart rate), 4.36 mm Hg (systolic blood pressure) and 0.88 on the Glasgow Coma Scale (GCS). Successful neurologic recovery has been documented following 5 hours of cardiopulmonary resuscitation (CPR) in the setting of profound accidental hypothermia (62.4°F or 16.9°C). Ideally, in patients in cardiac arrest, CPR should be maintained throughout the prehospital period. In a patient with a core temperature of less than 28°C, evidence supports alternating 5 minutes of CPR with less than or equal to 5 minutes without CPR, if feasible. With a core temperature less than 20°C, data support alternating 5 minutes of CPR with less than or equal to 10 minutes without CPR. Respiratory failure should be treated with endotracheal intubation and mechanical ventilation. Hypotension can be treated initially with warmed fluids. Placing the patient in a warm environment, removing all cold and wet clothes, and remembering to cover the patient after exposure should help prevent further heat loss.

The temperature should be confirmed by checking a core temperature (e.g., rectal, bladder, or esophageal) using a thermometer capable of recording very low temperatures. Patients should be placed on a cardiac monitor, and an ECG should be obtained. Laboratory testing is especially useful in the postresuscitative period, when complications begin. Laboratory tests should include a complete blood count (CBC), a chemistry panel with liver function tests, creatine phosphokinase (CPK) to evaluate for rhabdomyolysis, a coagulation profile, blood type and screen, arterial blood gas, and drug screen. A Foley catheter should be placed to assess urinary output.

### Rewarming Strategies

There are several methods of rewarming. The method of choice usually depends on the severity of hypothermia. During rewarming, the patient should be placed on a cardiac monitor with frequent measurements of blood pressure and temperature (via a rectal probe) for easy detection of complications of rewarming, such as rewarming-related hypotension, arrhythmias, and core temperature after-drop. It should be noted that the human body is capable of raising the body temperature through heat generation by approximately 1°C per hour.

### Passive External Warming

Passive external warming is ideal for patients with mild hypothermia (greater than 93°F or 34°C) who are otherwise healthy. It uses the patient's endogenous heat production for rewarming, and it involves simple, logical passive maneuvers that minimize heat dissipation. All wet clothing should be removed when using this method, and the patient should be covered with insulating materials. Patients who are warmed easily using this method can be safely discharged.

### Active External Rewarming

Active external rewarming should be considered for patients with core temperatures between 86°F and 92°F (30°C to 34°C). It involves exposing the patient's skin to exogenous heat sources. Radiant heat, thermal mattresses, electric heating blankets, and forced-air heating blankets are some available techniques. Heat applied externally is most effective if concentrated on the axillae, chest, and back, which exhibits the greatest potential for conductive heat transfer. Additionally, heat can be applied to the neck

region to prevent heat loss. Extremity placement of heat should be avoided. Also, localized pressure to skin that is cold should be avoided. Chemical heat packs do not provide sufficient heat transfer to increase core temperature and should not be used. The rate of temperature rise is approximately 2.7°F to 7.2°F (1.5°C to 4°C) per hour.

This method has several disadvantages. First, burn injuries can occur to the vasoconstricted skin. Second, any sort of immersion can hinder monitoring and other resuscitative activities. Finally and most important, active external rewarming produces a phenomenon called *core-temperature after-drop*. This refers to a drop in core temperature resulting from sudden peripheral vasodilation. This causes cold, acidic blood to return to the core. Hypotension and potentially fatal dysrhythmias can result. Focusing on rewarming the trunk only (rather than the trunk and extremities) can prevent these temperature gradients. In general, active external rewarming is used in conjunction with active core rewarming.

### Active Core Rewarming

Active core rewarming involves techniques to deliver direct heat internally. It should be used in patients with moderate to severe hypothermia (less than 86°F or 30°C). The simplest method entails administration of heated, humidified oxygen at 107.6°F to 114.8°F (42°C to 46°C), which can be used as adjunctive therapy, and intravenous saline solution warmed to 109.4°F (43°C). Saline should be administered via a central line at 150 to 200 mL/h. Gastric, bladder, and colonic irrigations have been used, but their relatively small surface areas usually limit their effect. Urinary bladder or gastric lavage (which is rarely used because of aspiration potential and electrolyte shifts) can rewarm at an hourly rate of 0.9°F to 1.8°F (0.5°C to 1°C).

Another method of active core rewarming is pleural irrigation using two large-bore (36°F or greater) thoracostomy tubes. One tube is placed at the midclavicular line and is connected to saline at 107.6°F (42°C). The other tube is placed at the posterior axillary line and connected to a chest tube drainage kit.

A more aggressive method of active core rewarming is via peritoneal lavage and dialysis, especially as adjunctive therapy. This can be accomplished using a standard diagnostic peritoneal lavage kit and introducing an 8-F catheter into the peritoneum using the Seldinger technique. This method affords the added advantage of allowing the serum potassium level and fluid status to be adjusted. Use of continuous or intermittent renal replacement therapy (RRT) with local anticoagulation using citrate can achieve rewarming rates of about 2°C per hour.

The most efficient and physiologic active core rewarming method is via extracorporeal warming or heated cardiopulmonary bypass. This is the method of choice for the most severe cases, patients with severe rhabdomyolysis, and patients who require CPR. Survival rates with no chronic neurologic sequelae as high as 75% have been documented. Excellent recovery has been documented from a nasopharyngeal temperature of 13.8°C (and a serum potassium of 11.3 mmol/L) caused by drowning with a submersion time of at least 83 minutes in icy sea water with slow rewarming with extracorporeal membrane oxygenation. Extracorporeal life support can be an effective rewarming tool in patients with prolonged cardiac arrest from accidental hypothermia, particularly in the absence of asphyxia, trauma, or severe hyperkalemia. Veno-arterial extracorporeal membrane oxygenation (VA-ECMO) is increasingly utilized for its ability to gradually increase core body temperature while providing respiratory and hemodynamic support. Rewarming rates up to 6°C per hour can be achieved via this modality. It should be considered, especially in pediatric patients or in individuals requiring prolonged support. Survival rates as high as 40% (with favorable neurologic outcome) have been documented.

Most arrhythmias are corrected by rewarming. Atrial dysrhythmias often occur during rewarming and generally resolve without treatment. Atropine is typically ineffective for cold-associated bradycardia. Ventricular tachycardia and fibrillation require electrocardioversion; automated external

### BOX 3 Drugs Displaying Reduced Metabolism or Clearance in Hypothermia

Suxamethonium (succinylcholine, Anectine)  
d-Tubocurarine  
Brain natriuretic peptide

defibrillator (AED) devices can be used as directed for pulseless ventricular tachycardia or ventricular fibrillation. Dopamine, epinephrine,<sup>1</sup> and vasopressin (Pitressin)<sup>1</sup> may be effective vasopressors for core temperatures above 30°C (86°F). External pacing may be ineffective. Empiric antibiotics may be given. However, the empiric use of levothyroxine (Synthroid)<sup>1</sup> and corticosteroids may be hazardous. Phenytoin (Dilantin)<sup>1</sup> might have cardiac-depressant qualities in the moderately hypothermic patient. Box 3 demonstrates drugs with possible decreased metabolism or clearance with resultant increase in toxicity in hypothermia.

For hypothermia caused by myxedema coma, levothyroxine (Synthroid) should be administered intravenously (at a dose of 250 to 500 µg over 30 to 60 seconds). Daily intravenous injections of 100 µg may be required for up to 7 days. Hydrocortisone (Solu-Cortef)<sup>1</sup> (200 to 400 mg IV daily) administration should also be considered. Other active core rewarming techniques are usually not required. Treatment of episodic, spontaneous hyperhidrosis hyperthermia or Shapiro syndrome often responds to clonidine (Catapres)<sup>1</sup> (up to 0.6 mg daily) through its actions on hypothalamic thermoregulation.

Indicators of grave prognosis include development of profound hyperkalemia (serum potassium greater than 10 mEq/L); elevated serum creatinine, serum sodium, or serum lactate concentration; lower prothrombin time; underlying medical conditions; intravascular thrombosis (fibrinogen less than 59 mg/dL); pH less than 6.5; and core temperature less than 82.4°F (28°C). Elevated serum potassium in a hypothermic patient may indicate that hypoxia preceded the onset of hypothermia. Submersion in cold water for over 10 minutes is associated with a poor prognosis; if the water is less than 43°F (6°C), survival is unlikely to occur if submerged for over 90 minutes.

### Peripheral Cold Injuries

Peripheral cold injuries span a spectrum ranging from minimal to severe tissue damage. Freezing and nonfreezing syndromes can cause these injuries. About 500 patients with frostbite are hospitalized yearly in the United States, with about an 80% male demographic and lower-extremity predominance. The average length of stay in critical care units and total hospital stay is approximately 7 and 10 days, respectively. Frostnip and frostbite are caused by exposure to freezing temperatures. *Frostnip* refers to the numbness and blue-white discoloration of the face and extremities that occur during exposure to freezing temperatures. It is a precursor to frostbite. It is characterized by reversible skin changes, including blanching and numbness with no permanent tissue damage, unlike frostbite. Nonfreezing injuries depend on whether the ambient environment during exposure was wet (trench or immersion foot) or dry (pernio or chilblain).

<sup>1</sup>Not FDA approved for this indication.

## Pathophysiology

During exposure to cold temperatures, the core body temperature is preserved to the detriment of the extremities. Frostbite occurs in four stages: prefreeze, freeze-thaw, vascular stasis, and late ischemic stages. The prefreeze phase occurs when the temperature of the extremities falls below 50°F (10°C) and cutaneous sensation is lost. Vasoconstriction also occurs along with leakage of intracellular fluid into the interstitium.

The freeze-thaw phase begins at the freezing point of water (32°F or 0°C) with the formation of ice crystals extracellularly. This further enhances the exit of water from the intracellular space under osmotic forces, resulting in cell shrinkage and, ultimately, damage. During the vascular stasis phase, plasma leakage and formation of ice crystals continue. Arachidonic acid breakdown products are then released from underlying damaged tissue. Both prostaglandin F<sub>2α</sub> and thromboxane A<sub>2</sub> produce platelet aggregation, leukocyte immobilization, and vasoconstriction.

Endothelial cells are sensitive to cold injury, and the microvasculature becomes distorted and clogged, leading to tissue ischemia. The late ischemic phase is characterized by ischemia, thrombosis, continued shunting, gangrene, autonomic dysfunction, and denaturation of tissue proteins. The tissue can eventually mummify and demarcate more than 60 to 90 days later.

## Clinical Presentation of Local Extremity Issues

### Frostnip and Frostbite

The face and ears are the most common sites prone to cold injury, followed by the hands and feet. Patients with frostnip usually have blanching and numbness of their fingertips. The skin has a firm or waxy texture. Often the patient is unaware of these changes. Frostnip is usually reversible. Frostbite has been classified as *superficial*, affecting the skin and subcutaneous tissue, or *deep*, affecting the bones, joints, and tendons. After rewarming an area with superficial frostbite, a clear blister may form; however, after rewarming an area with deep frostbite, a hemorrhagic blister may form. This classification, however, has no therapeutic or prognostic value given that frostbites can initially appear benign. Many weeks can pass before the demarcation between viable and nonviable tissue becomes apparent. Facial frostbite, with skin blistering, can also occur following halogenated (especially fluorinated) hydrocarbon inhalation abuse. This can appear initially as angioneurotic edema if it involves the oral mucosa membranes. Acute compartment syndrome of the foot and ankle, associated with gangrenous toe changes, has been described.

Although no prognostic factors can be entirely predictive, favorable factors include retained sensation, normal skin color, and clear rather than cloudy fluid in the blisters, if present. Poor prognostic features include nonblanching cyanosis, firm skin, and dark, fluid-filled blisters. Patients can present with pain, numbness, and a clumsy “chunk of wood” sensation in the affected extremity. The pain is initially described as a dull ache and evolves to become a throbbing sensation in about 48 to 72 hours.

### Chilblain

Chilblain, also referred to as *pernio*, results from repetitive exposure to cold, dry air. It manifests as painful erythematous nodules or cyanotic lesions often referred to as *cold sores*. These lesions usually develop on exposed surfaces after a delay of 12 to 14 hours and are characterized by pruritus and burning paresthesias. Young women, especially those with Raynaud phenomenon and/or a low body mass index, are at risk.

Chilblains are located on acral skin associated with cold exposure. They are usually located on the dorsum of the fingers, toes, and thighs, where blisters or ulcerations can develop in very severe cases. Perivascular lymphocytic infiltration with vacuolation of the basal layer is often seen on histologic analysis, especially when it is associated with an autoimmune disease (particularly lupus erythematosus). Susceptibility to chilblains increases when the ambient temperature is less than 10°C and relative humidity is 60%.

## Trench Foot and Immersion Foot

Trench foot occurs as a result of prolonged exposure (about 10 to 15 hours) to a damp, cold, nonfreezing environment (with temperature as high as 15°C or 59°F). It has been classically described among soldiers in World War I, many of whom were confined to cold and damp trenches for prolonged periods. Symptoms include numbness and painful paresthesias that can progress to a throbbing and burning sensation. Initial evaluation reveals a cold, pale extremity, with or without vesicles or bullae. Inflammatory serum markers, such as erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), may be elevated.

Immersion foot may be considered the sailor’s counterpart to trench foot. It occurs after prolonged immersion in cold water at temperatures above freezing.

## Treatment

Treatment of frostbite should begin with removing all wet or frozen clothing. For patients with moderate or severe hypothermia, initial resuscitative efforts should be geared toward raising their core temperature. The patient should be moved to a warm environment, and all wet clothing should be removed. The frozen extremity should be rewarmed by immersion in circulation water at 98.6°F to 102.2°F (37°C to 39°C) for about 15 to 30 minutes. Given the risk of thermal injury, the frozen parts should not be exposed to direct or dry heat (such as hair dryers, heating pads, or heat lamps). Do not rub or massage the affected area. The process should be continued until the extremity appears warm and well perfused. Following rewarming, the extremity should be air-dried and elevated. Because of the pain associated with reperfusion, there may be the temptation to abruptly abort the rewarming process. This can, however, promote further tissue damage.

Oral or intravenous fluid should be administered to prevent dehydration and vascular stasis. Because the pain is usually prominent at night, amitriptyline (Elavil)<sup>1</sup> at an initial dosage of 10 to 25 mg and a maximum of 100 mg may be helpful. Gabapentin (Neurontin)<sup>1</sup> also may be an alternative therapy. Parenteral analgesic medications—nonsteroidal antiinflammatory drugs (NSAIDs) and opioids—may be administered as needed to make the process more tolerable. Ibuprofen at a dose of 12 mg/kg twice daily (400 mg in adults twice daily, which can be increased to a maximum of 2400 mg daily) may be helpful for its analgesic and antiinflammatory effects.

Almost all authors agree that hemorrhagic blisters should not be débrided because of the risk of secondary desiccation of deep dermal layers, extending the injury. Débriding broken vesicles or bullae is also widely accepted; however, clear, intact vesicles may be broken and débrided or left intact. Topical aloe vera ointment (Dermaide Aloe)<sup>7</sup> or topical antibiotic ointments may be applied. Cold extremity wounds are not considered tetanus prone.

The injured tissue should be loosely covered with sterile, dry, bulky, nonadherent dressing. If possible, elevate the extremity above the cardiac level to decrease dependent edema. Hands and feet may be splinted and elevated to reduce edema. Because the damaged tissue is tetanus prone, patients whose tetanus status has not been updated may require a tetanus booster (Td).

Adjunctive agents that have been used for their antithrombotic and vasodilative properties with varying success include heparin,<sup>1</sup> steroids,<sup>1</sup> NSAIDs,<sup>1</sup> dimethylsulfoxide (DMSO, Rimso-50),<sup>1</sup> nonionic detergents,<sup>1</sup> dipyridamole (Persantine),<sup>1</sup> calcium channel blockers,<sup>1</sup> thrombolytics, pentoxifylline (Trental),<sup>1</sup> and phenoxybenzamine (Dibenzylamine).<sup>1</sup> Iloprost (Ventavis)<sup>1</sup> is a prostacyclin analogue that is a potent vasodilator that can inhibit platelet aggregation. It may also have fibrinolytic activity. The intravenous dosing is 0.5 ng/kg/min, which can be increased by 0.5 ng/kg/min at 30-minute intervals to a maximum dose of 2 ng/kg/min for up to 8 days. Although not yet approved by the U.S. Food and Drug Administration (FDA), it has been suggested for severe frostbite within 72 hours of injury. Hyperbaric oxygen with thrombolytic therapy has been used to treat severe frostbite of the hand. Negative pressure wound therapy, following blister excision, has been demonstrated to be beneficial in

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

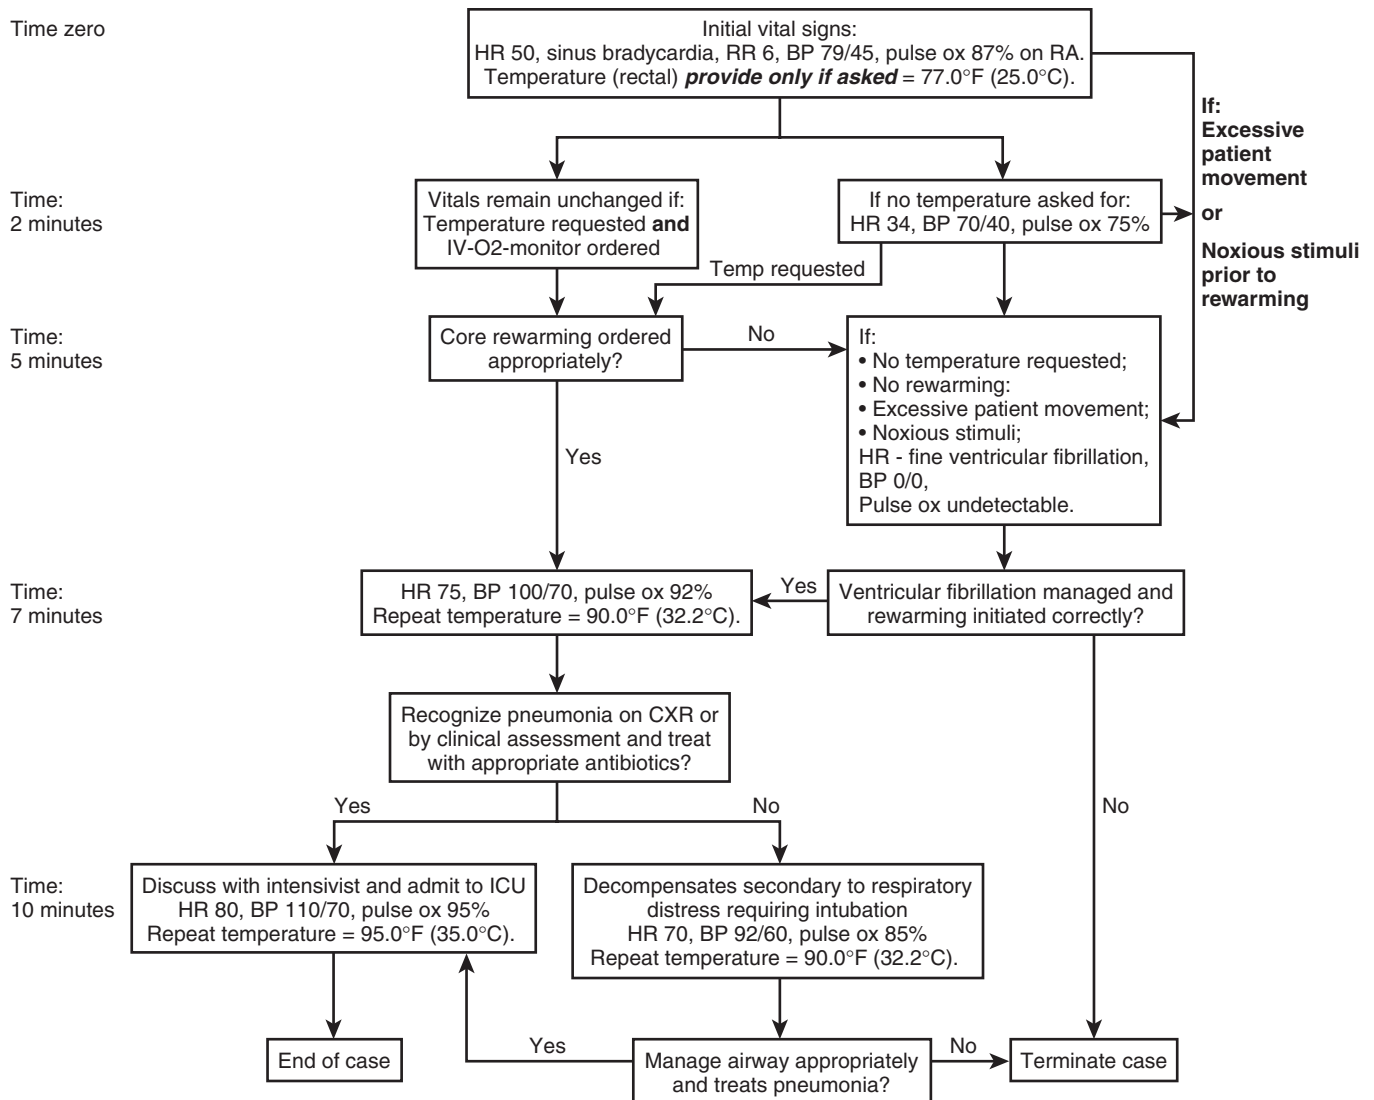

Figure 1 Hypothermia simulation flow diagram.

treating infant frostbite hand injuries. Following rewarming, intravenous tissue plasminogen activator (TPA, Activase)<sup>1</sup> with an initial 3-mg bolus followed by a 6- to 12-hour infusion of 1 mg/mL (10 mL/hour) heparin<sup>1</sup> at a dose of 500 units per hour administered concurrently has been utilized effectively with systemic anticoagulation and/or antiplatelet therapy to follow. Intra-arterial TPA (Activase)<sup>1</sup> has also been utilized. Surgical consultation is appropriate for guiding long-term management because some patients might need débridement of infections or skin grafts for nonhealing wounds. A sympathetic nerve block (sympathectomy) can relieve painful and refractory vasospasms.

A familial association of chilblain (associated with contractual arachnodactyly) has been described in Italy. Chilblain (pernio) may be treated with nifedipine<sup>1</sup> at an oral dose of 20 mg three times daily. Oral prednisolone (Millipred),<sup>1</sup> 0.5 mg/kg in two divided doses over 2 weeks, and topical glucocorticoids have been used to treat perniosis; pentoxifylline<sup>1</sup> (1200 mg/day in three divided doses for 2 weeks) has also been demonstrated to be effective. Acupuncture treatment (once weekly for 12 weeks) has been used to decrease cold sensitivity caused by second-degree frostbite in the fingertips.

### Sequelae

Late sequelae of frostbite include cold hypersensitivity, arthritis, numbness, chronic pain, ulceration, decreased sensation, and functional loss of the extremity. This is a result of early neuronal

damage and abnormal sympathetic tone. Patients with chronic symptoms should be advised to avoid nicotine and cold exposure while using NSAIDs. Tissue demarcation can occur 60 to 90 days after initial injury. Amputation decisions should be deferred unless there is supervening sepsis or gangrene. The ultimate tissue salvage after a spontaneous slough usually far exceeds the most optimistic initial estimates. A medical simulation flow diagram is presented in Figure 1.

## HEAT ILLNESS

Method of

Paul Cleland, MD

### CURRENT DIAGNOSIS

- Heat illness is a spectrum of disorders caused by environmental exposure to heat and is usually seen among athletes in hot and humid environments.
- Children, older adults, and poorly acclimatized individuals are at increased risk for developing exertional heat illness (EHI).
- Exercise-associated cramps are intense, prolonged, painful muscle spasms that occur during physical activity.
- Heat exhaustion is an elevation in core body temperature (<104°F) without central nervous system (CNS) dysfunction resulting in a collapse or difficulty continuing activity.
- Heat stroke is a life-threatening illness characterized by elevation in core body temperature (≥104°F) with CNS dysfunction (altered consciousness, seizure, coma) and usually end-organ damage.

### CURRENT THERAPY

- Acclimatization is key for prevention of EHI.
- Heat illness is most effectively managed by immediate recognition of the signs and symptoms and proper diagnosis.
- Core body temperature measurement *must* be done with a rectal thermometer
- Exercise-associated collapse
  - Continue walking after race to prevent development
  - Position the patient in the supine or Trendelenburg position, and start fluid administration
- Heat exhaustion
  - Provide rapid cooling with ice bags to areas adjacent to large vasculature (groin, neck, axilla).
  - Administer oral or intravenous (IV) fluid to correct for hydration deficit.
- Heat stroke
- Ensure the ability to maintain adequate circulation, airway, and breathing.
  - Ice-water immersion is the most effective way to provide rapid cooling.
  - The goal of cooling is to reduce and maintain a temperature below 101°F (38.3°C).
  - Transport to the hospital may be required if the patient's temperature is not reduced effectively or the patient does not return to normal mental status after 30 minutes of medical treatment.

Heat illness is a continuum of disease that can affect a wide array of individuals including athletes, firefighters, construction workers, soldiers, and others. Exertional heat illness (EHI) is a leading cause of death among young athletes and may be on the rise with possible climate change and increasing popularity of mass events such as marathons. Knowledge of the risk factors presented by the patient and the environment can provide clinicians with a better understanding toward prevention of heat illness. Early recognition and treatment of EHI can lead to significant reduction in the morbidity and mortality associated with this disease.

In the United States, most cases of EHI occur in summer months. Elevations in the ambient temperature and humidity as well as athletic deconditioning are predominant contributing factors. There is an increasing incidence of heat illness associated with decreased heat acclimation and an increase in the wet-bulb globe temperature (WBGT) index. The WBGT index is a tool used to assess the overall environmental conditions and can accurately predict the development of EHI in a particular setting to allow for modification of work or athletic events. High school and collegiate athletic programs that have protocols in place to stop practice, limit the duration of practice, or reduce the frequency of practice in high-heat situations have shown a decreased incidence of heat illness compared with those that do not.

It is important to understand the pathophysiology of heat regulation within the body to gain an accurate picture of heat illness. The human body has a great capacity to withstand drastic reductions in temperature to tolerate cold. However, only mild increases in core body temperature can result in severe consequences. Heat is generated by normal metabolic processes that occur continuously in our bodies and is also absorbed from the environment. Exercise generates additional heat from the skeletal muscles. When the hypothalamus detects a core body temperature increase, it sends signals to induce sweating and cutaneous vasodilation. Blood is then shunted to the skin and exercising skeletal muscle. Under normal conditions, the body is able to dissipate heat through evaporation, radiation, convection, and conduction. Evaporation is the primary means of heat dissipation and occurs as water is converted from its liquid form to its vapor form, but it becomes ineffective above a relative humidity of 75%. Radiation, convection, and conduction are also methods to dissipate heat but are decreasingly effective as the ambient temperature approaches the skin's temperature. When physiologic cooling mechanisms fail, heat is continually produced, and the core body temperature increases. As the temperature increases, cell damage occurs, and a systemic inflammatory response ensues, releasing cytokines throughout the body. Blood is shunted to the peripheral circulation, leading to organ hypoperfusion and ischemia. Organ failure and disseminated intravascular coagulation (DIC) eventually develop and result in death.

The injury caused by heat illness can be mitigated by acclimatization of the patient and is the most important factor to thrive in hot and humid conditions. Acclimatization occurs as the body is repeatedly exposed to certain levels of stress and then makes compensatory changes to allow for better performance the next time the body is under duress. This process occurs over 1 to 2 weeks of exposure to new conditions and appears to be lost with reexposure to the previous climate for about the same period. Several key changes occur as the body is exposed to heat, including production of heat shock proteins that give cells the ability to resist heat stress, decreased sweat temperature threshold, increased sweat production, decreased salt concentration in sweat, and increased skin blood flow. These factors all serve to aid the athlete under high-risk heat conditions to improve performance and alleviate potential heat illness. It is recommended that the athlete spend at least 2 weeks acclimatizing to the environment mimicking both temperature and humidity for maximal outcome. When athletes return to a more temperate environment after training, such as an air-conditioned room, they do not see the same benefit as they would with 24-hour exposure to the conditions. If

possible, air-conditioning should be restricted to nighttime only when the athlete is resting.

### Risk Factors

Although each person has unique genetic traits that determine how his or her body reacts to specific conditions, there are known congenital and acquired risk factors that may preclude an individual toward development of EHI. Exposure to a hot and humid environment may be the most obvious risk factor as ambient heat is transferred to the body and elevated humidity impairs the body's ability to dissipate heat. Poor conditioning, lack of acclimatization, obesity, and dehydration have been shown to increase the incidence of EHI. The use of prescription medications, supplements, and recreational drugs (Table 1) may cause disturbances in the capacity to dissipate or produce heat. Creatine supplementation does not appear to impair heat dissipation or cause a negative impact on hydration.

Children are at increased risk of developing heat illness for several physiologic reasons. A larger surface area-to-mass ratio allows for more heat absorption from the environment. Children also produce more heat compared with their adult counterparts because of higher basal metabolic rates. Fluid is conserved more efficiently in children than in adults, and consequently they have lower sweat rates as they depend more on non-evaporative forms of heat transfer for cooling. Children can make the same physiologic changes of acclimatization that adults can, though it appears to occur at a slower rate.

Environmental characteristics such as heat and humidity may play the largest role in development of heat illness. As mentioned earlier, the WBGT is a tool used to assess the overall environmental conditions and can accurately predict the development of EHI in a particular setting to allow for modification of work or athletic events. The WBGT is a measurement of temperature, relative humidity, and radiant heat from the sun and ground and is recommended over use of the heat index. A dangerous clinical situation is likely to develop when activities are performed with an elevated WBGT. It is recommended that endurance events be adjusted when the WBGT exceeds 82°F (28°C) and that only events that allow adequate rest and recovery are permitted to continue.

**TABLE 1** Substances That May Increase the Risk of Heat Illness

- Amphetamines
- Anticholinergic agents
- Antiepileptic agents
- Antihistamines
- Benzodiazepines
- Beta blockers
- Calcium channel blockers
- Cocaine
- Decongestants
- Diuretics
- Ergogenic stimulants
- Ethanol
- Laxatives
- Lithium
- Phenothiazines
- Tricyclic antidepressants

Data from Bouchama A, Knochel JP. Heat stroke, *N Engl J Med* 346(25):1978–1988, 2002; Wexler RK. Evaluation and treatment of heat-related illnesses, *Am Family Physician* 65(11):2307–2314, 2002.

### Heat Edema

Heat edema is caused by vasodilation of blood vessels resulting in swelling that is typically observed in the hands and feet. The core body temperature of the body is not elevated. Treatment begins with removal from the hot environment, elevation of the extremities, and possible use of compression with stockings or wrapping. Diuretics are not recommended.

### Heat Cramps

Also known as *exercise-associated cramps*, heat cramps present as intense pain, spasm, and prolonged muscle contraction as athletes undergo high-intensity activity. Although they are termed *heat cramps*, they are known to occur in cool settings as well, such as swimming and winter sports. The pathophysiology has not been entirely agreed upon but seems to stem from a neurogenic response to muscle fatigue in conjunction with fluid and electrolyte loss. To make the diagnosis, no signs of other illness may be present such as rhabdomyolysis, sickle cell disease or trait, or heat stroke, and it is important to take a thorough medical history to avoid pitfalls in the diagnosis.

Management consists of stretching and massaging the affected muscle and oral replacement of fluid and electrolytes. Intravenous (IV) fluids and benzodiazepines may be used for refractory cases. One study showed that ingestion of pickle juice at 1 mL/kg may cause a faster recovery from electrically induced muscle cramps when compared with deionized water. This would confirm the theory of a neurogenic-mediated process as the recovery occurred before the contents of the pickle juice reached the sites of action in the cramping skeletal muscle, with discontinuation of cramping seen at an average of 85 seconds compared with 134 seconds for deionized water.

### Exercise-Associated Collapse

Also termed *exercise-associated postural hypotension*, exercise-associated collapse (EAC) is an inability of the athlete to maintain a standing posture as a result of hypotension that develops commonly *after* an endurance event. Blood in circulation pools in the lower extremities as the athlete finishes the event and discontinues exercising. The skeletal muscles in the lower extremities normally exert a pressure on the corresponding vasculature, but as exercise ceases, the blood pools, causing an unexpected drop in cranial blood pressure, triggering collapse. Heat may play an indirect role in the development of EAC, but the terms *heat syncope* and *heat collapse* are incorrect because there is no elevation in the athlete's core body temperature. Athletes may develop dizziness, nausea, and vomiting as a result of the rapid decrease in blood pressure.

Athletes should be encouraged to continue activity such as walking or light activity at the end of events (rather than abrupt cessation or standing in place) to continue normal blood flow to avoid a sudden collapse, risking injury. If an athlete does collapse, treatment should begin with placing the patient in the supine or Trendelenburg position and keeping the legs and pelvis elevated. Administration of oral fluids containing glucose and electrolytes is helpful. IV fluid administration should be reserved for patients with hypotension (<110 systolic blood pressure) or an elevated pulse (>100 beats/min) who do not respond to oral fluid intake. Generally these athletes will respond favorably within 10 to 30 minutes and should be allowed to leave under their own power.

### Heat Exhaustion

Heat exhaustion occurs when the cardiovascular system is unable to provide adequate output to the body to continue to perform activity as a result of fatigue produced by exercise and environmental heat stress. This is clinically manifested most often by collapse or difficulty continuing activity that occurs *before* the event has finished. Core body temperature (rectal) is commonly elevated at 98.6°F to 104°F (37°C to 40°C). It may be accompanied by nausea, vomiting, diarrhea, headache, muscle cramping, tachycardia, hypotension, weakness, dehydration, and electrolyte depletion. Dehydration can be difficult to judge clinically as the only reliable assessment of dehydration is measurement of water loss that occurs through pre-weight and post-weight

measurements. A clear distinction between heat exhaustion and heat stroke is the development of central nervous system (CNS) dysfunction such as an altered level of consciousness, delirium, or seizure. Confusion may be present but should be mild and resolve quickly with treatment measures.

Athletes with heat exhaustion should be removed from the heat environment and placed in a cool, shaded, or air-conditioned environment. Vital signs including a rectal temperature should be measured to ensure that the proper diagnosis is made and to be able to monitor cooling status. Any excess clothing should be removed, and the patient should be placed in the supine or Trendelenburg position with the feet elevated. Cooling may be performed initially with placement of ice bags over the groin, axilla, and neck and water or ice-soaked towels over the head, trunk, and extremities. Immersion in an ice bath, tub of cold water, or simply running cold water from a hose over the athlete may be necessary, but these measures tend to be more for comfort as heat exhaustion is not life threatening. Oral administration of an electrolyte-containing solution is helpful to restore adequate hydration and assists in returning the cardiac output to normal. IV fluid administration is beneficial for patients who do not respond or are unable to take oral fluids. Patients who do not respond to these measures should be transported to a hospital to monitor for other developing conditions.

### Heat Stroke and Heat Injury

*Heat stroke* is defined as an elevated core body temperature above 104°F (40°C) with associated CNS dysfunction and end-organ damage. The CNS dysfunction can be observed in several ways including confusion, delirium, aggression or irritability, seizures, altered consciousness, and coma. Heat stroke can occur as classic heat stroke (non-exertional) or exertional heat stroke. Classic heat stroke usually afflicts the older adult population in the summer season and can be related to a lack of access to adequate air conditioning. Heat is continually absorbed from the environment and may be poorly dissipated secondary to other medical conditions and medications that preclude cooling. Exertional heat stroke is seen in a younger and more athletic population and does not necessarily occur in hot and humid environments. Other signs and symptoms are similar to those seen in heat exhaustion, but vital sign abnormalities are more likely to be present. The presence or absence of sweating does not make a diagnosis of heat stroke. Examining a collapsed individual can be difficult, and the differential diagnosis can extend beyond heat exhaustion and heat stroke to include cardiac arrhythmia and exercise-associated hyponatremia. It is important to maintain a degree of suspicion for those athletes who present with collapse but do not have an elevated core body temperature.

The term *heat injury* is not currently recognized by the World Health Organization as a diagnosis but was created by U.S. military physicians to further categorize patients suffering from heat illness. Heat injury is diagnosed as an elevation in core body temperature above 104°F (40°C) with associated end-organ damage, but it lacks the CNS dysfunction seen in heat stroke. Organs most commonly affected with heat stroke or heat injury include the liver, kidneys, and skeletal muscle (rhabdomyolysis).

Patients who present with heat stroke should be assessed beginning with basic life support measures. It is important to secure the airway and ensure that adequate circulation and breathing are maintained. An initial set of vital signs including a rectal temperature should be performed and repeated throughout the course of treatment. If a rectal thermometer is not available, avoid using other methods to determine temperature as they are not accurate to measure core body temperature in athletes who have been exercising. If available, rapid assessment of serum electrolytes including sodium and glucose should be performed, especially with longer-endurance events such as marathons. Rapid cooling should commence as soon as possible after the diagnosis is made because the prognosis worsens the longer the core body temperature is elevated. The most effective cooling measure is cold-water immersion (CWI) with a target water temperature of 35°F to 50°F. Expected cooling rates are about 1°F per 3 minutes or 1°C

per 5 minutes of immersion. Measurement with a rectal thermistor allows for continuous monitoring; if this is not available, measurement by a rectal thermometer should be done approximately once every 10 minutes. Cooling should continue until the core body temperature reaches 101°F (38.3°C). If no rectal thermometer is available, cooling should continue until the athlete begins to shiver, or about 15 to 20 minutes. Tarp-assisted cooling oscillation (TACO) is an alternative technique to CWI wherein the athlete is placed on a tarp with at least two individuals holding the edges of the tarp while ice and water are added on top of the patient. If other interventions must be performed (intubation, administration of IV medications or fluid) and CWI or TACO are not available, ice bags should be placed at the groin, axilla, and neck, and ice- or water-soaked towels should be placed over the rest of the body, or a hose can be used to douse the rest of the body. Fluid resuscitation should be performed, but careful attention should be paid to fluid overload as pulmonary edema can develop with rapid administration of IV fluids. These patients are still at risk for organ damage despite a rapid reduction in core body temperature; therefore it is usually necessary to transport them to the hospital, where appropriate monitoring and laboratory evaluation can be performed. Transport to the hospital is always required in patients who do not regain consciousness within 30 minutes of appropriate cooling and medical intervention or if appropriate response to cooling is not achieved.

### Return to Play

The prognosis for returning to physical activity after an episode of EHI is dependent on the individual and the severity of the illness incurred. Athletes who develop heat cramps or EAC should be allowed to return to activity as soon as they feel capable. Decisions about returning those who develop heat exhaustion or heat stroke are more complicated. These athletes should avoid physical activity for at least 7 days. All laboratory abnormalities should be corrected, and the athlete should feel physically and psychologically capable of returning. Once these conditions are met, a gradual progression of activity can begin in a cool or temperate environment. Acclimatization occurs over a period of approximately 2 weeks as activity is increased in duration and intensity and the individual is gradually reexposed to heat. Once the athlete is able to perform full-intensity workouts for 2 to 4 weeks in the heat, he or she may return to competition. For patients who fail to acclimatize at 4 weeks or who have had multiple episodes of EHI, an exercise heat tolerance test should be performed.

## HIGH ALTITUDE ILLNESS

Method of

Adrienne N. Kovalsky, DO, MPH; and Ryan M. Commins, MD

### CURRENT DIAGNOSIS

#### Acclimatization

- Symptoms include exertional dyspnea, increased respiratory rate, polyuria, peripheral edema, and insomnia.

#### High Altitude Headache (HAH)

- New-onset headache that fulfills at least two of the following:
  - Develops in temporal relation to altitude gain above 2500 m (8000 ft)
  - Worsens in conjunction with continued ascent and/or resolves within 24 hours of descent below 2500 m (8000 ft)
  - Includes at least two of the following characteristics: bilateral; mild or moderate intensity; aggravated by exertion, movement, straining, coughing, and/or bending

#### Acute Mountain Sickness (AMS)

- New-onset headache occurs within 12 hours of altitude gain above 2500 m (8000 ft), and
- Anorexia, nausea, vomiting, fatigue, weakness, dizziness, or lightheadedness (see Box 3).

#### High Altitude Cerebral Edema (HACE)

- Mental status changes or ataxia with preexisting AMS, or
- Mental status changes and ataxia without a prodrome of AMS

#### High Altitude Pulmonary Edema (HAPE)

- Relative hypoxemia in the setting of at least two signs or symptoms from each of the following lists:
  - Resting dyspnea, cough, weakness, decreased exercise performance, and chest tightness or congestion
  - Wheezing, rales, tachypnea, tachycardia, or central cyanosis

### CURRENT THERAPY

#### Insomnia or Sleep Disturbance

- Acetazolamide (Diamox)<sup>1</sup> 125 mg PO at bedtime is recommended.
- Consider diphenhydramine (Benadryl) 50 mg at bedtime, zolpidem (Ambien) 5–10 mg at bedtime, or temazepam (Restoril) 15 mg at bedtime for patients with no history of altitude illness.

#### High Altitude Headache

- Medications for headache include ibuprofen (Advil) 600–800 mg PO every 8 hours, acetaminophen (Tylenol) 650–1000 mg PO every 6 hours, enteric-coated aspirin (Ecotrin) 325–650 mg PO every 4 hours, oxygen by nasal cannula at 1–2 L/min, or acetazolamide<sup>1</sup> 125 mg PO twice daily.

#### Acute Mountain Sickness, Mild

- Avoid respiratory depressants, strenuous activity, or further ascent until the patient is asymptomatic.
- Acetazolamide 125–250 mg PO twice daily may be tried.
- Symptomatic treatment as for headache and nausea.

#### Acute Mountain Sickness, Moderate to Severe

- Stop ascent and rest until asymptomatic AND:

- Administer acetazolamide 250 mg PO twice daily.
- Oxygen (1–2 L) or hyperbaric chamber 2–4 psi may be used if available.
- Consider dexamethasone (Decadron)<sup>1</sup> 4 mg PO or IM every 6 hours as an adjunct or if acetazolamide is contraindicated.
- Monitor for mental status changes, confusion, or ataxia and descend immediately at onset.
- If symptoms are severe, or if there is no response to 24 hours of therapy, immediate descent of at least 500 m or to last asymptomatic altitude is the definitive treatment.

#### High Altitude Cerebral Edema

- Prepare for evacuation or emergent descent of at least 1000 m (3,280 ft).
- Administer dexamethasone<sup>1</sup> 8 mg PO, IM, or IV once followed by 4 mg every 6 hours.
- Consider adding acetazolamide<sup>1</sup> 250 mg PO twice daily as an adjunct.
- Early recognition and treatment are essential.

#### High Altitude Pulmonary Edema

- Bed rest with oxygen 4–6 L by nasal cannula.
- If the patient is not improving or if HAPE is severe, descend at least 500 m, avoiding exertion.
- Use a hyperbaric chamber at 2–4 psi if oxygen is unavailable or the patient is unable to descend.
- If oxygen is unavailable or the patient is unable to descend, or if the patient is not responding to either:
  - Give nifedipine (Procardia)<sup>1</sup> 10 mg PO once and 30 mg extended-release PO every 12 to 24 hours<sup>3</sup> (contraindicated in HACE).
  - Consider adding tadalafil (Cialis)<sup>1</sup> 10 mg PO twice daily<sup>3</sup>, sildenafil (Viagra)<sup>1</sup> 50 mg PO thrice daily<sup>3</sup>, or salmeterol (Serevent)<sup>1</sup> 125 µg inhaled twice daily<sup>3</sup>.
  - It is not advisable to use both nifedipine and a phosphodiesterase inhibitor; if this becomes necessary, carefully monitor blood pressure and stagger doses to prevent potential cerebral hypoperfusion.

#### Concurrent High Altitude Pulmonary and Cerebral Edema

- As always, immediate descent and supplemental oxygen therapy are critical.
- Treatment as for HAPE with the addition of dexamethasone.<sup>1</sup>

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

The appeal of travel to high altitude is vast. For many it is tourism, skiing, or mountaineering, but for others it is far more fundamental, as many travel to high altitudes for work. The number of people residing at elevations higher than 1500 m has risen significantly in the last two decades, and is approximately 440 million worldwide. While elevation greater than 1500 m (5000 ft) is generally considered high altitude (Denver, for example, is 1609 m or 5,278 ft), most high altitude illness occurs above 2500 m or 8000 ft. It is at these altitudes that the effects of hypoxia and decreasing barometric pressure start to be seen. Elevation greater than 5500 m (18,000 ft) is considered extreme altitude. Many persons become symptomatic during the adaptive process known as acclimatization, and some develop acute high altitude syndromes, including acute mountain sickness (AMS), high altitude cerebral edema (HACE), and high altitude pulmonary edema (HAPE). These syndromes are often preventable, but they have the potential to cause significant morbidity and mortality for the patient and for those involved in risky rescue efforts by land or air.

#### Epidemiology and Risk Factors

The incidence of altitude illnesses is highly variable and commonly idiosyncratic. At 3000 m (~10,000 ft) the incidence of AMS ranges from 4% to 58%, whereas the incidence of HAPE

and HACE generally is less than 1%. The occurrence of altitude illness depends on the rate of ascent, altitude of residence, exertion, prior history of altitude illness, and individual susceptibility. For each 1000 m (3,280 ft) above 2500 m (8,000 ft) the rate of AMS increases 13%. The most predictive risk factor for AMS is previous AMS, and the risk of recurrence in similar elevations is as high as 60%. Physical fitness does not alter susceptibility, whereas obesity is a risk factor. Tobacco smoking, asthma, and diabetes do not confer any additional risk. Certain medical conditions including chronic obstructive pulmonary disease, pulmonary hypertension, congestive heart failure, coronary artery disease, sickle cell disease, and sleep apnea increase risk of developing altitude illness. Stable and well-controlled conditions such as hypertension and diabetes do not appear to increase the risk for altitude illness. A more detailed discussion of some of these diseases is included later in the text.

#### Physiologic Adaptation and Pathophysiology

Hypoxia inducible factors (HIFs) are a family of transcription regulators that respond to level of oxygenation and ultimately control the physiologic response to hypoxia. In hypoxic conditions, they are able to increase transcription of hypoxia-responsive genes. The HIFs have a wide range of effects including increasing glycolysis and angiogenesis, stimulating erythropoiesis, regulating endothelial nitric oxide synthase, and controlling ventilation.

The physiologic response to altitude rests along one end of a spectrum of compensatory mechanisms that can evolve into high altitude syndromes. The pathophysiology of AMS and HACE is incompletely understood, but hypoxemia and changes in the brain itself have been implicated. Hypoxemia is thought to increase cerebral blood flow though it is unclear whether there is a true difference in cerebral blood flow in patients with and without AMS. Hypoxemia may also increase vascular permeability through various mechanisms. Changes that occur in the brain include edema, increased ICP, vascular distention due to increased intravascular pressure, and release of nociceptive chemicals or substances. The development of HAPE is usually preceded by an excessive rise in the pulmonary artery pressure in response to hypoxic vasoconstriction. However, other factors including alveolar inflammation, impaired sodium and water reabsorption by the alveolar epithelium and uneven hypoxic vasoconstriction may also play a role.

In the first few hours at high altitude, peripheral chemoreceptors are activated by hypoxia, leading to an increased respiratory rate. The increased minute ventilation reduces the dilutional effects of CO<sub>2</sub> in the alveolar air and causes a respiratory alkalosis. This subsequent alkalosis also improves oxygen binding in the lung but ultimately slows respiration. After 24 to 48 hours the kidneys excrete excess bicarbonate, normalizing the elevated pH that would otherwise prevent an adequate increase in respiration. This is the basis for acclimatization.

Periodic breathing is also more likely to occur at higher elevations owing to hypoxia and the resulting respiratory alkalosis. Altitude-dependent diuresis causes transient hemoconcentration in the first 1 to 2 days, with true erythropoiesis starting at 4 to 5 days. Long-term residence at altitude can cause polycythemia, increasing the risk for tissue infarction. With permanent residence at high altitude there is evidence that cognitive development may be slowed in children and that neuropsychological function is impaired in adults. Permanent residents will see improved maximal oxygen consumption at lower elevations. The most complex effects of hypobaric hypoxia are seen in the lung and the brain and are not completely understood.

#### Prevention

High altitude illness is a morbid and potentially fatal disease, and preventive measures should be employed. The most reliable way to prevent altitude illness is through graded ascent, thereby allowing sufficient time for acclimatization. A conservative guideline for activities above 2500 m (8,000 ft) is increasing sleep altitude by no more than 300 m (1000 ft) in a 24-hour period and

**BOX 1** Prevention of High Altitude Sickness

Ascent above 2500m (8,000ft) should be at a gradual rate of 300m per 24 hours, with an additional rest day for every 1000m (3,280ft) gain

With rapid ascent above 2500m (8,000ft), light activity may be helpful with acclimatization, but strenuous activity should be avoided for at least 48 hours.

Avoid respiratory depressants such as alcohol until acclimatized.

Five days of comparable altitude exposure should be undertaken within 2 months of ascent.

For AMS or HACE, begin prophylaxis 1 or 2 days before starting ascent:

- Acetazolamide 125 mg PO bid
- Dexamethasone<sup>1</sup> 2 mg q6 or 4 mg q12h for patients with sulfa allergy
- Prophylaxis is strongly recommended for patients with a history of AMS or HACE or for rapid ascent.

For persons with a history of HAPE, begin prophylaxis 1 day before starting ascent:

- Nifedipine<sup>1</sup> 30 mg BID<sup>3</sup>
- Salmeterol<sup>1</sup> (adjunct) 125 µg inhaled bid<sup>3</sup>
- Dexamethasone<sup>1</sup> 8 mg PO bid
- Tadalafil (Cialis)<sup>1</sup> 10 mg PO bid<sup>3</sup>
- Sildenafil (Viagra)<sup>1</sup> 50 mg PO tid<sup>3</sup>

Stop ascent with onset of even mild AMS to prevent evolution to HACE.

*Abbreviations:* AMS = acute mountain sickness; HACE = high altitude cerebral edema; HAPE = high altitude pulmonary edema.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

with an additional rest day every 1000m (3,280ft). If symptoms of AMS are noted, no further ascent should be attempted until they resolve in order to prevent more severe illness or evolution of HACE or HAPE. Additional preventive measures should be taken and are of particular importance for persons planning rapid ascent, whether on foot or flying directly into altitudes of 2500m (8,000ft) or greater. Light activity can accelerate acclimatization, but strenuous exertion should be avoided in the first 2 days. Pre-exposure of 5 days of comparable altitude within 2 months of ascent is protective. CNS depressants such as alcohol are thought to worsen effects of altitude, particularly overnight when respiration is already more depressed, and they should be avoided. Abrupt cessation of caffeine intake in chronic users may provoke withdrawal symptoms that can mimic AMS. If available, residing and working in an oxygen-enriched environment may also help reduce the incidence of AMS. Refer to [Box 1](#) for a summary.

Medical prophylaxis should be considered when graded ascent is not possible, whether on foot or flying directly into altitudes of 2500m (8,000ft) or greater, and for persons with any history of prior altitude illness returning to the same elevation. Prophylaxis is also advised for ascent profiles that are considered moderate to high risk in patients with unknown susceptibility, including planned ascent to more than 3000m (10,000ft) in one day, rapid ascent greater than 500m (1,640ft) per day above 3000m (10,000ft), or very rapid ascent to a final altitude greater than 4000m (13,000ft). This should be started the day prior to beginning ascent and continue until at a stable altitude for at least 2 to 4 days. If further ascent is undertaken, or if symptoms recur, prophylaxis can be restarted at any point.

The most effective medication for prophylaxis of AMS and HACE is acetazolamide (Diamox) 125 mg PO twice daily starting 1–2 days before ascent. This is a central-acting respiratory stimulant that causes a metabolic acidosis and ultimately facilitates acclimatization. Patients should be warned about side effects

**BOX 2** Medications for AMS, HACE, and HAPE**Acetazolamide**

Acetazolamide (Diamox) is a central-acting respiratory stimulant that causes a metabolic acidosis and ultimately facilitates acclimatization. It is effective in preventing and treating AMS and HACE.<sup>1</sup> Patients should be warned about side effects, including paresthesias, flat taste of carbonated beverages, and polyuria, particularly at night. Persons with a history of asthma, sulfonamide allergy, anaphylaxis, or penicillin allergy should try this medication under the supervision of a medical professional prior to departure. It should not be used in type 1 diabetics due to the risk for ketoacidosis. It also should not be used in chronic lung disease if FEV<sub>1</sub> is less than 25% predicted, in patients on potassium-wasting diuretics, or on long-term high doses of aspirin.

**Dexamethasone**

Dexamethasone (Decadron)<sup>1</sup> is also effective in the prevention and treatment of AMS and HACE, though its mechanism is not completely understood. Unlike with acetazolamide, symptoms can recur after stopping treatment, and it does not facilitate acclimatization. It is not recommended for prophylaxis of AMS unless acetazolamide is contraindicated, though it is the drug of choice for treatment of HACE. Use is cautioned in diabetics due to hyperglycemia and in patients at risk for amebiasis or strongyloides.

**Nifedipine**

Nifedipine (Procardia)<sup>1</sup> is a calcium channel blocker that inhibits its pulmonary vasoconstriction secondary to hypoxia at high altitude and is used in treatment and prevention of HAPE. Caution should be used with other antihypertensives due to risk for hypotension. Medications that inhibit the cytochrome P450 3A4 pathway, including macrolides, doxycycline, and azoles, may increase plasma concentrations and also precipitate hypotension. Ginkgo biloba<sup>7</sup> may also increase levels of nifedipine and cause hypotension and should be avoided.

**Tadalafil (Cialis) and sildenafil (Viagra)**

These are phosphodiesterase inhibitors<sup>1</sup> that cause pulmonary vasodilation and are used in preventing HAPE. They should not be used in conjunction with nitrates due to risk for significant hypotension, nor with alpha-blockers due to orthostatic hypotension. Medications that inhibit the cytochrome P450 3A4 pathway, including macrolides, doxycycline, and azoles, may increase plasma concentrations and also precipitate hypotension.

*Abbreviations:* AMS = acute mountain sickness; HACE = high altitude cerebral edema; HAPE = high altitude pulmonary edema

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

and possible allergy ([Box 2](#)). Dexamethasone (Decadron)<sup>1</sup> 2 mg every 6 hours or 4 mg every 12 hours also is effective, though its mechanism is not completely understood. Unlike with acetazolamide, symptoms can recur after stopping dexamethasone, and it does not facilitate acclimatization. It is not recommended for prophylaxis unless acetazolamide is contraindicated, and it is best saved for treatment of severe AMS or HACE. Ginkgo biloba<sup>7</sup> is no better than placebo at preventing AMS. Ibuprofen (Advil)<sup>1</sup> has not been shown to prevent AMS but does prevent high altitude headache.

Prophylaxis of HAPE has been studied in preventing recurrence in persons with a history of HAPE, though it also would be prudent to consider prophylaxis for anyone undertaking very rapid ascent. Numerous agents have been evaluated in patients with

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

history of HAPE and are listed in [Box 1](#). Nifedipine (Procardia)<sup>1</sup> is the preferred medication for prevention, with salmeterol (Serevent)<sup>1</sup> as a potential adjunct if there is significant history of HAPE and anticipated rapid ascent profile.

### Symptomatic Acclimatization and Disrupted Sleep

Many people experience symptoms of normal adaptation that do not always herald illness, but they should nonetheless always be completely evaluated. Expected symptoms include exertional dyspnea, polyuria, peripheral and facial edema, and nocturnal awakenings and insomnia. The most common side effects of normal acclimatization are disrupted sleep and mild peripheral edema. Acetazolamide<sup>1</sup> 125 mg at bedtime has been shown to decrease nocturnal oxygen saturation and lessen awakenings (see [Box 2](#)). Diphenhydramine (Benadryl)<sup>1</sup> 25 to 50 mg may also be used, but it does not have the same benefits. Studies have shown that zolpidem (Ambien)<sup>1</sup> 10 mg and temazepam (Restoril)<sup>1</sup> 15 mg are probably safe, but because studies have been small and targeted, these medications probably should be avoided whenever possible, particularly in persons with a history of altitude illness.

### High Altitude Headache

Headache is a common occurrence and does not always evolve into AMS. The headache is generally bilateral, and throbbing is exacerbated with coughing, bending, straining, and exertion, and is often worst early in the morning. There should be no other associated symptoms. Onset can occur within 1 hour but usually begins within 6 to 10 hours. Numerous medications are effective for treatment, including analgesics and medications used in prophylaxis of AMS. See the Current Therapy box for a complete listing.

### High Altitude Syndromes

#### Acute Mountain Sickness

In the setting of a recent gain in altitude, AMS is defined as headache with at least one of the following: anorexia, nausea, or vomiting; fatigue or weakness; or dizziness or lightheadedness. Clinically, a lack of headache with otherwise suggestive symptoms should not rule out AMS. As with high altitude headache, onset can occur within 1 hour but usually begins within 6 to 10 hours. Other symptoms can include decreased urine output, lassitude, and ataxia. All symptoms typically resolve within 2 to 3 days, though on occasion at higher altitudes symptoms can persist for days or weeks without progression or resolution. Examination is normal and no diagnostic studies are indicated. The differential includes dehydration, exhaustion, hangover, viral illness, carbon monoxide poisoning, caffeine withdrawal, migraine, and meningitis. Early recognition of AMS is essential in order to begin appropriate measures that might help prevent evolution to the potentially fatal HACE, which exists along the same spectrum.

If mild, AMS can be monitored at a stable altitude with no further ascent undertaken. Analgesics and antiemetics are effective for managing symptoms. Acetazolamide may be considered for mild AMS and is recommended for moderate to severe symptoms. Dexamethasone<sup>1</sup> may be added, or used in substitution if intolerant of or allergic to acetazolamide, for a short course (less than 5 days) while acclimatizing. Low-flow supplemental oxygen and hyperbaric chambers can be used as an adjunct for moderate to severe symptoms. Descent is advised for symptoms that progress after 24 hours of rest or treatment or for symptoms that are severe or stable but prolonged in order to prevent evolution to HACE, but graded ascent can be resumed once symptoms resolve. Immediate descent should be undertaken for ataxia, altered mental status, or any signs or symptoms of pulmonary edema. Refer to the Current Therapy box for dosing and summary.

### High Altitude Cerebral Edema

In the setting of a recent gain in altitude, HACE is defined as a change in mental status and/or ataxia in a person with AMS, or both mental status changes and ataxia in a person without AMS. There may be changes in mood or hallucinations. It generally progresses over 1 to 3 days, but it can also cause loss of consciousness within 12 hours. Examination has nonfocal neurologic findings with confusion. Papilledema may be seen, and rales are often present from concurrent HAPE. If computed tomography (CT) or magnetic resonance imaging (MRI) is available acutely, findings would be consistent with vasogenic edema. If a lumbar puncture is performed, increased opening pressure is usually present.

Differential diagnosis is similar to that for AMS but should be expanded to include diabetic ketoacidosis, hypoglycemia, electrolyte imbalances, brain tumor, stroke, acute psychosis, and seizure. After a long term at altitude or any length of time at very high altitudes blood can become hyperviscous and increasingly thrombogenic, so in these circumstances stroke should rise on the differential.

Early recognition is crucial in management of HACE to prevent evolution to irreversible disease. The most important element of treatment is descent of at least 1000 m (3,280 ft). Supplemental oxygen and hyperbaric bags may be used during descent and are imperative if descent is not possible. Dexamethasone<sup>1</sup> should be initiated, and should be continued after descent if symptoms persist. Acetazolamide<sup>1</sup> may be added. Dosages are listed in the Current Therapy box.

### High Altitude Pulmonary Edema

In the setting of a recent gain in altitude, HAPE is diagnosed with at least two of resting dyspnea, cough, weakness or decreased exercise performance, and chest tightness or congestion and two of wheezing or rales, tachypnea, tachycardia, or central cyanosis. There may also be an associated low-grade temperature elevation. Cough is initially dry but in late stages is productive of pink or bloody sputum. Onset often occurs during sleep, usually the second night at altitude, and often after the use of sleep aids that cause respiratory depression. It rarely occurs after 4 or 5 days at a stable altitude and should resolve within 48 hours of descent.

Examination is significant for rales that can begin in the right axilla and progress diffusely and for low-grade temperature elevation. Hypoxia, often very pronounced, is noted on pulse oximetry; oxygen levels will be disproportionately low for a given elevation. If available, chest radiography typically demonstrates bilaterally diffuse patchy opacities without pulmonary vascular changes, though initially they may be seen in the right middle lobe. Computed tomography of the chest typically shows a patchy peripheral and nodular distribution of edema. Ultrasound may be more readily available than radiography in remote locations and through the use of the comet-tail technique may be helpful in identifying HAPE and differentiating from pneumonia or other conditions.

HAPE can occur in conjunction with severe AMS or HACE. Differential includes heart failure, acute myocardial ischemia, pulmonary embolus, asthma, bronchitis, and pneumonia. Among the altitude illnesses, HAPE is associated with the highest rate of mortality but, unlike HACE, it is unlikely to cause long-term sequelae if treated appropriately. As with all altitude illness, removing the hypoxic stimulus is the central principle in management, and with HAPE it is also the most effective. This can be done with descent, supplemental oxygen, or a hyperbaric chamber. If available, supplemental oxygen and bed rest may be sufficient. If the pulmonary edema is severe, descent is the definitive treatment and should be undertaken without delay. Exertion and cold stress should be avoided during descent. Nifedipine (Adalat, Procardia)<sup>1</sup> and salmeterol (Serevent)<sup>1</sup> may be of benefit in treatment of HAPE, but they are not as effective as oxygen or descent and should be used as an adjunct or if no other alternatives exist.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

Dual vasodilating agent use (nifedipine<sup>1</sup> and a phosphodiesterase inhibitor<sup>1</sup>) is not recommended, but if attempted when no alternatives exist, doses should be staggered and blood pressure carefully monitored to prevent potentially disastrous hypotension and cerebral hypoperfusion. Refer to the Current Therapy box for dosing. Reascent may be considered 2 to 3 days after resolution, but risk of recurrence is significantly higher.

## Other High Altitude Disorders

### Upper Respiratory Disorders

Rhinorrhea, chronic cough, and noninfectious pharyngitis and bronchitis are commonly seen at high altitude and very prevalent at extreme altitude. Sputum is often purulent. Onset of high altitude bronchitis and chronic cough is generally after strenuous activity, and use of a balaclava to increase humidification of inhaled air may help prevent this. Symptoms may become severe enough to cause rib fracture. Comprehensive studies on the most effective treatment are lacking, but symptomatic therapies may be helpful, including decongestant nasal sprays, inhaled corticosteroids and beta agonists, and codeine-based cough medications; the latter should never be used in the pediatric population or in combination with other opiate medications or benzodiazepines. Infectious upper respiratory syndromes should remain in the differential; however, viral etiologies are most common with judicious consideration of antibiotic therapy.

### High Altitude Retinopathy (HAR)

Hypoxia is known to cause hyperemia and engorgement of the retinal vessels at any elevation, and will be seen above 2500 meters (8,000 ft) in the setting of hypobaric hypoxia. Evolution to retinal hemorrhage indicates the presence of high altitude retinopathy (HAR) and may occur above 4000 meters (13,000 ft). Macular or vitreous hemorrhage, disc edema, and cotton wool spots can be seen in more severe HAR. There may be a delay between ascent and onset of hemorrhage. The retinopathy is generally asymptomatic; however, scotomas and visual field deficits may occur, particularly with macular hemorrhage.

Lower oxygen saturation, higher ascent, strenuous exertion, and longer duration at high altitude are associated with HAR. Higher baseline intraocular pressure, hypercoagulable disorders, and aspirin and NSAID use also appear to be risk factors. Slower ascent and improved acclimatization are protective. Acetazolamide does not appear to affect incidence. Recent research has not shown a definitive correlation between HAR and AMS or HACE.

Most HAR will resolve within days to weeks of descent. Rarely visual deficits have persisted longer. Descent is recommended for any premacular hemorrhage due to higher risk to central vision and unclear long-term prognosis, as well as any new visual deficits. Given the potential risk of worsening retinopathy, diabetics and other patients with risk for or preexisting retinopathy should avoid travel to elevations greater than 4000 meters (13,000 ft), and consult with their ophthalmologist if such travel is unavoidable or if any travel is intended above 2500 meters (8,000 ft).

### Chronic High Altitude Diseases

Residence above 2500 meters (8,000 ft) in the United States is rising, and numbers in the hundreds of millions worldwide. Prevalence is dependent on many factors, most notably residence altitude and ethnicity. Ethnic groups with longer history of high altitude residence, such as Tibetans, have improved adaptation and lower prevalence compared to other ethnic groups at the same elevation. Prevalence increases with increasing altitude, even among more adapted ethnic groups.

*Chronic Mountain Sickness (CMS)*. Symptoms include headache, dizziness, dyspnea, palpitations, insomnia, fatigue, arthralgias, myalgias, distal peripheral paresthesias, anorexia, and cognitive dysfunction. Diagnosis is made by excessive erythrocytosis (hemoglobin greater than 19 g/dL in women or 21 g/dL in men) in the setting of severe hypoxemia (there is not yet consensus on threshold value, but less than <85% is highly suggestive),

normal pulmonary function tests, and chronic residence above 2500 meters (8,000 ft). Pulmonary hypertension and heart failure may also be present. Patients with a history of antecedent chronic pulmonary disease such as COPD or other medical condition that may account for hypoxia are excluded from this diagnosis, as the presentation cannot be fully attributed to altitude, though consideration for a diagnosis of secondary CMS may be made. Phlebotomy, optimally with isovolemic hemodilution, provides temporary benefit and may result in more significant recurrence and is not recommended as a long-term solution. Consideration may be made for severe symptoms or as a short-term bridge to permanent resettlement at lower elevation. Supplemental oxygen, slow breathing technique, a supervised mild to moderate exercise regimen, and intermittent pulses of acetazolamide<sup>1</sup> 250 mg per day for three weeks have all been found to help. Other medications are still being studied. Strenuous activity should be avoided. Definitive therapy is migration to lower elevations, upon which CMS will slowly resolve, but will reappear upon return to high altitude. Periodic travel to lower altitude is recommended if permanent migration is not possible.

*High Altitude Pulmonary Hypertension (HAPH)*. Symptoms include cough, dyspnea, cyanosis, and insomnia, and may include physical findings of right heart failure. Diagnosis is made by a mean pulmonary artery pressure greater than 30 mmHg or systolic pulmonary artery pressure greater than 50 mmHg measured at altitude of residence with moderate hypoxemia, absence of excessive erythrocytosis, and chronic residence above 2500 meters (8,000 ft) after the exclusion of chronic lung disease and other causes of pulmonary hypertension. Screening diagnosis should be made by echocardiography and confirmed via invasive measurement. As with CMS, definitive therapy is migration to low altitude. If this is not feasible, calcium channel blockers and phosphodiesterase inhibitors may be of benefit. Early referral to a pulmonary hypertension specialist is recommended.

### Additional Considerations

Traveling to high altitude with children, during pregnancy or in the setting of chronic medical conditions includes additional considerations, some of which are summarized below. Patients should include consultation with the patient's pediatrician, obstetrician, or specialist prior to travel. Complete medication list, including as-needed prescriptions for travel, such as antibiotics, should be carefully reviewed for interactions, contraindications, and dose adjustments prior to prescribing medications for prevention or treatment of altitude illness. Refer to [Box 2](#) for a limited summary.

### Children

Susceptibility of the pediatric population to altitude illness is comparable to that of the adult population. Travel to high altitude should not be undertaken in first 4 to 6 weeks or in prematurity. It should also be avoided in any children with history of cardiopulmonary conditions, Down syndrome, at increased risk for pulmonary hypertension, or a recent upper respiratory illness. Presentation will generally mimic that in adults; however, assessment of nonverbal children is more complicated with criteria including fussiness, decreased playfulness, decreased appetite, and sleep disturbance. Physical findings are similar to the adult population and may also include agitation, productive cough, cyanosis, and tachycardia. Management and prevention are comparable with the following dosage adjustments: acetazolamide\* 2.5 mg/kg every 12 hours can be used for prevention and treatment of both AMS and HACE<sup>1</sup>. Dexamethasone<sup>1</sup> 0.15 mg/kg every 6 hours should be used for treatment of severe AMS and HACE, in conjunction with descent. Medications to prevent and treat HAPE have not been adequately studied in the pediatric population.

<sup>1</sup>Not FDA approved for this indication.

\*Acetazolamide is approved for use in children aged 12 years and older only.

## Pregnant Women

Women who travel to high altitude during pregnancy are at higher risk for preterm labor, but the rate of complications does not appear to be significantly changed in the setting of uncomplicated low-risk pregnancy, and travel to 2500 meters (8,000 ft) is likely safe. While exercise during pregnancy is associated with better outcome, it should be minimized the first few days at high altitude while acclimatizing, and strenuous exertion should be avoided. Most medications used for the treatment of high altitude illness are rated category C for pregnancy, and priority should be made for descent rather than medical management of altitude illness. Travel to high altitude should be avoided in any pregnancy that is complicated or not low risk. Residence at high altitude during pregnancy is associated with a decrease in birth rate in proportion to the increase in altitude, as well as increased complications, although highland ancestry is protective.

## Hypertension

Blood pressure response to high altitude is variable. Adequately controlled hypertension should not confer any additional risk for altitude illness. Any patient requiring more than one medication or maximum dose of one medication should travel with a blood pressure cuff and monitor their blood pressure. These patients should also develop an algorithm with their physician for how to manage elevated blood pressure and when to decrease or hold doses.

## Coronary Artery Disease (CAD)

All patients with known history or antecedent symptoms should undergo risk stratification, cardiac stress testing, and consult with their cardiologist. Patients with stable CAD who are able to exercise will likely tolerate travel to high altitude. It is advisable to avoid exertion until acclimatized, or for at least 4 to 5 days. Subsequent exertion should be below tolerated exertion at their elevation of residence, and strenuous exercise should be avoided. Other patients, including those with abnormal stress tests, angina, or acute coronary syndrome within six months without revascularization, should not travel to altitude.

## Heart Failure

High altitude may increase risk for decompensation of chronic heart failure, and patients with poorly compensated heart failure should avoid travel. If heart failure is stable and controlled, patients may tolerate travel to altitude less than 3000 meters, but physical activity should remain below what is tolerated at their altitude of residence. These patients should monitor their body weight and develop an algorithm with their physician for how to adjust diuretics for increasing edema or weight gain.

## Respiratory Conditions

**Asthma.** Allergic asthma will likely improve at high altitude, but asthma that is exercise- or cold-induced may be made worse. An optimized pre-travel medical regimen should be continued, and these patients should travel with additional rescue medications, including bronchodilators and corticosteroids. Patients should travel with an up-to-date asthma action plan and know where to seek medical attention for an exacerbation that cannot be managed independently. Travel should be avoided in moderate persistent or severe asthma, history of hospitalization, or recent exacerbation.

**Chronic Obstructive Pulmonary Disease (COPD).** Studies evaluating patients with COPD at high altitude are limited, and data from commercial flights assess exposure of insufficient duration to evaluate risk for high altitude illness. Those who are chronically hypoxemic may have some tolerance to hypobaric hypoxia due to their adaptations to chronic hypoxia. Data is more limited on patients with chronic carbon dioxide retention, and these patients should avoid travel to high altitude. Those with an FEV<sub>1</sub> < 1 liter should travel with supplemental oxygen. If FEV<sub>1</sub> is 1–1.5 liters, patients should be assessed by their pulmonologist for possible initiation of supplemental oxygen after

arrival at altitude. If supplemental oxygen is already being utilized, the anticipated increase in flow rate may be estimated by the ratio of higher to lower barometric pressure. Patients who have dyspnea at rest or with minimal exertion should not travel to altitudes higher than residence. High-altitude travel also should be avoided if there is a history of frequent recurrent exacerbations or hospitalizations. The home medical regimen should be optimized, and patients should travel with additional rescue medications and inhalers. All patients should travel with a pulse oximeter and seek medical attention for new persistent respiratory symptoms, hypoxia, or fatigue. Acetazolamide should not be used in patients with severe COPD or history of CO<sub>2</sub> retention.

**Pulmonary Hypertension.** Patients with pulmonary hypertension are at increased risk for developing HAPE and should be educated about the clinical presentation and treatment of HAPE. If mean pulmonary arterial pressure is 35 mm Hg or greater, or if systolic pulmonary arterial pressure is 50 mm Hg or greater, patients should travel with supplemental oxygen. If not on vasodilator therapy, these patients should also be started on nifedipine<sup>1</sup> 30mg SR BID. Those with milder pulmonary hypertension should monitor oxygen saturation and consider prophylaxis with nifedipine<sup>1</sup> 30mg SR BID. Pre-travel evaluation by a pulmonary hypertension specialist is recommended.

**Sleep Apnea.** Patients with obstructive sleep apnea tend to do better at high altitudes than those with central sleep apnea, but both of these populations should continue CPAP while at altitude. Older machines may lack pressure-compensating features and thus need intended CPAP pressure adjusted at high altitude. In patients not using CPAP, acetazolamide prophylaxis is recommended.

**Other Considerations.** Travel to high altitude should be avoided in patients with obesity hypoventilation or bilateral carotid body resection. If such travel is unavoidable, supplemental oxygen should be used and any home use of CPAP should be continued while at altitude.

## Diabetes Mellitus

Patients with controlled type 1 diabetes do not appear to be at higher risk for AMS. Those with type II diabetes may be at higher risk for AMS, possibly related to other underlying risk factors and the metabolic syndrome. The elevated risk for cerebrovascular accident in diabetics may be further increased at high altitude. The prevalence of diabetes is lower at higher altitudes.

Metabolism and glucose control will change at altitude. Basal metabolic rate will increase, appetite may be suppressed, and absorption may be slowed, but hypoxia also causes hyperglycemia. Close glucose monitoring is imperative. Glucose-monitoring devices may lose accuracy, though glucose dehydrogenase-based glucometers may have more reliable performance. Malfunction risk is decreased if devices are kept warm. Acetaminophen may cause hyperglycemia, and care should be taken in use for HAH. Hydration is also particularly important for diabetic patients, particularly type 1, which can be self monitored by urine output and color.

Despite the above changes at altitude that suggest later administration of prandial insulin, there may also be a delay in the effects of rapid-acting insulin with increasing elevation, which may require earlier administration. This will also be affected by rate of ascent, acclimatization, exertion, and of course diet. Given this variability and individual response, patients should track their specific responses upon ascent and factor this in during descent, particularly if rapid, as is often the case. Glucose should be checked at a greater frequency to assess response, and any insulin administration should be adjusted accordingly. Continuous glucose monitoring may help track trends but, given the lag time compared to capillary testing and lack of studies at high altitude, probably only be used in conjunction with capillary testing.

<sup>1</sup> Not FDA approved for this indication.

In Type 1 diabetes, travel to altitude induces hyperglycemia initially and with any acute hypoxia or further ascent. After acclimatization there is a decrease in fasting glucose, and a further drop with exertion. The initial hypoxia-induced hyperglycemia may contribute to ketonuria as well as ketoacidosis, particularly with rapid ascent. This is particularly notable at very high to extreme elevations, and increased exertion and decreased appetite at these elevations may not be adequate to compensate for this hyperglycemia. Risk for DKA is increased due to these metabolic effects of altitude as well as the increased risk infectious diarrhea in some high-altitude regions, changes in diet, and certain medications. As symptoms of AMS, HACE, and diarrheal illness may mimic DKA, onset of symptoms of AMS or HACE, diarrhea in the setting of hyperglycemia, or suspected DKA warrants immediate descent.

Use of an insulin pump at altitude in controlled type 1 diabetics appears safe without significant pump dysfunction, though with rapid pressure changes such as cabin pressurization during air travel there have been reports of bubble formation affecting insulin delivery. It is advisable to also carry injectable insulin in case of pump failure. Use of acetazolamide is not advisable for type 1 diabetics due to increased risk for acidosis and diuresis increasing risk for dehydration. Dexamethasone should also be avoided due to the risk for hyperglycemia. This should be reserved for treatment of severe AMS, HACE, or if descent is not possible but emergent descent is a priority.

Type 2 diabetics do not appear to have the same extent of glycemic changes, though they may also experience hyperglycemia with initial ascent and hypoxia. Once acclimatized, they may need to decrease doses of sulfonylurea medications and insulin due to increased basal metabolic rate. It may be safe to use acetazolamide with caution in type 2 diabetes if not on insulin. Dexamethasone will cause hyperglycemia.

All travel companions should be educated on the signs and symptoms of hyper- and hypoglycemia, diabetic ketoacidosis (DKA) if applicable, overlap between these and AMS, HACE, and gastrointestinal illness, and how these conditions should be managed. Patients with poorly controlled or brittle diabetes should not travel to high altitude. Sedentary patients are advised to discuss cardiac stress testing with their physician.

## MARINE POISONINGS, ENVENOMATIONS, AND TRAUMA

Method of

Allen Perkins, MD, MPH

### CURRENT DIAGNOSIS

- History of exposure is necessary for diagnosis.
- Ingested toxins can cause unusual symptoms, predominately gastrointestinal.
- Jellyfish envenomation is very painful but almost always self-limited.
- Trauma management follows principles of dirty wounds.
- Specific marine pathogens should be covered if contamination is suspected.

### CURRENT THERAPY

#### Ingestions

- Avoidance is the best strategy.
- Early decontamination with activated charcoal (Actidose-Aqua) can reduce duration of symptoms.
- Symptomatic care is generally sufficient.

#### Jellyfish

- Remove visible stingers.
- Control pain with topical analgesia.

#### Trauma

- Avoiding water at feeding time can help avoid injury.
- If envenomation is suspected, consider hot water immersion.
- Tetanus status should be checked.
- Antibiotic coverage should take marine pathogens into account.

The United States has more than 80,000 miles of coastline, and more people are enjoying water-dependent recreation activities such as scuba diving, snorkeling, and surfing. As a consequence, people are more likely to suffer trauma, envenomation, or poisoning related to an encounter with a marine creature, which will come to the attention of a physician. The science of marine medicine is limited; hence, treatment of these conditions is largely based on case reports and expert opinion; very few randomized, controlled studies are

**BOX 1** Symptom Patterns Associated With Ciguatera Fish Poisoning**Gastrointestinal Pattern**

Onset 15 minutes to 24 hours, typically worsens, lasts 1–2 days and resolves

- Nausea and/or vomiting
- Profuse, watery diarrhea
- Abdominal pain

**Neurologic Pattern**

Onset up to 24 hours after ingestion, commonly nonphysiologic pattern, can last several months

- Numbness and paresthesias
- Vertigo
- Ataxia
- Severe weakness or lethargy
- Severe myalgia
- Decreased vibration and pain sensations
- Diffuse pain pattern
- Cold sensation reversal
- Coma

**Cardiovascular Pattern**

Onset up to 24 hours after ingestion is uncommon but occurs rapidly

- Bradycardia
- Hypotension
- Cardiovascular collapse

available. Misdiagnosis is common, especially when the patient has returned from vacationing or when the patient has been poisoned by improperly handled seafood. This article describes common ailments and injuries occurring as a consequence of direct contact with sea creatures and discusses management and prevention.

**Ingestions****Ciguatera Fish Poisoning****Epidemiology**

Ciguatera fish poisoning (CFP) is the most commonly reported marine toxin disease in the world. It is caused by human ingestion of reef fish that have bioaccumulated sufficient amounts of the dinoflagellate *Gambierdiscus toxicus*, either through direct ingestion or through ingestion of smaller reef fish. Although limited to tropical regions, it is heat and cold tolerant, is lipid soluble, and can survive transport to other areas. The toxin becomes more concentrated as it passes up the food chain; fish such as amberjack, grouper, and snapper pose less of a risk than predatory fish such as barracuda and moray eel. Ciguatera fish poisoning affects at least 50,000 people worldwide annually, and there are several thousand cases of poisoning in Puerto Rico, the U.S. Virgin Islands, Hawaii, and Florida each year.

**Clinical Features**

Patients can exhibit a primarily gastrointestinal (diarrhea, abdominal cramps, and vomiting), neurologic (parasthesias, diffuse pain, blurred vision), cardiac (bradycardia), or mixed pattern of symptoms. Additionally, a cold sensation reversal, in which a patient perceives the cold temperatures as a hot sensation and vice versa, occurs in 80% of patients and is considered pathognomonic for ciguatera poison (Box 1).

The attack rate is high. As many as 80% to 100% of people who ingest affected fish develop symptoms depending on the size of the fish and the toxin load. Ingestion of internal organs where the toxin accumulates (e.g., liver, roe) is associated with more severe symptoms, but avoiding these organs is not protective. The symptoms are also related to the number of exposures over time, and patients typically have more severe symptoms with subsequent exposures. There is no

age-related susceptibility, and no immunity is acquired through exposure.

Symptoms typically begin 1 to 6 hours after ingestion, although a delay of 12 to 24 hours can occur. Duration is 7 to 14 days, and neurologic symptoms occasionally persist for months to years. Chronic ciguatera syndrome can also occur as a constellation of symptoms such as general malaise, depression, headaches, muscle aches, and dysesthesias in the extremities. Patients with chronic disease report recurrences with ingestion of fish, ethanol, caffeine, and nuts up to 6 months after the acute illness resolves.

**Diagnosis**

The diagnosis should be entertained in any patient who has neurologic, gastrointestinal, or cardiac symptoms and a history of ingesting predatory fish within the past 24 hours. The symptom constellation can be similar to other ingestions, such as certain shellfish toxins, and differentiation requires knowledge of the patient's diet for the previous day. Additionally, scombroid and type E botulinum poisoning should be considered, but these are unlikely if the patient did not ingest ill-appearing game. Other poisonings, such as organophosphates, can produce a similar symptom complex. There are no currently available clinical assays to assist in making the diagnosis, which is based on clinical suspicion and knowledge of the patient's diet history.

**Treatment**

If CFP is suspected soon after ingestion, I would consider gut decontamination with activated charcoal (Actidose-Aqua) because it can reduce the toxin load and subsequent symptoms. Initial symptomatic treatment typically consists of fluid replacement to replace gastrointestinal losses.

Atropine (AtroPen) is used in patients who have bradycardia. Temporary electrical pacing may be used for refractory symptoms, and pressors may be needed in cases of severe hypotension. Neurologic symptoms are problematic because of their extended course as well as their severity. Mannitol (Osmitol)<sup>1</sup> is often cited as effective in reducing the duration of neurologic symptoms, but I would use it with caution because the only double-blind trial failed to show any benefit. There are many local remedies used throughout the world that are said to be successful, which likely attests to the self-limited course of the ingestion in most cases. Table 1 offers more details regarding treatments currently used for CFP.

**Prevention**

Prevention is difficult except by avoiding ingestion of affected reef fish. The toxin is not deactivated by cooking, freezing, smoking, or salting. There are no outward signs of ciguatera: The fish look, taste, and smell normal. Although several commercial assays are available, they are neither sensitive nor specific enough to be relied on to prevent CFP.

To decrease the risk of CFP, I recommend the following steps: Avoid warm-water reef fish, especially those caught where ciguatera poisoning is known to occur; avoid moray eel injection; avoid ingesting large game fish; avoid consuming the internal organs; and limit the amount of initial ingestion if you are in an area where ciguatera is known to occur. Additionally, patients traveling to distant locales should be made aware that, although the vast majority of cases result from direct ingestion, there have been cases of CFP passed through sexual contact and through breast milk, so they should be wary of body fluid contact if ciguatoxin is endemic to the area, if for no other reasons.

**Scombroid****Epidemiology**

Scombroid poisoning (also known as histamine fish poisoning) results from improper handling of certain fish between the time the fish is caught and the time it is cooked. In the United States it is most common in Hawaii and California. Improper preservation and refrigeration lead to histamine and histamine-like substances being produced in the dark meat of certain fish through a conversion of

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Treatment for Ciguatera Fish Poisoning

DRUG	DOSE	INDICATION
Activated charcoal (Actidose-Aqua)	Children <1 y: 1 g/kg Children 1–12 y: 25–50 g Adults: 25–100 g	Gut emptying and decontamination More effective in first hour
Antiemetics (no preference)	Administer per dosing recommendations	Intractable nausea and/or vomiting
Intravenous fluid bolus and infusion (normal saline or lactated Ringer's as initial)	Per volume replacement protocols	Hypovolemia
Atropine (AtroPen)	0.5–1.0 mg IV every 3–5 min to a maximum dose of 0.04 mg/kg per episode Maximum total dose: 3 mg for adults, 2 mg for adolescents, 1 mg for young children	Bradycardia
Pressors: Dopamine (Intropin), dobutamine (Dobutrex), epinephrine	Varies with clinical response	Hypotension, shock
Antihistamines (no preference)	Administer per dosing recommendations	Pruritus
Mannitol (Osmitol) <sup>1</sup>	1 g/kg of a 20% solution given IV over several h Adult dose: 25–100 g, titrate to urinary output of 100 mL/h	Neurologic symptoms, double-blind study did not show benefit
Amitriptyline (Elavil) <sup>1</sup>	25–75 mg PO bid for patients >25 kg	Pruritus, dysesthesias

<sup>1</sup>Not FDA approved for this indication.

histidine to histamine by bacterial decarboxylases. Members of the family Scombridae, such as tuna and mackerel, contain the highest amounts of this substance, but both scombroid and nonscombroid fish have been associated with the disease. The production of toxins requires the introduction of bacteria during the handling process, primarily during storage at high temperatures. It is the total amount of histamine, the presence of other biogenic amines, and individual susceptibility that determine the severity of the symptoms.

#### Clinical Features

The patient develops a histamine reaction 20 to 30 minutes after ingestion. Symptoms can be cutaneous, gastrointestinal, neurologic, or hemodynamic, or any combination of these. Cutaneous symptoms include flushing, urticaria and conjunctival injection, and localized edema; gastrointestinal symptoms include dry mouth, nausea, vomiting, diarrhea, and abdominal cramping; neurologic symptoms include severe headache and dizziness; and hemodynamic symptoms include palpitations and hypotension. In severe cases there can be bronchospasm and respiratory distress. These symptoms typically come on rapidly (within several minutes) and last less than 6 to 8 hours. Flushing is the most consistent clinical sign, occurring on exposed areas so it typically resembles sunburn. Diarrhea is also very common, occurring in 75% of symptomatic patients.

#### Diagnosis

As with ciguatera, the diagnosis is one of history. If the time between ingestion and illness is short and the patient has ingested a type of fish previously implicated in scombroid, then a tentative diagnosis can be made. The diagnosis is often confused with an allergic reaction. It can be distinguished from allergy by the lack of a previous allergic reaction as well as by testing the remaining fish for histamine, although testing is rarely warranted.

#### Treatment

Treatment is the same as for any histamine reaction, the cornerstone of which is antihistamine. Diphenhydramine (Benadryl) 50 mg for adults and 0.5–1 mg/kg/dose for children, repeated every 4 hours until symptoms abate, is delivered either intravenously or intramuscularly in severe cases and orally for milder cases. For severe cases, cimetidine (Tagamet)<sup>1</sup> 300 mg for adults,

20 mg/kg for children, either orally or intravenously, might be added for more complete histamine-receptor blockade. In cases where ingestion was recent, consider induced emesis using syrup of ipecac: 15 mL for children younger than 12 years or 30 mL otherwise. Most patients require only reassurance, and pharmacologic treatment will be unnecessary. It should be stressed to the patient that this is not an *allergic* reaction to fish, because the histamine is exogenous. Prevention is possible in regions where food storage and preparation are monitored through identification and removal of suspect fish.

#### Other Ingested Toxins

In addition to the toxins just discussed, ingestion of certain other marine creatures can lead to problems.

Ingestion of bivalves harvested from contaminated waters has been associated with hepatitis A, Norwalk virus, *Vibrio parahaemolyticus* and *Vibrio vulnificans* infections, the latter two particularly problematic and occasionally fatal in immunocompromised patients. I counsel patients likely to be immunocompromised, including diabetics and those with known liver disease, to avoid uncooked bivalves.

Shellfish are occasionally known to contain one or more of several toxins acquired through bioaccumulation of certain algae. These dinoflagellates tend to bloom in summer months. The symptoms occur immediately after ingestion and last several hours and are typically neurologic or gastrointestinal, or both. The shellfish poisoning syndromes are known as paralytic, neurologic, diarrheal, or amnesic depending on the predominant symptom. The care is typically supportive. Public health officials typically monitor local mollusk populations fairly carefully and alert the public to possible hazards.

Ingestion of the flesh of certain puffer fish has been associated with tetrodotoxin poisoning. The flesh of the fish (fugu) is considered a delicacy. The toxin builds up in internal organs such as the liver and the roe. If the toxin is ingested, it is likely to be fatal, but there are certified chefs who are trained in avoiding the toxin when preparing the dish. Despite this precaution, as many as 50 deaths occur in Japan annually from exposure to this toxin. Avoiding this puffer fish and avoiding the ingestion of certain other exotic animals (such as the blue-ringed octopus) eliminate the risk of acquiring this toxin.

<sup>1</sup>Not FDA approved for this indication.

## Envenomations

Many marine creatures are venomous, and beachgoers experience clinically significant envenomations with some regularity. Jellyfish and related creatures (Cnidarians), sea urchins (Echinodermata), and stingrays (Chondrichthyes) are some of the more commonly identified marine animals involved with envenomations.

### Jellyfish

These invertebrates have stinging cells called *nematocytes*, which carry nematocysts that continue to function when separated from the larger organism. For example, jellyfish nematocysts can sting if the tentacle is separated and after the jellyfish is dead. The venom is antigenic and causes a reaction of a dermatonecrotic, hemolytic, cardiopathic, or neurotoxic nature. The severity of the reaction depends on several variables, including the number of nematocysts that discharge, the toxicity of the coelenterate involved, and each patient's unique antigenic response.

### Clinical Features

Although occasionally fatal as a consequence of an anaphylactic response in the United States and Caribbean, the primary concern in these areas with contact is pain, which is almost always self-limiting. Other, less common symptoms include paresthesias, nausea, headaches, and chills. The symptoms may last up to 2 to 3 days. Certain Pacific jellyfish primarily found in the waters around Australia have a more potent toxin and are much more likely to cause death (which is still very uncommon). Additionally, the Irukandji syndrome, which occurs in the Pacific, is a suite of symptoms including muscle spasms, vomiting, hypertension, incessant coughing, and occasionally heart failure and brain hemorrhage. Almost all exposed people, regardless of the geographic location, do not have a severe reaction, and the principles of first aid are primarily the same throughout the world.

### Treatment

In my experience, treatment is mostly concerned with limiting pain and neurologic symptoms, because anaphylaxis and other severe reactions are rare, and the following general guidelines can be applied. In the field, either the victim or a companion should remove any visible tentacles. To do so requires using care, with gloves or forceps being optimal to prevent further stings. If a towel is used, any nematocysts remaining on the towel can still discharge. Salt water can be used to wash off the nematocysts. Urine, household vinegar, fresh water, and rubbing with sand should be avoided.

Should the victim present to the physician's office or emergency department, topical lidocaine (4%)<sup>1</sup> should be liberally applied for 30 minutes or until the pain subsides, followed by removal of the nematocysts, usually through use of the gloved hand or with forceps. Another method for removing the nematocysts is to apply shaving cream or baking soda slurry to the area and scrape off the nematocysts with a razor. Applications of cold, in the form of an ice pack, and immersion in hot water have variously been shown to improve pain, but because of the self-limited nature of the discomfort, it is hard to gauge an optimum therapy. Either is probably acceptable until the patient is comfortable. Meat tenderizer has been found to be ineffective. Local anesthetics, antihistamines, and steroids are all used to control prolonged symptoms, based on anecdotal experience. Antibiotics are not generally necessary. In the rare cases of cardiovascular collapse, supportive care and principles of treatment of anaphylaxis should be followed. A delayed hypersensitivity reaction can occur 1 to 3 days out, which will almost certainly be self-limited and can be treated with oral antihistamines and topical steroids if symptoms are severe.

Sea bather's itch is a form of jellyfish sting caused by the larvae of the thimble jellyfish. It is characterized by a painful, itchy rash under the edges of the bathing suit or wet suit. It can occasionally progress to a papular rash. Topical steroids can be used to relieve symptoms.

### Prevention

Prevention is mostly a matter of common sense. Staying away from the organism (the tentacles can extend several meters from the body of the organism) and staying out of the water when jellyfish

are known to be present are the most effective. There is a commercially available product, Safe Sea, which has been shown to reduce the number of nematocyst discharges and thus the severity of the sting should a swimmer need to be in the water when jellyfish are present. Wetsuits and other protective gear are ineffective.

### Echinoderms

The Echinoderm family includes sea urchins. Urchins have toxin-coated spines that break off, leaving calcareous material in the wound, which can potentially cause infection. Symptoms include local pain, burning, and local discoloration. The discoloration is thought to be a temporary tattooing of the skin resulting from dye in the spines; absence of a spine is indicated if the discoloration spontaneously resolves within 48 hours. Theoretically, hot water disables the toxin, although there is no evidence in humans that it is effective. If a spine is present and easily accessible, it should be removed with fingers or forceps. If it is close to a joint or neurovascular structure, it should be surgically removed. If the spines do not cause symptoms, retained pieces will likely reabsorb into the skin.

### Stingrays

Although many fish are venomous, stingrays are the most clinically important, accounting for an estimated 1500 mostly minor injuries in the United States annually. These creatures partially bury themselves in the shallow, sandy bottom of the ocean, leading water enthusiasts to accidentally step on them or grab at what they think is a seashell.

### Clinical Features

Stingrays have a spine at the base of their tail, which contains a venom gland. The spine, including the venom gland, is broken off and may be left in the resulting wound. The venom has vasoconstrictive properties that can lead to cyanosis and necrosis with poor wound healing and infection. Symptoms can include immediate and intense pain, salivation, nausea, vomiting, diarrhea, muscle cramps, dyspnea, seizures, headaches, and cardiac arrhythmias. Fatalities are rare and mostly a consequence of exsanguination at the scene or penetration of a vital organ.

### Treatment

Home care should include rinsing the area thoroughly with fresh water if available (salt water if not) and removing any foreign body. If the damage is minimal, the victim may soak the wound in warm water at home. The victim should watch for signs of infection and seek care for excessive bleeding, retained foreign body, or infection.

For severe wounds that lead the victim to seek medical attention, treatment should include achieving hemostasis followed by submersion of the affected region in hot but not scalding water (42–45 °C, 108–113 °F) for 30 to 90 minutes or until the pain resolves. Spines and stingers are typically radiopaque, so radiographs or an ultrasound should be obtained if a retained spine is suspected. The wound should be thoroughly cleansed, and delayed closure should be allowed. Tetanus immunization status should be reviewed and updated as appropriate. Surgical exploration may be necessary to remove residual foreign bodies. Prophylactic antibiotics are typically not necessary unless there is a residual foreign body or if the patient is immunosuppressed. If the wound becomes infected, *Staphylococcus* and *Streptococcus* species are the most common pathologic organisms. Unique to the marine environment are *Vibrio vulnificus* and *Mycobacterium marinum*, and antibiotic coverage should include coverage for all of these (Table 2).

### Other Venomous Sea Creatures

Seasnakes are venomous creatures found most commonly in the Indo-Pacific area. Bites are uncommon (and envenomation is even less common), but should they occur, the toxin is very potent. The care is supportive. There is antivenom, which may be available in areas where the snakes are endemic.

Certain other fish and octopi have been associated with envenomation and occasional death. Most are tropical such as the stonefish, scorpionfish, and rabbitfish and the blue-ringed octopus.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Antibiotic Choices in Marine Injuries

DRUG	DOSAGE	
	PEDIATRIC	ADULT
<b>Outpatient Management</b>		
Ciprofloxacin (Cipro) <sup>1</sup>	20–30 mg/kg/day PO × 14 d <sup>1</sup>	500 mg PO bid × 14 d
Levofloxacin (Levaquin) <sup>1</sup>		750 mg PO qd × 14 d
Doxycycline (Vibramycin, Doryx) <sup>1</sup>	>8 y: 2.2 mg/kg PO qd × 14 d	100 mg bid × 14 d
<b>Inpatient Management</b>		
	<b>Preferred</b>	
Ceftazidime (Fortaz, Tazicef) <sup>1</sup> plus	150 mg/kg/d q8h	1 g IV q8h
PO or IV quinolone or doxycycline	See outpatient dosing above	See outpatient dosing above
<b>Alternative</b>		
Clindamycin <sup>1</sup> plus	25 to 40 mg/kg per day	600 mg IV q 8 hours
PO or IV quinolone or doxycycline	See outpatient dosing	See outpatient dosing

<sup>1</sup>Not FDA approved for this indication.

Abbreviation: TMP-SMX = trimethoprim-sulfamethoxazole.

Certain varieties of catfish have venom as well. Envenomations are rare, and if they occur, treatment is based on good first-aid principles and antivenom where available (mostly in tropical areas).

Certain cone shells contain a toxin that can be fatal. This toxin is injected by the mollusk into the victim from a proboscis, which it extends from the small end of the cone. Treatment is primarily supportive.

### Trauma

Abrasions, bites, and lacerations are usually the result of a marine animal's instinct to protect itself against a perceived danger. The most commonly involved marine animals are octopi, sharks, moray eels, and barracuda. The trauma alone creates problems for patients, but the trauma can be further complicated by envenomation. It is often difficult to identify the marine animal involved in the attack. Treatment is for the most part symptomatic, with local cleansing and topical dressing usually sufficing. If the wound becomes infected, antibiotics should cover common organisms (see Table 2).

### Environmental Hazards

Abrasions from the ambient environment are also common. These wounds should be thoroughly cleansed with soap and water and a topical antibiotic applied, because the wounds can contain toxins and are commonly contaminated with bacteria. Coral contains nematocysts and also has very sharp edges. Scuba divers in particular suffer from coral cuts in the course of their recreational diving. If these wounds become infected, coverage for *Vibrio* species should be included as well.

### Sharks

Although shark attacks receive a lot of publicity, there are only around 50 such attacks worldwide annually and they result in fewer than 10 deaths. The majority of the deaths are in South Africa. Typically these attacks involve the tiger, great white, gray reef, and bull sharks. Attacks occur in shallow water within 100 feet of shore during the evening hours when sharks tend to feed. Common sense dictates avoiding areas where aggressive shark feeding has been noted.

Sequelae of a shark attack range from abrasions to death from hemorrhage. Abrasions and lacerations can occur when sharks brush or aggressively investigate humans. Soft tissue damage, fractures, and neurovascular damage result from such attacks. The majority of attacks result in minor injuries that require simple suturing. Morbidity increases in wounds that are greater than 20 cm or where more than one myofascial compartment is lost. General principles of first aid in marine animal injuries are found in Box 2. Although it would seem self-evident, practices such as urinating on the injury, applying oil or gasoline to injuries, and

### BOX 2

#### Management of Marine Trauma

- Remove the victim from the water.
- Ensure airway control.
- Control bleeding.
- Do not remove the wet suit if the victim is wearing one.
- Attempt to identify the animal involved in the injury.
- If the injury is severe, transport the victim to a hospital.
- If envenomation is suspected, consider hot water immersion.
- Irrigate the wound with normal saline.
- Perform surgical débridement of the wound as appropriate.
- If sutures must be placed, place them loosely and allow drainage. Primary suturing should be avoided in puncture wounds, crush injuries, and wounds in the distal extremities.
- Start appropriate antibiotics if indicated.

application of any strong oxidizing agents, such as strong bases or acids, should be counseled against when doing patient education regarding self-care.

**Introduction and Epidemiology**

According to the national Toxic Exposure Surveillance System (TESS), over 2.4 million potentially toxic exposures were reported last year to Poison Control Centers throughout the United States. Poisonings were responsible for 1183 deaths and more than 500,000 hospitalizations. Poisoning accounts for 2% to 5% of pediatric hospital admissions, 10% of adult admissions, 5% of hospital admissions in the elderly (>65 years of age), and 5% of ambulance calls. In one urban hospital, drug-related emergencies accounted for 38% of the emergency department visits. An evaluation of a medical intensive care unit and step-down unit over a 3-month period indicated that poisonings accounted for 19.7% of admissions.

The largest number of fatalities resulting from poisoning reported to the TESS are caused by analgesics. The other principal toxicologic causes of fatalities are antidepressants, sedative hypnotics/antipsychotics, stimulants/street drugs, cardiovascular agents, and alcohols. Less than 1% of overdose cases reaching the hospitals result in fatality. However, patients presenting in deep coma to medical care facilities have a fatality rate of 13% to 35%. The largest single cause of coma of inapparent etiology is drug poisoning.

Pharmaceutical preparations are involved in 50% of poisonings. The number one pharmaceutical agent involved in exposures is acetaminophen. The severity of the manifestations of acute poisoning exposures varies greatly depending on whether the poisoning was intentional or unintentional. Unintentional exposures make up 85% to 90% of all poisoning exposures. The majority of cases are acute, occurring in children younger than 5 years of age, in the home, and resulting in no or minor toxicity. Many are actually ingestions of relatively nontoxic substances that require minimal medical care. Intentional poisonings, such as suicides, constitute 10% to 15% of exposures and may require the highest standards of medical and nursing care and the use of sophisticated equipment for recovery. Intentional ingestions are often of multiple substances and frequently include ethanol, acetaminophen, and aspirin. Suicides make up 54% of the reported fatalities. About 25% of suicides are attempted with drugs. Sixty percent of patients who take a drug overdose use their own medication and 15% use drugs prescribed for close relatives. The majority of the drug-related suicide attempts involve a central nervous system (CNS) depressant, and coma management is vital to the treatment.

**Assessment and Maintenance of the Vital Functions**

The initial assessment of all patients in medical emergencies follows the principles of basic and advanced cardiac life support. The adequacy of the patient's airway, degree of ventilation, and circulatory status should be determined. The vital functions should be established and maintained. Vital signs should be measured frequently and should include body core temperature. The assessment of vital functions should include the rate numbers (e.g., respiratory rate) and indications of effectiveness (e.g., depth of respirations and degree of gas exchange). [Table 1](#) gives important measurements and vital signs.

Level of consciousness should be assessed by immediate AVPU (Alert, responds to Verbal stimuli, responds to Painful stimuli, and Unconscious). If the patient is unconscious, one must assess the severity of the unconsciousness by the Glasgow Coma Scale ([Table 2](#)).

If the patient is comatose, management requires administering 100% oxygen, establishing vascular access, and obtaining blood for pertinent laboratory studies. The administration of glucose, thiamine, and naloxone, as well as intubation to protect the airway, should be considered. Pertinent laboratory studies include arterial blood gases (ABG), electrocardiography (ECG),

determination of blood glucose level, electrolytes, renal and liver tests, and acetaminophen plasma concentration in all cases of intentional ingestions. Radiography of the chest and abdomen may be useful. The severity of a stimulant's effects can also be assessed and should be documented to follow the trend.

The examiner should completely expose the patient by removing clothes and other items that interfere with a full evaluation. One should look for clues to etiology in the clothes and include the hat and shoes.

**Prevention of Absorption and Reduction of Local Damage Exposure**

Poisoning exposure routes include ingestion (76.8%), dermal (8%), ophthalmologic (5%), inhalation (6%), insect bites and stings (4%), and parenteral injections (0.5%). The effect of the toxin may be local, systemic, or both.

Local effects (skin, eyes, mucosa of respiratory or gastrointestinal tract) occur where contact is made with the poisonous substance. Local effects are nonspecific chemical reactions that depend on the chemical properties (e.g., pH), concentration, contact time, and type of exposed surface.

Systemic effects occur when the poison is absorbed into the body and depend on the dose, the distribution, and the functional reserve of the organ systems. Shock and hypoxia are part of systemic toxicity.

**Delayed Toxic Action**

Therapeutic doses of most pharmaceuticals are absorbed within 90 minutes. However, the patient with exposure to a potential toxin may be asymptomatic at this time because a sufficient amount has not yet been absorbed or metabolized to produce toxicity at the time the patient presents for care.

Absorption can be significantly delayed under the following circumstances:

1. Drugs with anticholinergic properties (e.g., antihistamines, belladonna alkaloids, diphenoxylate with atropine [Lomotil], phenothiazines, and tricyclic antidepressants).
2. Modified release preparations such as sustained-release, enteric-coated, and controlled-release formulations have delayed and prolonged absorption.
3. Concretions may form (e.g., salicylates, iron, glutethimide, and meprobamate [Equanil]) that can delay absorption and prolong the toxic effects. Large quantities of drugs tend to be absorbed more slowly than small quantities.

Some substances must be metabolized into a toxic metabolite (acetaminophen, acetonitrile, ethylene glycol, methanol, methylene chloride, parathion, and paraquat). In some cases, time is required to produce a toxic effect on organ systems (*Amanita phalloides* mushrooms, carbon tetrachloride, colchicine, digoxin [Lanoxin], heavy metals, monoamine oxidase inhibitors, and oral hypoglycemic agents).

**Initial Management**

1. Stabilization of airway, breathing, and circulation and protection of same.
2. Identification of specific toxin or toxic syndrome.
3. Initial treatment: D50W; consider thiamine, naloxone (Narcan), oxygen, and antidotes if needed.
4. Physical assessment.
5. Decontamination: Gastrointestinal tract, skin, eyes.

**Decontamination**

In the asymptomatic patient who has been exposed to a toxic substance, decontamination procedures should be considered if the patient has been exposed to potentially toxic substances in toxic amounts.

Ocular exposure should be immediately treated with water irrigation for 15 to 20 minutes with the eyelids fully retracted. One should not use neutralizing chemicals. All caustic and corrosive injuries should be evaluated with fluorescein dye and by an ophthalmologist.

**TABLE 1** Important Measurements and Vital Signs

AGE	BODY SURFACE AREA (M <sup>2</sup> )	WEIGHT (KG)	HEIGHT (CM)	PULSE (BPM) RESTING	BLOOD PRESSURE			RESPIRATORY RATE (RPM)
					HYPOTENSION	SIGNIFICANT	SEVERE

		4	Flexion withdrawal
		3	Decorticate flexion
		2	Decerebrate flexion
		1	None
Verbal response: adult	Oriented and converses	5	Cries, smiles, coos
	Disoriented but converses	4	Cries or screams
	Inappropriate words	3	Inappropriate sounds
	Incomprehensible sounds	2	Grunts
	None	1	Gives no response
Verbal response: child	Oriented	5	
	Words or babbles	4	
	Vocal sounds	3	
	Cries or moans to stimuli	2	
	None	1	

Data from Teasdale G, Jennett B: Assessment of coma impaired consciousness. *Lancet* 2:83, 1974; Simpson D, Reilly P: Pediatric coma scale. *Lancet* 2:450, 1982; Seidel J: Preparing for pediatric emergencies. *Pediatr Rev* 16:470, 1995.

Dermal exposure is treated immediately with copious water irrigation for 30 minutes, not a forceful flushing. Shampooing the hair, cleansing the fingernails, navel, and perineum, and irrigating the eyes are necessary in the case of an extensive exposure. The clothes should be specially bagged and may have to be discarded. Leather goods can become irreversibly contaminated and must be abandoned. Caustic (alkali) exposures can require hours of irrigation. Dermal absorption can occur with pesticides, hydrocarbons, and cyanide.

Injection exposures (e.g., snake envenomation) can be treated with venom extractors. Venom extractors can be used within

minutes of envenomation, and proximal lymphatic constricting bands or elastic wraps can be used to delay lymphatic flow and immobilize the extremity. Cold packs and tourniquets should not be used and incision is generally not recommended. Substances of abuse may be injected intravenously or subcutaneously. In these cases, little decontamination can be done.

Inhalation exposure to toxic substances is managed by immediate removal of the victim from the contaminated environment by protected rescuers.

Gastrointestinal exposure is the most common route of poisoning. Gastrointestinal decontamination historically has been done

by gastric emptying: induction of emesis, gastric lavage, administration of activated charcoal, and the use of cathartics or whole bowel irrigation. No procedure is routine; it should be individualized for each case. If no attempt is made to decontaminate the patient, the reason should be clearly documented on the medical record (e.g., time elapsed, past peak of action, ineffectiveness, or risk of procedure).

### Gastric Emptying Procedures

The gastric emptying procedure used is influenced by the age of the patient, the effectiveness of the procedure, the time of ingestion (gastric emptying is usually ineffective after 1 hour postingestion), the patient's clinical status (time of peak effect has passed or the patient's condition is too unstable), formulation of the substance ingested (regular release versus modified release), the amount ingested, and the rapidity of onset of CNS depression or stimulation (convulsions). Most studies show that only 30% (range, 19% to 62%) of the ingested toxin is removed by gastric emptying under optimal conditions. It has not been demonstrated that the choice of procedure improved the outcome.

A mnemonic for gathering information is STATS:

- S—substance
- T—type of formulation
- A—amount and age
- T—time of ingestion
- S—signs and symptoms

The examiner should attempt to obtain AMPLE information about the patient:

- A—age and allergies
- M—available medications
- P—past medical history including pregnancy, psychiatric illnesses, substance abuse, or intentional ingestions
- L—time of last meal, which may influence absorption and the onset and peak action
- E—events leading to present condition

The intent of the patient should also be determined.

The Regional Poison Center should be consulted for the exact ingredients of the ingested substance and the latest management. The treatment information on the labels of products are notoriously inaccurate.

### Ipecac Syrup

Syrup of ipecac-induced emesis has virtually no use in the emergency department. Although at one time it was considered most useful in young children with a recent witnessed ingestion, it is no longer advised in most cases. Current guidelines from the American Association of Poison Control Centers have significantly limited the indications for inducing emesis because the risk most often exceeds the benefit derived from this procedure. The Poison Control Center should be called if inducing emesis is being considered.

Contraindications or situations in which induction of emesis is inappropriate include the following:

- Ingestion of caustic substance
- Loss of airway protective reflexes because of ingestion of substances that can produce rapid onset of CNS depression (e.g., short-acting benzodiazepines, barbiturates, nonbarbiturate sedative-hypnotics, opioids, tricyclic antidepressants) or convulsions (e.g., camphor [Ponstel], chloroquine [Aralen], codeine, isoniazid [Nydrazid], mefenamic acid, nicotine, propoxyphene [Darvon], organophosphate insecticides, strychnine, and tricyclic antidepressants)
- Ingestion of low-viscosity petroleum distillates (e.g., gasoline, lighter fluid, kerosene)
- Significant vomiting prior to presentation or hematemeses
- Age under 6 months (no established dose, safety, or efficacy data)
- Ingestion of foreign bodies (emesis is ineffective and may lead to aspiration)

- Clinical conditions including neurologic impairment, hemodynamic instability, increased intracranial pressure, and hypertension
- Delay in presentation (more than 1 hour postingestion)

The dose of syrup of ipecac in the 6- to 9-month-old infant is 5 mL; in the 9- to 12-month-old, 10 mL; and in the 1- to 12-year-old, 15 mL. In children older than 12 years and in adults, the dose is 30 mL. The dose can be repeated once if the child does not vomit in 15 to 20 minutes. The vomitus should be inspected for remnants of pills or toxic substances, and the appearance and odor should be documented. When ipecac is not available, 30 mL of mild dishwashing soap (not dishwasher detergent) can be used, although it is less effective.

Complications are very rare but include aspiration, protracted vomiting, rarely cardiac toxicity with long-term abuse, pneumothorax, gastric rupture, diaphragmatic hernia, intracranial hemorrhage, and Mallory-Weiss tears.

### Gastric Lavage

Gastric lavage should be considered only when life-threatening amounts of substances were involved, when the benefits outweigh the risks, when it can be performed within 1 hour of the ingestion, and when no contraindications exist.

The contraindications are similar to those for ipecac-induced emesis. However, gastric lavage can be accomplished after the insertion of an endotracheal tube in cases of CNS depression or controlled convulsions. The patient should be placed with the head lower than the hips in a left-lateral decubitus position. The location of the tube should be confirmed by radiography, if necessary, and suctioning equipment should be available.

Contraindications to gastric lavage include the following:

- Ingestion of caustic substances (risk of esophageal perforation)
- Uncontrolled convulsions, because of the danger of aspiration and injury during the procedure
- Ingestion of low-viscosity petroleum distillate products
- CNS depression or absent protective airway reflexes, without endotracheal protection
- Significant cardiac dysrhythmias
- Delay in presentation (more than 1 hour postingestion)

**Size of Tube.** The best results with gastric lavage are obtained with the largest possible orogastric tube that can be reasonably passed (nasogastric tubes are not large enough to remove solid material). In adults, a large-bore orogastric Lavacuator hose or a No. 42 French Ewald tube should be used; in young children, orogastric tubes are generally too small to remove solid material and gastric lavage is not recommended.

The amount of fluid used varies with the patient's age and size. In general, aliquots of 50 to 100 mL per lavage are used in adults. Larger amounts of fluid may force the toxin past the pylorus. Lavage fluid is 0.9% saline.

Complications are rare and may include respiratory depression, aspiration pneumonitis, cardiac dysrhythmias as a result of increased vagal tone, esophageal-gastric tears and perforation, laryngospasm, and mediastinitis.

### Activated Charcoal

Oral activated charcoal adsorbs the toxin onto its surface before absorption. According to recent guidelines set forth by the American Academy of Clinical Toxicology, activated charcoal should not be used routinely. Its use is indicated only if a toxic amount of substance has been ingested and is optimally effective within 1 hour of the ingestion. Because of the slow absorption of large quantities of toxin, activated charcoal may be beneficial after 1 hour postingestion.

Activated charcoal does not effectively adsorb small molecules or molecules lacking carbon (Table 3). Activated charcoal adsorption may be diminished by milk, cocoa powder, and ice cream.

**TABLE 3** Substances Poorly Adsorbed by Activated Charcoal

C	Caustics and corrosives
H	Heavy metals (arsenic, iron, lead, mercury)
A	Alcohols (ethanol, methanol, isopropanol) and glycols (ethylene glycols)
R	Rapid onset of absorption (cyanide and strychnine)
C	Chlorine and iodine
O	Others insoluble in water (substances in tablet form)
A	Aliphatic hydrocarbons (petroleum distillates)
L	Laxatives (sodium, magnesium, potassium, and lithium)

There are a few relative contraindications to the use of activated charcoal:

1. Ingestion of caustics and corrosives, which may produce vomiting or cling to the mucosa and falsely appear as a burn on endoscopy.
2. Comatose patient, in whom the airway must be secured prior to activated charcoal administration.
3. Patient without presence of bowel sounds.

*Note:* Activated charcoal was shown not to interfere with effectiveness of *N*-acetylcysteine in cases of acetaminophen overdose, so it is no longer contraindicated as was thought in the past.

The usual initial adult dose is 60 to 100 g and the dose for children is 15 to 30 g. It is administered orally as a slurry mixed with water or by nasogastric or orogastric tube. *Caution:* Be sure the tube is in the stomach. Cathartics are not necessary.

Although repeated dosing with activated charcoal may decrease the half-life and increase the clearance of phenobarbital, dapson, quinidine, theophylline, and carbamazepine (Tegretol), recent guidelines indicate there is insufficient evidence to support the use of multiple-dose activated charcoal unless a life-threatening amount of one of the substances mentioned is involved. At present there are no controlled studies that demonstrate that multiple-dose activated charcoal or cathartics alter the clinical course of an intoxication. The dose varies from 0.25 to 0.50 g/kg every 1 to 4 hours, and continuous nasogastric tube infusion of 0.25 to 0.5 g/kg/h has been used to decrease vomiting.

Gastrointestinal dialysis is the diffusion of the toxin from the higher concentration in the serum of the mesenteric vessels to the lower levels in the gastrointestinal tract mucosal cell and subsequently into the gastrointestinal lumen, where the concentration has been lowered by intraluminal adsorption of activated charcoal.

Complications of treatment with activated charcoal include vomiting in 50% of cases, desorption (especially with weak acids in intestine), and aspiration (at least a dozen cases of aspiration have been reported). There are many cases of unreported pulmonary aspirations and “charcoal lungs,” intestinal obstruction or pseudoobstruction (three case reports with multiple dosing, none with a single dose), empyema following esophageal perforation, and hypermagnesemia and hypernatremia, which have been associated with repeated concurrent doses of activated charcoal and saline cathartics. Catharsis was used to hasten the elimination of any remaining toxin in the gastrointestinal tract. There are no studies to demonstrate the effectiveness of cathartics, and they are no longer recommended as a form of gastrointestinal decontamination.

#### Whole-Bowel Irrigation

With whole-bowel irrigation, solutions of polyethylene glycol (PEG) with balanced electrolytes are used to cleanse the bowel

without causing shifts in fluids and electrolytes. The procedure is not approved by the US Food and Drug Administration (FDA) for this purpose.

**Indications.** The procedure has been studied and used successfully in cases of iron overdose when abdominal radiographs reveal incomplete emptying of excess iron. There are additional indications for other types of ingestions, such as with body-packing of illicit drugs (e.g., cocaine, heroin).

The procedure is to administer the solution (GoLYTELY or Colyte), orally or by nasogastric tube, in a dose of 0.5 L per hour in children younger than 5 years of age and 2 L per hour in adolescents and adults for 5 hours. The end point is reached when the rectal effluent is clear or radiopaque materials can no longer be seen in the gastrointestinal tract on abdominal radiographs.

**Contraindications.** These measures should not be used if there is extensive hematemesis, ileus, or signs of bowel obstruction, perforation, or peritonitis. Animal experiments in which PEG was added to activated charcoal indicated that activated charcoal-salicylates and activated charcoal-theophylline combinations resulted in decreased adsorption and desorption of salicylate and theophylline and no therapeutic benefit over activated charcoal alone. Polyethylene solutions are bound by activated charcoal in vitro, decreasing the efficacy of activated charcoal.

Dilutional treatment is indicated for the immediate management of caustic and corrosive poisonings but is otherwise not useful. The administration of diluting fluid above 30 mL in children and 250 mL in adults may produce vomiting, reexposing the vital tissues to the effects of local damage and possible aspiration.

Neutralization has not been proven to be either safe or effective.

Endoscopy and surgery have been required in the case of body-packer obstruction, intestinal ischemia produced by cocaine ingestion, and iron local caustic action.

#### Differential Diagnosis of Poisons on the Basis of Central Nervous System Manifestations

Neurologic parameters help to classify and assess the need for supportive treatment as well as provide diagnostic clues to the etiology. **Table 4** lists the effects of CNS depressants, CNS stimulants, hallucinogens, and autonomic nervous system anticholinergics and cholinergics.

CNS depressants are cholinergics, opioids, sedative-hypnotics, and sympatholytic agents. The hallmarks are lethargy, sedation, stupor, and coma. In exception to the manifestations listed in **Table 4**, (a) barbiturates may produce an initial tachycardia; (b) convulsions are produced by codeine, propoxyphene (Darvon), meperidine (Demerol), glutethimide, phenothiazines, methaqualone, and tricyclic and cyclic antidepressants; (c) benzodiazepines rarely produce coma that will interfere with cardiorespiratory functions; and (d) pulmonary edema is common with opioids and sedative-hypnotics.

The CNS stimulants are anticholinergic, hallucinogenic, sympathomimetic, and withdrawal agents. The hallmarks of CNS stimulants are convulsions and hyperactivity.

There is considerable overlapping of effects among the various hallucinogens, but the major hallmark manifestation is hallucinations.

#### Guidelines for In-Hospital Disposition

Classification of patients as high risk depends on clinical judgment. Any patient who needs cardiorespiratory support or has a persistently altered mental status for 3 hours or more should be considered for intensive care.

Guidelines for admitting patients older than 14 years of age to an intensive care unit, after 2 to 3 hours in the emergency department, include the following:

1. Need for intubation
2. Seizures

**TABLE 4** Agents with Central Nervous System (CNS) Effects

AGENTS	GENERAL MANIFESTATIONS	AGENTS	GENERAL MANIFESTATIONS
<b>CNS Depressants</b>		<b>Hallucinogens</b>	
Alcohols and glycols (S-H)	Bradycardia	Amphetamines <sup>‡</sup>	Tachycardia and dysrhythmias
Anticonvulsants (S-H)	Bradypnea	Anticholinergics	Tachypnea
Antidysrhythmics (S-H)	Shallow respirations	Cardiac glycosides	Hypertension
Antihypertensives (S-H)	Hypotension	Cocaine	Hallucinations, usually visual
Barbiturates (S-H)	Hypothermia	Ethanol withdrawal	Disorientation
Benzodiazepines (S-H)	Flaccid coma	Hydrocarbon inhalation (abuse)	Panic reaction
Butyrophenones (Syly)	Miosis	Mescaline (peyote)	Toxic psychosis
β-Adrenergic blockers (Syly)	Hypoactive bowel sounds	Mushrooms (psilocybin)	Moist skin
Calcium channel blockers (Syly)		Phencyclidine	Mydriasis (reactive)
Digitalis (Syly)			Hyperthermia
Opioids			Flashbacks
Lithium (mixed)			
Muscle relaxants		<b>Anticholinergics</b>	
Phenothiazines (Syly)		Antihistamines	Tachycardia, dysrhythmias (rare)
Nonbarbiturate/benzodiazepine glutethimide, methaqualone, methyprylon, sedative-hypnotics (chloral hydrate, ethchlorvynol, bromide)		Antispasmodic gastrointestinal preparations	Tachypnea
		Antiparkinsonian preparations	Hypertension (mild)
		Atropine	Hyperthermia
		Cyclobenzaprine (Flexeril)	Hallucinations (“mad as a hatter”)
		Mydriatic ophthalmologic agents	Mydriasis (unreactive) (“blind as a bat”)
Tricyclic antidepressants (late Syly)		<b>Over-the-counter sleep agents</b>	
		Plants ( <i>Datura</i> spp.)/mushrooms	Flushed skin (“red as a beet”)
<b>CNS Stimulants</b>			Dry skin and mouth (“dry as a bone”)
Amphetamines (Sy)	Tachycardia	Phenothiazines (early)	Hypoactive bowel sounds
Anticholinergics*	Tachypnea and dysrhythmias	Scopolamine	Urinary retention
Cocaine (Sy)	Hypertension	Tricyclic/cyclic antidepressants (early)	Lilliputian hallucinations (“little people”)
Camphor (mixed)	Convulsions		
Ergot alkaloids (Sy)	Toxic psychosis	<b>Cholinergics</b>	
Isoniazid (mixed)	Mydriasis (reactive)	Bethanechol (Urecholine)	Bradycardia (muscarinic)
Lithium (mixed)	Agitation and restlessness	Carbamate insecticides (Carbaryl)	Tachycardia (nicotinic effect)
Lysergic acid diethylamide (H)	Moist skin	Edrophonium	Miosis (muscarinic)
Hallucinogens (H)	Tremors	Organophosphate insecticides (Malathion, parathion)	Diarrhea (muscarinic)
Mescaline and synthetic analogues		Parasympathetic agents (physostigmine, pyridostigmine)	Hypertension (variable)
Metals (arsenic, lead, mercury)		Toxic mushrooms ( <i>Clitocybe</i> spp.)	Hyperactive bowel sounds
Methylphenidate (Ritalin) (Sy)			Excess urination (muscarinic)
Monoamine oxidase inhibitors (Sy)			Excess salivation (muscarinic)
Pemoline (Cylert) (Sy)			Lacrimation (muscarinic)
Phencyclidine (H) <sup>†</sup>			Bronchospasm (muscarinic)
Salicylates (mixed)			Muscle fasciculations (nicotinic)
Strychnine (mixed)			Paralysis (nicotinic)
Sympathomimetics (Sy) (phenylpropanolamine, theophylline, caffeine, thyroid)			
Withdrawal from ethanol, β-adrenergic blockers, clonidine, opioids, sedative-hypnotics (W)			

Abbreviations: H = hallucinogen; S-H = sedative-hypnotic; Sy = sympathomimetic; Syly = sympatholytic; W = withdrawal.

\* Anticholinergics produce dry skin and mucosa and decreased bowel sounds.

<sup>†</sup>Phencyclidine may produce miosis.

<sup>‡</sup>The amphetamine hybrids are methylene dioxymethamphetamine (MDMA, ecstasy, “Adam”) and methylene dioxyamphetamine (MDA, “Eve”), which are associated with deaths.

3. Unresponsiveness to verbal stimuli
4. Arterial carbon dioxide pressure greater than 45 mm Hg
5. Cardiac conduction or rhythm disturbances (any rhythm except sinus arrhythmia)
6. Close monitoring of vital signs during antidotal therapy or elimination procedures
7. The need for continuous monitoring
8. QRS interval greater than 0.10 second, in cases of tricyclic antidepressant poisoning
9. Systolic blood pressure less than 80 mm Hg
10. Hypoxia, hypercarbia, acid-base imbalance, or metabolic abnormalities
11. Extremes of temperature
12. Progressive deterioration or significant underlying medical disorders

### Use of Antidotes

Antidotes are available for only a relatively small number of poisons. An antidote is not a substitute for good supportive care. Table 5 summarizes the commonly used antidotes, their indications, and their methods of administration. The Regional Poison Control Center can give further information on these antidotes.

### Enhancement of Elimination

The acceptable methods for elimination of absorbed toxic substances are dialysis, hemoperfusion, exchange transfusion, plasmapheresis, enzyme induction, and inhibition. Methods of increasing urinary excretion of toxic chemicals and drugs have been studied extensively, but the other modalities have not been well evaluated.

In general, these methods are needed in only a minority of cases and should be reserved for life-threatening circumstances when a definite benefit is anticipated.

### Dialysis

Dialysis is the extrarenal means of removing certain substances from the body, and it can substitute for the kidney when renal failure occurs. Dialysis is not the first measure instituted; however, it may be lifesaving later in the course of a severe intoxication. It is needed in only a minority of intoxicated patients.

Peritoneal dialysis uses the peritoneum as the membrane for dialysis. It is only 1/20 as effective as hemodialysis. It is easier to use and less hazardous to the patient but also less effective in removing the toxin; thus it is rarely used except in small infants.

Hemodialysis is the most effective dialysis method but requires experience with sophisticated equipment. Blood is circulated past a semipermeable extracorporeal membrane. Substances are removed by diffusion down a concentration gradient. Anticoagulation with heparin is necessary. Flow rates of 300 to 500 mL/min can be achieved, and clearance rates may reach 200 or 300 mL/min.

Dialyzable substances easily diffuse across the dialysis membrane and have the following characteristics: (a) a molecular weight less than 500 daltons and preferably less than 350; (b) a volume of distribution less than 1 L/kg; (c) protein binding less than 50%; (d) high water solubility (low lipid solubility); and (e) high plasma concentration and a toxicity that correlates reasonably with the plasma concentration. Considerations for hemodialysis and hemoperfusion are cases of serious ingestions (the nephrologist should be notified immediately), and cases involving a compound that is ingested in a potentially lethal dose and the rapid removal of which may improve the prognosis. Examples of the latter are ethylene glycol 1.4 mL/kg 100% solution or equivalent and methanol 6 mL/kg 100% solution or equivalent. Common dialyzable substances include alcohol, bromides, lithium, and salicylates.

The patient-related criteria for dialysis are (a) anticipated prolonged coma and the likelihood of complications; (b) renal

compromise (toxin excreted or metabolized by kidneys and dialyzable chelating agents in heavy metal poisoning); (c) laboratory confirmation of lethal blood concentration; (d) lethal dose poisoning with an agent with delayed toxicity or known to be metabolized into a more toxic metabolite (e.g., ethylene glycol, methanol); and (e) hepatic impairment when the agent is metabolized by the liver, and clinical deterioration despite optimal supportive medical management. Table 6 gives plasma concentrations above which removal by extracorporeal measures should be considered.

The contraindications to hemodialysis include the following: (a) substances are not dialyzable; (b) effective antidotes are available; (c) patient is hemodynamically unstable (e.g., shock); and (d) presence of coagulopathy because heparinization is required.

Hemodialysis also has a role in correcting disturbances that are not amenable to appropriate medical management. These are easily remembered by the “vowel” mnemonic:

A—refractory acid-base disturbances

E—refractory electrolyte disturbances

I—intoxication with dialyzable substances (e.g., ethanol, ethylene glycol, isopropyl alcohol, methanol, lithium, and salicylates)

O—overhydration

U—uremia

Complications of dialysis include hemorrhage, thrombosis, air embolism, hypotension, infections, electrolyte imbalance, thrombocytopenia, and removal of therapeutic medications.

### Hemoperfusion

Hemoperfusion is the parenteral form of oral activated charcoal. Heparinization is necessary. The patient's blood is routed extracorporeally through an outflow arterial catheter with a filter-adsorbing cartridge (charcoal or resin) and returned through a venous catheter. Cartridges must be changed every 4 hours. The blood glucose, electrolytes, calcium, and albumin levels; complete blood cell count; platelets; and serum and urine osmolarity must be carefully monitored. This procedure has extended extracorporeal removal to a large range of substances that were formerly either poorly dialyzable or nondialyzable. It is not limited by molecular weight, water solubility, or protein binding, but it is limited by a volume distribution greater than 400 L, plasma concentration, and rate of flow through the filter. Activated charcoal cartridges are the primary type of hemoperfusion currently available in the United States.

The patient-related criteria for hemoperfusion are (a) anticipated prolonged coma and the likelihood of complications; (b) laboratory confirmation of lethal blood concentrations; (c) hepatic impairment when an agent is metabolized by the liver; and (d) clinical deterioration despite optimally supportive medical management.

The contraindications are similar to those for hemodialysis.

Limited data are available as to which toxins are best treated with hemoperfusion. Hemoperfusion has proved useful in treating glutethimide intoxication, phenobarbital overdose, and carbamazepine, phenytoin, and theophylline intoxication.

Complications include hemorrhage, thrombocytopenia, hypotension, infection, leukopenia, depressed phagocytic activity of granulocytes, decreased immunoglobulin levels, hypoglycemia, hypothermia, hypocalcemia, pulmonary edema, and air and charcoal embolism.

### Hemofiltration

Continuous arteriovenous or venovenous hemodiafiltration (CAVHD or CVVHD, respectively) has been suggested as an alternative to conventional hemodialysis when the need for rapid removal of the drug is less urgent. These procedures, like peritoneal dialysis, are minimally invasive, have no significant impact on hemodynamics, and can be carried out continuously for many hours. Their role in the management of acute poisoning remains uncertain, however.

**TABLE 5** Initial Doses of Antidotes for Common Poisonings

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
<b>N-Acetyl Cysteine (NAC, Mucomyst):</b> Stock level to treat 70 kg adult for 24 h: 25 vials, 20%, 30 mL	Acetaminophen, carbon tetrachloride (experimental)	140 mg/kg loading, followed by 70 mg/kg q4h for 17 doses 150 mg/kg in 200 mL of D <sub>5</sub> W over 1 h, then 50 mg/kg in 1 liter D <sub>5</sub> W over 16 h	PO IV	Nausea, vomiting. Dilute to 5% with sweet juice or flat cola. Useful for those who cannot tolerate oral route.
<b>Atropine:</b> Stock level to treat 70 kg adult for 24 h: 1 g (1 mg/mL in 1, 10 mL)	Organophosphate and carbamate pesticides: bradycardiacs, β-adrenergics, calcium channel blockers/nerve agents	<i>Child:</i> 0.02–0.05 mg/kg repeated q5–10 min to max of 2 mg as necessary until cessation of secretions <i>Adult:</i> 1–2 mg q5–10 min as necessary. Dilute in 1–2 mL of 0.9% saline for ET instillation. <i>IV infusion dose:</i> Place 8 mg of atropine in 100 mL D <sub>5</sub> W or saline. Conc. = 0.08 mg/mL; dose range = 0.02–0.08 mg/kg/h or 0.25–1 mL/kg/h. Severe poisoning may require supplemental doses of IV atropine intermittently in doses of 1–5 mg until drying of secretions occurs.	IV/ET	Tachycardia, dry mouth, blurred vision, and urinary retention. Ensure adequate ventilation before administration.
<b>Calcium Chloride (10%):</b> Stock level to treat 70 kg adult for 24 h: 10 vials 1 g (1.35 mEq/mL)	Hypocalcemia, fluoride, calcium channel blockers, β-blockers, oxalates, ethylene glycol, hypermagnesemia	0.1–0.2 mL/kg (10–20 mg/kg) slow push q10 min up to max 10 mL (1 g). Since calcium response lasts 15 min, some may require continuous infusion 0.2 mL/kg/h up to maximum of 10 mL/h while monitoring for dysrhythmias and hypotension.	IV	Administer slowly with BP and ECG monitoring and have magnesium available to reverse calcium effects. Tissue irritation, hypotension, dysrhythmias from rapid injection. Contraindications: digitalis glycoside intoxication.
<b>Calcium Gluconate (10%):</b> Stock level to treat 70 kg adult for 24 h: 20 vials 1 g (0.45 mEq/mL)	Hypocalcemia, fluoride, calcium channel blockers, hydrofluoric acid; black widow envenomation	0.3–0.4 mL/kg (30–40 mg/kg) slow push; repeat as needed up to max dose 10–20 mL (1–2 g).	IV	Same comments as calcium chloride.
<b>Infiltration of Calcium Gluconate</b>	Hydrofluoric acid skin exposure	Dose: Infiltrate each square cm of affected dermis/subcutaneous tissue with about 0.5 mL of 10% calcium gluconate using a 30-gauge needle. Repeat as needed to control pain.	Infiltrate	
<b>Intra-arterial Calcium Gluconate</b>	Hydrofluoric acid skin exposure	Infuse 20 mL of 10% calcium gluconate (not chloride) diluted in 250 mL D <sub>5</sub> W via the radial or brachial artery proximal to the injury over 3–4 h.		Alternatively, dilute 10 mL of 10% calcium gluconate with 40–50 mL of D <sub>5</sub> W.
<b>Calcium Gluconate Gel:</b> Stock level: 3.5 g	Hydrofluoric acid skin exposure	2.5 g USP powder added to 100 mL water-soluble lubricating jelly, e.g., K-Y jelly or Lubifax (or 3.5 mg into 150 mL). Some use 6 g of calcium carbonate in 100 g of lubricant. Place injured hand in surgical glove filled with gel. Apply q4h. If pain persists, calcium gluconate injection may be needed (above).	Dermal	Powder is available from Spectrum Pharmaceutical Co. in California: 800-772-8786. Commercial preparation of Ca gluconate gel is available from Pharmascience in Montreal, Quebec: 514-340-1114.
<b>Cyanide Antidote Kit:</b> Stock level to treat 70 kg adult for 24 h: 2 Lilly Cyanide Antidote kits	Cyanide Hydrogen sulfide (nitrites are given only)  Do not use sodium thiosulfate for hydrogen sulfide  Individual portions of the kit can be used in certain circumstances (consult PCC)	Amyl nitrite: 1 crushable ampule for 30 sec of every min. Use new amp q3 min.  May omit step if venous access is established.	Inhalation	If methemoglobinemia occurs, do not use methylene blue to correct this because it releases cyanide.

**TABLE 5** Initial Doses of Antidotes for Common Poisonings—cont'd

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
	Cyanide Hydrogen sulfide (nitrites are given only) Do not use sodium thiosulfate for hydrogen sulfide Individual portions of the kit can be used in certain circumstances (consult PCC)	Sodium nitrite: <i>Child</i> : 0.33 mL/kg of 3% solution if hemoglobin level is not known, otherwise based on tables with product. <i>Adult</i> : up to 300 mg (10 mL). Dilute nitrite in 100 mL 0.9% saline, administer slowly at 5 mL/min. Slow infusion if fall in BP.	IV	If methemoglobinemia occurs, do not use methylene blue to correct this because it releases cyanide.
	Do not use sodium thiosulfate for hydrogen sulfide Individual portions of the kit can be used in certain circumstances (consult PCC)	Sodium thiosulfate: <i>Child</i> : 1.6 mL/kg of 25% solution, may be repeated q30–60 min to a maximum of 12.5 g or 50 mL in adult. Administer over 20 min.	IV	Nausea, dizziness, headache. Tachycardia, muscle rigidity, and bronchospasm (rapid administration).
<b>Dantrolene Sodium (Dantrium)</b> : Stock level to treat 70 kg adult for 24 h: 700 mg, 35 vials (20 mg/vial)	Malignant hyperthermia	2–3 mg/kg IV rapidly. Repeat loading dose every 10 min. If necessary up to a maximum total dose of 10 mg/kg. When temperature and heart rate decrease, slow the infusion 1–2 mg/kg q6h for 24–28 h until all evidence of malignant hyperthermia syndrome has subsided. Follow with oral doses 1–2 mg/kg four times a day for 24 h as necessary.	IV/PO	Hepatotoxicity occurs with cumulative dose of 10 mg/kg. Thrombophlebitis (best given in central line). Available as 20 mg lyophilized dantrolene powder for reconstruction, which contains 3 g mannitol and sodium hydroxide in 70-mL vial. Mix with 60 mL sterile distilled water without a bacteriostatic agent and protect from light. Use within 6 hours after reconstituting.
<b>Deferoxamine (Desferal)</b> : Stock level to treat 70 kg adult for 24 h: 17 vials (500 mg/amp)	Iron	IV infusion of 15 mg/kg/h (3 mL/kg/h; 500 mg in 100 mL D <sub>5</sub> W) max 6 g/d Rates of >45 µg/kg/h if conc >1000 µg/dL.	Preferred IV: avoid therapy >24 h	Hypotension (minimized by avoiding rapid infusion rates) DFO challenge test 50 mg/kg is unreliable if negative.
<b>Diazepam (Valium)</b> : Stock level to treat 70 kg adult for 24 h: 200 mg, 5 mg/mL; 2, 10 mL	Any intoxication that provokes seizures when specific therapy is not available (e.g., amphetamines, PCP, barbiturate and alcohol withdrawal) Chloroquine poisoning	<i>Adult</i> , 5–10 mg IV (max 20 mg) at a rate of 5 mg/min until seizure is controlled. May be repeated 2 or 3 times. <i>Child</i> , 0.1–0.3 mg/kg up to 10 mg IV slowly over 2 min.	IV	Confusion, somnolence, coma, hypotension. Intramuscular absorption is erratic. Establish airway and administer 100% oxygen and glucose.
<b>Digoxin-Specific Fab Antibodies (Digibind)</b> : Stock level to treat 70 kg adult for 24 h: 20 vials	Digoxin, digitoxin, oleander tea with the following: (1) Imminent cardiac arrest or shock (2) Hyperkalemia >5.0 mEq/L (3) Serum digoxin >5 ng/mL (child) at 8–12 h post ingestion in adults (4) Digitalis delirium (5) Ingestion over 10 mg in adults or 4 mg in child (6) Bradycardia or second- or third-degree heart block unresponsive to atropine (7) Life-threatening digitoxin or oleander poisoning	(1) If amount ingested is known total dose × bioavailability (0.8) = body burden. The body burden + 0.6 (0.5 mg of digoxin is bound by 1 vial of 38 mg of Fab) = # vials needed. (2) If amount is unknown but the steady state serum concentration is known in ng/mL: Digoxin: ng/mL: (5.6 L/kg Vd) × (wt kg) = µg body burden. Body burden + 100 = mg body burden/0.5 = # vials needed. Digitoxin body burden = ng/mL × (0.56 L/kg Vd) × (wt kg) Body burden + 1000 = mg body burden/0.5 = # vials needed. (3) If the amount is not known, it is administered in life-threatening situations as 10 vials (400 mg) IV in saline over 30 min in adults. If cardiac arrest is imminent, administer 20 vials (adult) as a bolus.	IV	Allergic reactions (rare), return of condition being treated with digitalis glycoside. Administer by infusion over 30 min through a 0.22-µ filter. If cardiac arrest imminent, may administer by bolus. Consult PCC for more details.

*Continued*

<b>Dimercaprol (BAL in Peanut Oil):</b> Stock level to treat 70 kg adult for 24 h: 1200 mg (4 amps—100 mg/mL 10% in oil in 3 mL amp)	Chelating agent for arsenic, mercury, and lead	3–5 mg/kg q4h usually for 5–10 d	Deep IM	Local infection site pain and sterile abscess, nausea, vomiting, fever, salivation, hypertension, and nephrotoxicity (alkalinize urine).
<b>2,3 Dimercaptosuccinic Acid (DMSA Succimer):</b> 100 mg/capsule: 20 capsules	Used as a chelating agent for lead, especially blood lead levels >45 µg/dL. May also be used for symptomatic mercury exposure	10 mg/kg 3 × daily for 5 days followed by 10 mg/kg 2 × daily for 14 days	PO	Precautions: monitor AST/ALT; use with caution in G6PD-deficient patients. Avoid concurrent iron therapy. Relatively safe antidote, rarely severe, uncommon minor skin rashes may occur.
<b>Diphenhydramine (Benadryl):</b> Antiparkinsonian action. Stock level to treat a 70 kg adult for 24 h: 5 vials (10 mg/mL, 10 mL each)	Used to treat extrapyramidal symptoms and dystonia induced by phenothiazines, phencyclidine, and related drugs	<i>Children:</i> 1–2 mg/kg IV slowly over 5 min up to maximum 50 mg followed by 5 mg/kg/24 h orally divided every 6 h up to 300 mg/24 h <i>Adults:</i> 50 mg IV followed by 50 mg orally four times daily for 5–7 d. <i>Note:</i> Symptoms abate within 2–5 min after IV.	IV	Fatal dose: 20–40 mg/kg. Dry mouth, drowsiness.
<b>Ethanol (Ethyl Alcohol):</b> Stock level to treat 70 kg adult for 24 h: 3 bottles 10% (1 L each)	Methanol, ethylene glycol	10 mL/kg loading dose concurrently with 1.4 mL/kg (average) infusion of 10% ethanol (consult PCC for more details)	IV	Nausea, vomiting, sedation. Use 0.22-µ filter if preparing from bulk 100% ethanol.
<b>Flumazenil (Romazicon):</b> Stock level to treat 70 kg adult for 24 h: 4 vials (0.1 mg/mL, 10 mL)	Benzodiazepines (may also be beneficial in the treatment of hepatic encephalopathy)	Administer 0.2 mg (2 mL) IV over 30 sec (pediatric dose not established, 0.01 mg/kg), then wait 3 min for a response, then if desired consciousness is not achieved, administer 0.3 mg (3 mL) over 30 sec, then wait 3 min for response, then if desired consciousness is not achieved, administer 0.5 mg (5 mL) over 30 sec at 60-sec intervals up to a maximum cumulative dose of 3 mg (30 mL) (1 mg in children). Because effects last only 1–5 h, if patient responds, monitor carefully over next 6 h for re sedation. If multiple repeated doses, consider a continuous infusion of 0.2–1 mg/h.	IV	Nausea, vomiting, facial flushing, agitation, headache, dizziness, seizures, and death. It is not recommended to improve ventilation. Its role in CNS depression needs to be clarified. It should not be used routinely in comatose patients. It is <b>contraindicated</b> in cyclic antidepressant intoxications, stimulant overdose, long-term benzodiazepine use (may precipitate life-threatening withdrawal), if benzodiazepines are used to control seizures, in head trauma.
<b>Folic Acid (Folvite):</b> Stock level to treat 70 kg adult for 24 h: 4 100-mg vials	Methanol/ethylene glycol (investigational)	1 mg/kg up to 50 mg q4h for 6 doses	IV	Uncommon
<b>Fomepizole (4-MP, Antizol):</b> Stock level to treat 70 kg adult: 4 1.5-mL vials (1 g/mL)	Ethylene glycol  Methanol	Loading dose: 15 mg/kg (0.015 mL/kg) IV followed by maintenance dose of 10 mg/kg (0.01 mL/kg) q12h for 4 doses, then 15 mg/kg q12h until ethylene glycol levels are <20 mg/dL. Fomepizole can be given to patients undergoing hemodialysis (dose q4h).	IV	Suggested: co-administer folate 50 mg IV (child 1 mg/kg), thiamine 100 mg/d (child 50 mg), and pyridoxine 50 mg IV/IM q6h until intoxication is resolved. Monitor for urinary oxalate crystals. Adverse reactions include headache, nausea, and dizziness. Antizole should be diluted in 100 mL 0.9% saline or D <sub>5</sub> W and mixed well. Antizole should not be given undiluted.

**TABLE 5** Initial Doses of Antidotes for Common Poisonings—cont'd

ANTIDOTE	USE	DOSE	ROUTE	ADVERSE REACTIONS/COMMENTS
<b>Glucagon:</b> Stock level to treat 70 kg adult for 24 h: 10 vials, 10 units	β-Blocker, calcium channel blocker	3–10 mg in adult, then infuse 2–5 mg/h (0.05–0.1 mg/kg in child, then infuse 0.07 mg/kg/h) Large doses up to 100 mg/24 h used	IV	Use D <sub>5</sub> W, not 0.9% saline, to reconstitute the glucagon (rather than diluent of Eli Lilly, which contains phenol). Vomiting precautions.
<b>Magnesium Sulfate:</b> Stock level to treat 70 kg adult for 24 h: approx 25 g (50 mL of 50% or 200 mL of 12.5%)	Torsades de pointes	<i>Adult:</i> 2 g (20 mL or 20%) over 20 min. If no response in 10 min, repeat and follow by continuous infusion 1 g/h. <i>Children:</i> 25–50 mg/kg initially and maintenance is 30–60 mg/kg/24 h (0.25–0.5 mEq/kg/24 h) up to 1000 mg/24 h. (Dose not studied in controlled fashion.)	IV	Use with caution if renal impairment is present.
<b>Methylene Blue:</b> Stock level to treat 70 kg adult for 24 h: 5 amps (10 mg/10 mL)	Methemoglobinemia	0.1–0.2 mL/kg of 1% solution, slow infusion, may be repeated q30–60 min	IV	Nausea, vomiting, headache, dizziness.
<b>Naloxone (Narcan):</b> Stock level to treat 70 kg adult for 24 h: 3 vials (1 mg/mL, 10 mL)	Comatose patient; decreased respirations <12; opioids	In postoperative opioid depression reversal, IV 0.1–0.5 μg/kg q2 min as needed and may repeat up to a total dose of 1 μg/kg In <b>suspected overdose</b> , administer IV 0.1 mg/kg in a child younger than 5 years of age up to 2 mg; in older children and adults administer 2 mg every 2 min up to a total of 10–20 mg. Can also be administered into the endotracheal tube. If no response by 10 mg, a pure opioid intoxication is unlikely. If <b>opioid abuse</b> is suspected, <b>restraints</b> should be in place before administration; <b>initial dose</b> 0.1 mg to avoid withdrawal and violent behavior. The initial dose is then doubled every minute progressively to a total of 10 mg. A <b>continuous infusion</b> has been advocated because many opioids outlast the short half-life of naloxone (30–60 min). The <b>naloxone infusion hourly rate</b> to produce a response is equal to the effective dose required (improvement in ventilation and arousal). An additional dose may be required in 15–30 min as a bolus.	IV, ET	<b>Larger doses</b> of naloxone may be required for more poorly antagonized synthetic opioid drugs: buprenorphine (Buprenex), codeine, dextromethorphan, fentanyl, pentazocine (Talwin), propoxyphene (Darvon), diphenoxylate, nalbuphine (Nubain), new potent “designer” drugs, or long-acting opioids such as methadone (Dolophine). <b>Complications.</b> Although naloxone is safe and effective, there are rare reports of complications (<1%) of pulmonary edema, seizures, hypertension, cardiac arrest, and sudden death. The infusions are titrated to avoid respiratory depression and opioid withdrawal manifestations. Tapering of infusions can be attempted after 12 h and when the patient is stable.
<b>Physostigmine (Antilirium):</b> Stock level to treat 70 kg adult for 24 h: 2–4 mg (2 mL each)	Anticholinergic agents (not routinely used, only indicated if life-threatening complications)	<i>Child:</i> 0.02 mg/kg slow push to max 2 mg q30–60 min <i>Adult:</i> 1–2 mg q5 min to max 6 mg.	IV	Bradycardia, asystole, seizures, bronchospasm, vomiting, headaches. Do not use for cyclic antidepressants.
<b>Pralidoxime (2PAM, Protopan):</b> Stock level to treat 70 kg adult for 24 h: 12 vials (1 g per 20 mL)	Organophosphates/nerve agents	Child ≤12 y, 25–50 mg/kg max (4 mg/min); >12 y, 1–2 g/dose in 250 mL of 0.9% saline over 5–10 min. Max 200 mg/min. Repeat q6–12 h for 24–48 h. Max adult 6 g/d. Alternative: Maintenance infusion 1 g in 100 mL, of 0.9% saline at 5–20 mg/kg/h (0.5–12 mL/kg/h) up to max 500 mg/h or 50 mL/h. Titrate to desired response. End point is absence of fasciculations and return of muscle strength.	IV	Nausea, dizziness, headache; tachycardia, muscle rigidity, bronchospasm (rapid administration).
<b>Pyridoxine (Vitamin B<sub>6</sub>):</b> Stock level to treat 70 kg adult for 24 h: 100 mg/mL 10% solution. For a 70 kg patient, 10 g = 10 vials	Seizures from isoniazid or <i>Gyromitra</i> mushrooms, ethylene glycol	<i>Isoniazid: Unknown amount ingested:</i> 5 g (70 mg/kg) in 50 mL D <sub>5</sub> W over 5 min + diazepam 0.3 mg/kg IV at rate of 1 mg/min in child or 10 mg dose at rate up to 5 mg/min in adults. Use different site (synergism). May repeat q5–20 min until seizure controlled. Up to 375 mg/kg have been given (52 g). <i>Known amount:</i> 1 g for each gram isoniazid ingested over 5 min with diazepam (dose above) <i>Gyromitra mushroom:</i> Child 25 mg/kg or 2–5 g, adults IV over 15–30 min to max 20 g	IV	After seizure is controlled, administer remainder of pyridoxine 1 g/1 g isoniazid total 5 g as infusion over 60 min. Adverse reactions uncommon; do not administer in same bottle as sodium bicarbonate. For <i>Gyromitra</i> mushrooms, some use PO 25 mg/kg/d early when mushroom ingestion is suspected.

*Continued*

<b>Sodium Bicarbonate</b> ( $\text{NaHCO}_3$ ): Stock level to treat 70 kg adult for 24 h: 10 ampules or syringes (500 mEq)	Tricyclic antidepressant cardiotoxicity (QRS >0.12 sec; ventricular tachycardia, severe conduction disturbances); metabolic acidosis: phenothiazine toxicity <i>Salicylate</i> : to keep blood pH 7.5–7.55 (not >7.55) and urine pH 7.5–8.0. Alkalinization recommended if salicylate conc. >40 mg/dL in acute poisoning and at lower levels if symptomatic in chronic intoxication, 2 mEq/kg will raise blood pH 0.1 unit	<i>Ethylene glycol</i> : 100 mg IV daily. 1–2 mEq/kg undiluted as a bolus. If no effect on cardiotoxicity, repeat twice a few minutes apart <i>Adult</i> with clear physical signs and laboratory findings of acute moderate or severe salicylism: Bolus 1–2 mEq/kg followed by infusion of 100–150 mEq $\text{NaHCO}_3$ added to 1 L of 5% dextrose at rate of 200–300 mL/h <i>Child</i> : Bolus same as adult followed by 1–2 mEq/kg in infusion of 20 mL/kg/h 5% dextrose in 0.45% saline Add potassium when patient voids Rate and amount of the initial infusion, if patient is volume depleted: 1 h to achieve urine output of 2 mL/kg/h and urine pH 7–8 In mild cases without acidosis and urine pH >6, administer 5% dextrose in 0.9% saline with 50 mEq/L or 1 mEq/kg $\text{NaHCO}_3$ as maintenance to replace ongoing renal losses. If acidemia is present and pH <7.2, add 2 mEq/kg as loading dose followed by 2 mEq/kg q3–4h to keep pH at 7.5–7.55. If acidemia is present, recommend isotonic $\text{NaHCO}_3$ , 3 ampules to 1 L of D <sub>5</sub> W at 10–15 mL/kg/h or sufficient to produce normal urine flow and a urine pH of 7.5 or higher	IV	Monitor sodium, potassium, and blood pH because fatal alkalemia and hyponatremia have been reported. Monitor both urine and blood pH. Do not use the urine pH alone to assess the need for alkalinization because of the paradoxical aciduria that may occur. Adjust the urine pH to 7.5–8 by $\text{NaHCO}_3$ infusion. After urine output established, add potassium 40 mEq/L.
	<i>Long-acting barbiturates</i> : Phenobarbital and primidone (Mysoline). <i>Note</i> : Alkalinization is ineffective for the short- or intermediate-acting barbiturates	$\text{NaHCO}_3$ : 2 mEq/kg during the first hour or 100 mEq in 1 L of D <sub>5</sub> W with 40 mEq/L potassium at a rate of 100 mL/h in adults Adequate potassium is necessary to accomplish alkalinization	IV	Additional sodium bicarbonate and potassium chloride may be needed. Adjust the urine pH to 7.5–8 by $\text{NaHCO}_3$ infusion.
<b>Thiamine</b> : 100 mg/mL, 2 vials	Thiamine deficiency, ethylene glycol poisoning, alcoholism	100 mg IV followed with 100 mg V/IM for 5–7 days in an alcoholic and followed by 100 mg/d orally	IV/IM	
<b>Vitamin K1 (Aqua Mephyton)</b> : 10 mg/1–5 mL; 5-mg tablets	Warfarin anticoagulant or rodenticide toxicity	Oral 0.4 mg/kg/dose child, 10–25 mg adults. If evidence of bleeding, administer vitamin K <sub>1</sub> SC, IV 0.6 mg/kg/dose child and up to 25–50 mg adults for 6 hours depending on severity	PO/SC, IV	Give vitamin K daily until PT/INR are normal. Examine stools and urine for evidence of bleeding.

*Abbreviations*: ALT = alanine aminotransferase; amp = ampule; AST = aspartate aminotransferase; BAL = British anti-Lewisite; BP = blood pressure; conc. = concentration; ECG = electrocardiogram; ET = endotracheal; G6PD = glucose-6-phosphate dehydrogenase; IM = intramuscular; IV = intravenous; PCC = poison control center; PO = oral; PT = prothrombin time; SC = subcutaneous.

**TABLE 6** Plasma Concentrations Above Which Removal by Extracorporeal Measures Should Be Considered

DRUG	PLASMA CONCENTRATION	PROTEIN BINDING (%)	VOLUME DISTRIBUTION (L/KG)	METHOD OF CHOICE
Amanitin	NA	25	1.0	HP
Ethanol	500–700 mg/dL	0	0.3	HD
Ethchlorvynol	150 µg/mL	35–50	3–4	HP
Ethylene glycol	25–50 µg/mL	0	0.6	HD
Glutethimide	100 µg/mL	50	2.7	HP
Isopropyl alcohol	400 mg/dL	0	0.7	HD

Meprobamate (Equanil)	100 µg/mL	0	NA	HP
Methanol	50 mg/dL	0	0.7	HD
Methaqualone	40 µg/dL	20–60	6.0	HP
Other barbiturates	50 µg/dL	50	0–1	HP
Paraquat	0.1 mg/dL	poor	2.8	HP > HD
Phenobarbital	100 µg/dL	50	0.9	HP > HD
Salicylates	80–100 mg/dL	90	0.2	HD > HP
Theophylline		0	0.5	
Chronic	40–60 µg/mL			HP
Acute	80–100 µg/mL			HP
Trichlorethanol	250 µg/mL	70	0.6	HP

*Abbreviations:* HD = hemodialysis; HP = hemoperfusion; HP > HD = hemoperfusion preferred over hemodialysis.

Data from Winchester JF: Active methods for detoxification. In Haddad LM, Winchester JF (eds). *Clinical Management of Poisoning and Drug Overdose*, 2nd ed. Philadelphia, WB Saunders, 1990; Balsam L, Cortisidis GN, Fienfeld DA: Role of hemodialysis and hemoperfusion in the treatment of intoxications. *Contemp Manage Crit Care* 1:61, 1991.

*Note:* Cartridges for charcoal hemoperfusion are not readily available anymore in most locations. So hemodialysis may be substituted in these situations. In mixed or chronic drug overdoses, extracorporeal measures may be considered at lower drug concentrations.

### Plasmapheresis

Plasmapheresis consists of removal of a volume of blood. All the extracted components are returned to the blood except the plasma, which is replaced with a colloid protein solution. There are limited clinical data on guidelines and efficacy in toxicology. Centrifugal and membrane separators of cellular elements are used. It can be as effective as hemodialysis or hemoperfusion for removing toxins that have high protein binding, and it may be useful for toxins not filtered by hemodialysis and hemoperfusion.

Plasmapheresis has been anecdotally used in treating intoxications with the following agents: paraquat (removed 10%), propranolol (removed 30%), quinine (removed 10%), L-thyroxine (removed 30%), and salicylate (removed 10%). It has been shown to remove less than 10% of digoxin, phenobarbital, prednisolone, and tobramycin. Complications include infection; allergic reactions including anaphylaxis; hemorrhagic disorders; thrombocytopenia; embolus and thrombus; hypervolemia and hypovolemia; dysrhythmias; syncope; tetany; paresthesia; pneumothorax; acute respiratory distress syndrome; and seizures.

### Supportive Care, Observation, and Therapy for Complications

#### Altered Mental Status

If airway protective reflexes are absent, endotracheal intubation is indicated for a comatose patient or a patient with altered mental status. If respirations are ineffective, ventilation should be instituted, and if hypoxemia persists, supplemental oxygen is indicated. If a cyanotic patient fails to respond to oxygen, the practitioner should consider methemoglobinemia.

### Hypoglycemia

Hypoglycemia accompanies many poisonings, including with ethanol (especially in children), clonidine (Catapres), insulin, organophosphates, salicylates, sulfonylureas, and the unripe fruit or seed of a Jamaican plant called ackee. If hypoglycemia is present or suspected, glucose should be administered immediately as an intravenous bolus. Doses are as follows: in a neonate, 10% glucose (5 mL/kg); in a child, 25% glucose 0.25 g/kg (2 mL/kg); and in an adult, 50% glucose 0.5 g/kg (1 mL/kg).

A bedside capillary test for blood glucose is performed to detect hypoglycemia, and the sample is sent to the laboratory for confirmation. If the glucose reagent strip visually reads less than 150 mg/dL, one administers glucose. Venous blood should be used rather than capillary blood for the bedside test if the patient is in shock or is hypotensive. Large amounts of glucose given rapidly to nondiabetic patients may cause a transient reactive hypoglycemia and hyperkalemia and may accentuate damage in ischemic cerebrovascular and cardiac tissue. If focal neurologic signs are present, it may be prudent to withhold glucose, because hypoglycemia causes focal signs in less than 10% of cases.

### Thiamine Deficiency Encephalopathy

Thiamine is administered to avoid precipitating thiamine deficiency encephalopathy (Wernicke-Korsakoff syndrome) in alcohol abusers and in malnourished patients. The overall incidence of thiamine deficiency in ethanol abusers is 12%. Thiamine 100 mg intravenously should be administered around the time of the glucose administration but not necessarily before the glucose. The clinician should be prepared to manage the anaphylaxis that sometimes is caused by thiamine, although it is extremely rare.

## Opioid Reactions

Naloxone (Narcan) reverses CNS and respiratory depression, miosis, bradycardia, and decreased gastrointestinal peristalsis caused by opioids acting through  $\mu$ ,  $\kappa$ , and  $\delta$  receptors. It also affects endogenous opioid peptides (endorphins and enkephalins), which accounts for the variable responses reported in patients with intoxications from ethanol, benzodiazepines, clonidine (Catapres), captopril (Capoten), and valproic acid (Depakote) and in patients with spinal cord injuries. There is a high sensitivity for predicting a response if pinpoint pupils and circumstantial evidence of opioid abuse (e.g., track marks) are present.

In cases of suspected overdose, naloxone 0.1 mg/kg is administered intravenously initially in a child younger than 5 years of age. The dose can be repeated in 2 minutes, if necessary up to a total dose of 2 mg. In older children and adults, the dose is 2 mg every 2 minutes for five doses up to a total of 10 mg. Naloxone can also be administered into an endotracheal tube if intravenous access is unavailable. If there is no response after 10 mg, a pure opioid intoxication is unlikely. If opioid abuse is suspected, restraints should be in place before the administration of naloxone, and it is recommended that the initial dose be 0.1 to 0.2 mg to avoid withdrawal and violent behavior. The initial dose is then doubled every minute progressively to a total of 10 mg. Naloxone may unmask concomitant sympatho-mimetic intoxication as well as withdrawal.

Larger doses of naloxone may be required for more poorly antagonized synthetic opioid drugs: buprenorphine (Buprenex), codeine, dextromethorphan, fentanyl and its derivatives, pentazocine (Talwin), propoxyphene (Darvon), diphenoxylate, nalbuphine (Nubain), and long-acting opioids such as methadone (Dolophine).

Indications for a continuous infusion include a second dose for recurrent respiratory depression, exposure to poorly antagonized opioids, a large overdose, and decreased opioid metabolism, as with impaired liver function. A continuous infusion has been advocated because many opioids outlast the short half-life of naloxone (30 to 60 minutes). The hourly rate of naloxone infusion is equal to the effective dose required to produce a response (improvement in ventilation and arousal). An additional dose may be required in 15 to 30 minutes as a bolus. The infusions are titrated to avoid respiratory depression and opioid withdrawal manifestations. Tapering of infusions can be attempted after 12 hours and when the patient's condition has been stabilized.

Although naloxone is safe and effective, there are rare reports of complications (less than 1%) of pulmonary edema, seizures, hypertension, cardiac arrest, and sudden death.

## Agents Whose Roles Are Not Clarified

Nalmefene (Revex), a long-acting parenteral opioid antagonist that the FDA has approved, is undergoing investigation, but its role in the treatment of comatose patients and patients with opioid overdose is not clear. It is 16 times more potent than naloxone, and its duration of action is up to 8 hours (half-life 10.8 hours, versus naloxone 1 hour).

Flumazenil (Romazicon) is a pure competitive benzodiazepine antagonist. It has been demonstrated to be safe and effective for reversing benzodiazepine-induced sedation. It is not recommended to improve ventilation. Its role in cases of CNS depression needs to be clarified. It should not be used routinely in comatose patients and is not an essential ingredient of the coma therapeutic regimen. It is contraindicated in cases of co-ingestion of cyclic antidepressant intoxication, stimulant overdose, and long-term benzodiazepine use (may precipitate life-threatening withdrawal) if benzodiazepines are used to control seizures. There is a concern about the potential for seizures and cardiac dysrhythmias that may occur in these settings.

## Laboratory and Radiographic Studies

An electrocardiogram (ECG) should be obtained to identify dysrhythmias or conduction delays from cardiotoxic

medications. If aspiration pneumonia (history of loss of consciousness, unarousable state, vomiting) or noncardiac pulmonary edema is suspected, a chest radiograph is needed. Electrolyte and glucose concentrations in the blood, the anion gap, acid-base balance, the arterial blood gas (ABG) profile (if patient has respiratory distress or altered mental status), and serum osmolality should be measured if a toxic alcohol ingestion is suspected. Table 7 lists appropriate testing on the basis of clinical toxicologic presentation. All laboratory specimens should be carefully labeled, including time and date. For potential legal cases, a "chain of custody" must be established. Assessment of the laboratory studies may provide a clue to the etiologic agent.

## Electrolyte, Acid-Base, and Osmolality Disturbances

Electrolyte and acid-base disturbances should be evaluated and corrected. Metabolic acidosis (usually low or normal pH with a low or normal/high  $\text{PaCO}_2$  and low  $\text{HCO}_3^-$ ) with an increased anion gap (AG) is seen with many agents in cases of overdose.

The AG is an estimate of those anions other than chloride and  $\text{HCO}_3^-$  necessary to counterbalance the positive charge of sodium. It serves as a clue to causes, compensations, and complications. The AG is calculated from the standard serum electrolytes by subtracting the total  $\text{CO}_2$  (which reflects the actual measured bicarbonate) and chloride from the sodium:  $(\text{Na} - [\text{Cl} + \text{HCO}_3^-]) = \text{AG}$ . The potassium is usually not used in the calculation because it may be hemolyzed and is an intracellular cation. The lack of anion gap does not exclude a toxic etiology.

The normal gap is usually 7 to 11 mEq/L by flame photometer. However, there has been a "lowering" of the normal AG to  $7 \pm 4$  mEq/L by the newer techniques (e.g., ion selective electrodes or colorimetric titration). Some studies have found AGs to be relatively insensitive for determining the presence of toxins.

It is important to recognize anion gap toxins, such as salicylates, methanol, and ethylene glycol, because they have specific antidotes, and hemodialysis is effective in management of cases of overdose with these agents.

Table 8 lists the reasons for increased AG, decreased anion gap, or no gap. The most common cause of a decreased AG is

**TABLE 7** Patient Condition/Systemic Toxin and Appropriate Tests

CONDITION	TESTS
Comatose	Toxicologic tests (acetaminophen, sedative-hypnotic, ethanol, opioids, benzodiazepine), glucose.
Respiratory toxicity	Spirometry, FEV <sub>1</sub> , arterial blood gases, chest radiograph, monitor O <sub>2</sub> saturation
Cardiac toxicity	ECG 12-lead and monitoring, echocardiogram, serial cardiac enzymes (if evidence or suspicion of a myocardial infarction), hemodynamic monitoring
Hepatic toxicity	Enzymes (AST, ALT, GGT), ammonia, albumin, bilirubin, glucose, PT, PTT, amylase
Nephrotoxicity	BUN, creatinine, electrolytes (Na, F, Mg, Ca, PO <sub>4</sub> ), serum and urine osmolality, 24-hour urine for heavy metals if suspected, creatine kinase, serum and urine myoglobin, urinalysis and urinary sodium
Bleeding	Platelets, PT, PTT, bleeding time, fibrin split products, fibrinogen, type and match

*Abbreviations:* ALT = alanine transaminase; AST = aspartate transaminase; BUN = blood urea nitrogen; ECG = electrocardiogram; FEV<sub>1</sub> = forced expiratory volume in 1 second; GGT =  $\gamma$ -glutamyltransferase; PT = prothrombin time; PTT = partial thromboplastin time.

**TABLE 8** Etiologies of Metabolic Acidosis

NORMAL ANION GAP HYPERCHLOREMIC	INCREASED ANION GAP NORMOCHLOREMIC	DECREASED ANION GAP
Acidifying agents	Methanol	Laboratory error <sup>†</sup>
Adrenal insufficiency	Uremia*	Intoxication—bromine, lithium
Anhydrase inhibitors	Diabetic ketoacidosis*	Protein abnormal

Osteotomies	Isoniazid	
Obstructive uropathies	Iron	
Renal tubular acidosis	Lactic acidosis <sup>†</sup>	
Diarrhea, uncomplicated*	Ethanol,* ethylene glycol*	
Dilutional	Salicylates, starvation solvents	
Sulfamylon		

\*Indicates hyperosmolar situation. Studies have found that the anion gap may be relatively insensitive for determining the presence of toxins.

<sup>†</sup>Lactic acidosis can be produced by intoxications of the following: carbon monoxide, cyanide, hydrogen sulfide, hypoxia, ibuprofen, iron, isoniazid, phenformin, salicylates, seizures, theophylline.

laboratory error. Lactic acidosis produces the largest AG and can result from any poisoning that results in hypoxia, hypoglycemia, or convulsions.

Table 9 lists other blood chemistry derangements that suggest certain intoxications.

Serum osmolality is a measure of the number of molecules of solute per kilogram of solvent, or mOsm/kg water. The osmolality is molecules of solute per liter of solution, or mOsm/L water at a specified temperature. Osmolarity is usually the calculated value and osmolality is usually a measured value. They are considered interchangeable where 1 L equals 1 kg. The normal serum osmolality is 280 to 290 mOsm/kg. The freezing point serum osmolality measurement specimen and the serum electrolyte specimens for calculation should be drawn simultaneously.

The serum osmolal gap is defined as the difference between the measured osmolality determined by the freezing point method and the calculated osmolality. It is determined by the following formula (BUN is blood urea nitrogen):

$$(\text{Sodium} \times 2) + (\text{BUN}/3) + (\text{Glucose}/20)$$

This gap estimate is normally within 10 mOsm of the simultaneously measured serum osmolality. Ethanol, if present, may be included in the equation to eliminate its influence on the osmolal gap (the ethanol concentration divided by 4.6; Table 10).

The osmolal gap is not valid in cases of shock and postmortem state. Metabolic disorders such as hyperglycemia, uremia, and dehydration increase the osmolality but usually do not cause gaps greater than 10 mOsm/kg. A gap greater than 10 mOsm/mL suggests that unidentified osmolal-acting substances are present: acetone, ethanol, ethylene glycol, glycerin, isopropyl alcohol, isoniazid, ethanol, mannitol, methanol, and trichloroethane. Alcohols and glycols should be sought when the degree of obtundation exceeds that expected from the blood ethanol concentration or when other clinical conditions exist: visual loss (methanol), metabolic acidosis (methanol and ethylene glycol), or renal failure (ethylene glycol).

A falsely elevated osmolal gap can be produced by other low molecular weight un-ionized substances (dextran, diuretics, sorbitol, ketones), hyperlipidemia, and unmeasured electrolytes (e.g., magnesium).

Note: A normal osmolal gap may be reported in the presence of toxic alcohol or glycol poisoning, if the parent compound is already metabolized. This situation can occur when the osmolal gap is measured after a significant time has elapsed since the ingestion. In cases of alcohol and glycol intoxication, an early osmolal gap is a result of the relatively nontoxic parent drug and delayed metabolic acidosis, and an anion gap is a

**TABLE 9** Blood Chemistry Derangements in Toxicology

DERANGEMENT	TOXIN
Acetonemia without acidosis	Acetone or isopropyl alcohol
Hypomagnesemia	Ethanol, digitalis
Hypocalcemia	Ethylene glycol, oxalate, fluoride
Hyperkalemia	β-Blockers, acute digitalis, renal failure
Hypokalemia	Diuretics, salicylism, sympathomimetics, theophylline, corticosteroids, chronic digitalis
Hyperglycemia	Diazoxide, glucagon, iron, isoniazid, organophosphate insecticides, phenylurea insecticides, phenytoin (Dilantin), salicylates, sympathomimetic agents, thyroid vasopressors
Hypoglycemia	β-Blockers, ethanol, insulin, isoniazid, oral hypoglycemic agents, salicylates
Rhabdomyolysis	Amphetamines, ethanol, cocaine, or phencyclidine, elevated creatine phosphokinase

**TABLE 10** Conversion Factors for Alcohols and Glycols

ALCOHOLS/ GLYCOLS	1 MG/DL IN BLOOD RAISES OSMOLALITY MOSM/L	MOLECULAR WEIGHT	CONVERSION FACTOR
Ethanol	0.228	40	4.6
Methanol	0.327	32	3.2
Ethylene glycol	0.190	62	6.2
Isopropanol	0.176	60	6.0
Acetone	0.182	58	5.8
Propylene glycol	NA	72	7.2

Example: Methanol osmolality. Subtract the calculated osmolality from the measured serum osmolality (freezing point method) = osmolal gap × 3.2 (one-tenth molecular weight) = estimated serum methanol concentration.

Note: This equation is often not considered very reliable in predicting the actual measured blood concentration of these alcohols or glycols.

result of the more toxic metabolites. The serum concentration is calculated as

$$\text{mg/dL} = \text{mOsm gap} \times \text{MW of substance divided by } 10.$$

### Radiographic Studies

Chest and neck radiographs are useful for suspected pathologic conditions such as aspiration pneumonia, pulmonary edema, and foreign bodies and to determine the location of the endotracheal tube. Abdominal radiographs can be used to detect radiopaque substances.

The mnemonic for radiopaque substances seen on abdominal radiographs is CHIPES:

C—chlorides and chloral hydrate

H—heavy metals (arsenic, barium, iron, lead, mercury, zinc)

I—iodides

P—PlayDoh, Pepto-Bismol, phenothiazine (inconsistent)

E—enteric-coated tablets

S—sodium, potassium, and other elements in tablet form (bismuth, calcium, potassium) and solvents containing chlorides (e.g., carbon tetrachloride)

### Toxicologic Studies

Routine blood and urine screening is of little practical value in the initial care of the poisoned patient. Specific toxicologic analyses and quantitative levels of certain drugs may be extremely helpful. One should always ask oneself the following questions: (a) How will the result of the test alter the management? and (b) Can the result of the test be returned in time to have a positive effect on therapy?

Owing to long turnaround time, lack of availability, factors contributing to unreliability, and the risk of serious morbidity without supportive clinical management, toxicology screening is estimated to affect management in less than 15% of cases of drug overdoses or poisonings. Toxicology screening may look specifically for only 40 to 50 drugs out of more than 10,000 possible drugs or toxins and more than several million chemicals. To detect many different drugs, toxic screens usually include methods with broad specificity, and sensitivity may be poor for some drugs, resulting in false-negative or false-positive findings. On the other hand, some drugs present in therapeutic amounts may be detected on the screen, even though they are causing no clinical symptoms. Because many agents are not sought or detected during a toxicologic screening, a negative result does not always rule out poisonings. The specificity of toxicologic tests is dependent on the method and the laboratory. The presence of other drugs, drug metabolites, disease states, or incorrect sampling may cause erroneous results.

For the average toxicologic laboratory, false-negative results occur at a rate of 10% to 30% and false-positives at a rate of 0% to 10%. The positive screen predictive value is approximately 90%. A negative toxicology screen does not exclude a poisoning. The negative predictive value of toxicologic screening is approximately 70%. For example, the following benzodiazepines may not be detected by some routine immunoassay benzodiazepine screening tests: alprazolam (Xanax), clonazepam (Klonopin), temazepam (Restoril), and triazolam (Halcion).

The “toxic urine screen” is generally a qualitative urine test for several common drugs, usually substances of abuse (cocaine and metabolites, opioids, amphetamines, benzodiazepines, barbiturates, and phencyclidine). Results of these tests are usually available within 2 to 6 hours. Because these tests may vary with each hospital and community, the physician should determine exactly which substances are included in the toxic urine screen of his or her laboratory. Tests for ethylene glycol, red blood cell cholinesterase, and serum cyanide are not readily available.

For cases of ingestion of certain substances, quantitative blood levels should be obtained at specific times after the ingestion to avoid spurious low values in the distribution phase, which result from incomplete absorption. The detection time for drugs is influenced by many variables, such as type of substance, formulation,

amount, time since ingestion, duration of exposure, and half-life. For many drugs, the detection time is measured in days after the exposure.

### Common Poisons

#### Acetaminophen (Paracetamol, *N*-Acetyl-Paraaminophenol)

##### *Toxic Mechanism*

At therapeutic doses of acetaminophen, less than 5% is metabolized by P450-2E1 to a toxic reactive oxidizing metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). In a case of overdose, there is insufficient glutathione available to reduce the excess NAPQI into nontoxic conjugate, so it forms covalent bonds with hepatic intracellular proteins to produce centrilobular necrosis. Renal damage is caused by a similar mechanism.

##### *Toxic Dose*

The therapeutic dose of acetaminophen is 10 to 15 mg/kg, with a maximum of five doses in 24 hours for a maximum total daily dose of 4 g. An acute single toxic dose is greater than 140 mg/kg, possibly greater than 200 mg/kg in a child younger than age 5 years. Factors affecting the P450 enzymes include enzyme inducers such as barbiturates and phenytoin (Dilantin), ingestion of isoniazid, and alcoholism. Factors that decrease glutathione stores (alcoholism, malnutrition, and HIV infection) contribute to the toxicity of acetaminophen. Alcoholics ingesting 3 to 4 g/d of acetaminophen for a few days can have depleted glutathione stores and require *N*-acetylcysteine therapy at 50% below hepatotoxic blood acetaminophen levels on the nomogram.

##### *Kinetics*

Peak plasma concentration is usually reached 2 to 4 hours after an overdose. Volume distribution is 0.9 L/kg, and protein binding is less than 50% (albumin).

Route of elimination is by hepatic metabolism to an inactive nontoxic glucuronide conjugate and inactive nontoxic sulfate metabolite by two saturable pathways; less than 5% is metabolized into reactive metabolite NAPQI. In patients younger than 6 years of age, metabolic elimination occurs to a greater degree by conjugation via the sulfate pathway.

The half-life of acetaminophen is 1 to 3 hours.

##### *Manifestations*

The four phases of the intoxication’s clinical course may overlap, and the absence of a phase does not exclude toxicity.

- Phase I occurs within 0.5 to 24 hours after ingestion and may consist of a few hours of malaise, diaphoresis, nausea, and vomiting or produce no symptoms. CNS depression or coma is not a feature.
- Phase II occurs 24 to 48 hours after ingestion and is a period of diminished symptoms. The liver enzymes, serum aspartate aminotransferase (AST) (earliest), and serum alanine aminotransferase (ALT) may increase as early as 4 hours or as late as 36 hours after ingestion.
- Phase III occurs at 48 to 96 hours, with peak liver function abnormalities at 72 to 96 hours. The degree of elevation of the hepatic enzymes generally correlates with outcome, but not always. Recovery starts at about 4 days unless hepatic failure develops. Less than 1% of patients with a history of overdose develop fulminant hepatotoxicity.
- Phase IV occurs at 4 to 14 days, with hepatic enzyme abnormalities resolving. If extensive liver damage has occurred, sepsis and disseminated intravascular coagulation may ensue.

Transient renal failure may develop at 5 to 7 days with or without evidence of hepatic damage. Rare cases of myocarditis and pancreatitis have been reported. Death can occur at 7 to 14 days.

##### *Laboratory Investigations*

The therapeutic reference range is 10 to 20 µg/mL. For toxic levels, see the nomogram presented in Figure 1.

Appropriate and reliable methods for analysis are radioimmunoassay, high-pressure liquid chromatography, and gas

**Figure 1** Nomogram for acetaminophen intoxication. *N*-acetylcysteine therapy is started if levels and time coordinates are above the lower line on the nomogram. Continue and complete therapy even if subsequent values fall below the toxic zone. The nomogram is useful only in cases of acute single ingestion. Levels in serum drawn before 4 hours may not represent peak levels. From Rumack BH, Matthew H: Acetaminophen poisoning and toxicity. *Pediatrics* 55:871, 1975.

**TABLE 11** Protocol for *N*-Acetylcysteine Administration

ROUTE	LOADING DOSE	MAINTENANCE DOSE	COURSE	FDA APPROVAL
Oral	140 mg/kg	70 mg/kg every 4 h	72 h	Yes
Intravenous	150 mg/kg over 15 min	50 mg/kg over 4 h followed by 100 mg/kg over 16 h	20 h	Yes

chromatography. Spectroscopic assays often give falsely elevated values: bilirubin, salicylate, salicylamide, diflunisal (Dolobid), phenols, and methyl dopa (Aldomet) increase the acetaminophen level. Each 1 mg/dL increase in creatinine increases the acetaminophen plasma level 30 µg/mL.

If a toxic acetaminophen level is reached, liver profile (including AST, ALT, bilirubin, and prothrombin time), serum amylase, and blood glucose must be monitored. A complete blood cell count (CBC); platelet count; phosphate, electrolytes, and bicarbonate level measurements; ECG; and urinalysis are indicated.

**Management**

**Gastrointestinal Decontamination.** Although ipecac-induced emesis may be useful within 30 minutes of ingestion of the toxic substance, we do not advise it because it could result in vomiting of the activated charcoal. Gastric lavage is not necessary. Studies

have indicated that activated charcoal is useful within 1 hour after ingestion. Activated charcoal does adsorb *N*-acetylcysteine (NAC) if given together, but this is not clinically important. However, if activated charcoal needs to be given along with NAC, separate the administration of activated charcoal from the administration of NAC by 1 to 2 hours to avoid vomiting.

***N*-Acetylcysteine (Mucomyst).** NAC (Table 11), a derivative of the amino acid cysteine, acts as a sulfhydryl donor for glutathione synthesis, as surrogate glutathione, and may increase the nontoxic sulfation pathway resulting in conjugation of NAPQI. Oral NAC should be administered within the first 8 hours after a toxic amount of acetaminophen has been ingested. NAC can be started while one awaits the results of the blood test for acetaminophen plasma concentration, but there is no advantage to giving it before 8 hours. If the acetaminophen concentration result after 4 hours following ingestion is above the upper line

on the modified Rumack-Matthew nomogram (see [Figure 1](#)), one should continue with a maintenance course. Repeat blood specimens should be obtained 4 hours after the initial level is measured if it is greater than 20 mg/mL, which is below the therapy line, because of unexpected delays in the peak by food and co-ingestants. Intravenous NAC (see [Table 11](#)) is approved in the United States.

There have been a few cases of anaphylactoid reaction and death by the intravenous route.

#### Variations in Therapy

In patients with chronic alcoholism, it is recommended that NAC treatment be administered at 50% below the upper toxic line on the nomogram.

If emesis occurs within 1 hour after NAC administration, the dose should be repeated. To avoid emesis, the proper dilution from 20% to 5% NAC must be used, and it should be served in a palatable vehicle, in a covered container through a straw. If this administration is unsuccessful, a slow drip over 30 to 60 minutes through a nasogastric tube or a fluoroscopically placed nasoduodenal tube can be used. Antiemetics can be used if necessary: metoclopramide (Reglan) 10 mg per dose intravenously 30 minutes before administration of NAC (in children, 0.1 mg/kg; maximum, 0.5 mg/kg/d) or ondansetron (Zofran) 32 mg (0.15 mg/kg) by infusion over 15 minutes and repeated for three doses if necessary. The side effects of these antiemetics include anaphylaxis and increases in liver enzymes.

Some investigators recommend variable durations of NAC therapy, stopping the therapy if serial acetaminophen blood concentrations become nondetectable and the liver enzyme levels (ALT and AST) remain normal after 24 to 36 hours.

There is a loss of efficacy if NAC is initiated 8 or 10 hours postingestion, but the loss is not complete, and NAC may be initiated 36 hours or more after ingestion. Late treatment (after 24 hours) decreases the rates of morbidity and mortality in patients with fulminant liver failure caused by acetaminophen and other agents.

Extended relief formulations (*ER* embossed on caplet) contain 325 mg of acetaminophen for immediate release and 325 mg for delayed release. A single 4-hour postingestion serum acetaminophen concentration can underestimate the level because *ER* formulations can have secondary delayed peaks. In cases of overdose of the *ER* formulation, it is recommended that additional acetaminophen levels be obtained at 4-hour intervals after the initial level is measured. If any level is in the toxic zone, therapy should be initiated.

It is recommended that pregnant patients with toxic plasma concentrations of acetaminophen be treated with NAC to prevent hepatotoxicity in both fetus and mother. The available data suggest no teratogenicity to NAC or acetaminophen.

Indications for NAC therapy in cases of chronic intoxication are a history of ingestion of 3 to 4 g for several days with elevated liver enzyme levels (AST and ALT). The acetaminophen blood concentration is often low in these cases because of the extended time lapse since ingestion and should not be plotted on the Rumack-Matthew nomogram. Patients with a history of chronic alcoholism or those on chronic enzyme inducers may also present with elevated liver enzyme levels and should be considered for NAC therapy if they have a history of taking acetaminophen on a chronic basis, because they are considered to be at a greater risk for hepatotoxicity despite a low acetaminophen blood concentration.

Specific support care may be needed to treat liver failure, pancreatitis, transient renal failure, and myocarditis.

Liver transplantation has a definite but limited role in patients with acute acetaminophen overdose. A retrospective analysis determined that a continuing rise in the prothrombin time (4-day peak, 180 seconds), a pH of less than 7.3 2 days after the overdose, a serum creatinine level of greater than 3.3 mg/dL, severe hepatic encephalopathy, and disturbed coagulation factor VII/V ratio greater than 30 suggest a poor prognosis and may be

indicators for hepatology consultation for consideration of liver transplantation.

Extracorporeal measures are not expected to be of benefit.

#### Disposition

Adults who have ingested more than 140 mg/kg and children younger than 6 years of age who have ingested more than 200 mg/kg should receive therapy within 8 hours postingestion or until the results of the 4-hour postingestion acetaminophen plasma concentration are known.

#### Amphetamines

The amphetamines include illicit methamphetamine (“Ice”), diet pills, and formulations under various trade names. Analogues include MDMA (3,4-methylenedioxymethamphetamine, known as “ecstasy,” “XTC,” or “Adam”) and MDA (3,4-methylenedioxyamphetamine, known as “Eve”). MDA is a common hallucinogen and euphoriant “club drug” used at “raves,” which are all-night dances. Use of methamphetamine and designer analogues is on the rise, especially among young people between the ages of 12 and 25 years. Other similar stimulants are phenylpropanolamine and cocaine.

#### Toxic Mechanism

Amphetamines have a direct CNS stimulant effect and a sympathetic nervous system effect by releasing catecholamines from  $\alpha$ - and  $\beta$ -adrenergic nerve terminals but inhibiting their reuptake.

Hallucinogenic MDMA has an additional hazard of serotonin effect (refer to serotonin syndrome in the SSRI section). MDMA also affects the dopamine system in the brain. Because of its effects on 5-hydroxytryptamine, dopamine, and norepinephrine, MDMA can lead to serotonin syndrome associated with malignant hyperthermia and rhabdomyolysis, which contributes to the potentially life-threatening hyperthermia observed in several patients who have used MDMA.

Phenylpropanolamine stimulates only the  $\beta$ -adrenergic receptors.

#### Toxic Dose

In children, the toxic dose of dextroamphetamine is 1 mg/kg; in adults, the toxic dose is 5 mg/kg. The potentially fatal dose of dextroamphetamine is 12 mg/kg.

#### Kinetics

Amphetamine is a weak base with pKa of 8 to 10. Onset of action is 30 to 60 minutes, and peak effects are 2 to 4 hours. The volume distribution is 2 to 3 L/kg.

Through hepatic metabolism, 60% of the substance is metabolized into a hydroxylated metabolite that may be responsible for psychotic effects.

The half-life of amphetamines is pH dependent—8 to 10 hours in acid urine (pH <6.0) and 16 to 31 hours in alkaline urine (pH >7.5). Excretion is by the kidney—30% to 40% at alkaline urine pH and 50% to 70% at acid urine pH.

#### Manifestations

Effects are seen within 30 to 60 minutes following ingestion.

Neurologic manifestations include restlessness, irritation and agitation, tremors and hyperreflexia, and auditory and visual hallucinations. Hyperpyrexia may precede seizures, convulsions, paranoia, violence, intracranial hemorrhage, psychosis, and self-destructive behavior. Paranoid psychosis and cerebral vasculitis occur with chronic abuse.

MDMA is often adulterated with cocaine, heroin, or ketamine, or a combination of these, to create a variety of mood alterations. This possibility must be taken into consideration when one manages patients with MDMA ingestions, as the symptom complex may reflect both CNS stimulation and CNS depression.

Other manifestations include dilated but reactive pupils, cardiac dysrhythmias (supraventricular and ventricular), tachycardia, hypertension, rhabdomyolysis, and myoglobinuria.

### Laboratory Investigations

The clinician should monitor ECG and cardiac readings, ABG and oxygen saturation, electrolytes, blood glucose, BUN, creatinine, creatine kinase, cardiac fraction if there is chest pain, and liver profile. Also, one should evaluate for rhabdomyolysis and check urine for myoglobin, cocaine and metabolites, and other substances of abuse. The peak plasma concentration of amphetamines is 10 to 50 ng/mL 1 to 2 hours after ingestion of 10 to 25 mg. The toxic plasma concentration is 200 ng/mL. When the rapid immunoassays are used, cross-reactions can occur with amphetamine derivatives (e.g., MDA, "ecstasy"), brompheniramine (Dimetane), chlorpromazine (Thorazine), ephedrine, phenylpropranolamine, phentermine (Adipex-P), phenmetrazine, ranitidine (Zantac), and Vicks Inhaler (L-desoxyephedrine). False-positive results may occur.

### Management

Management is similar to management for cocaine intoxication. Supportive care includes blood pressure and temperature control, cardiac monitoring, and seizure precautions. Diazepam (Valium) can be administered. Gastrointestinal decontamination can be undertaken with activated charcoal administered up to 1 hour after ingestion.

Anxiety, agitation, and convulsions are treated with diazepam. If diazepam fails to control seizures, neuromuscular blockers can be used and the electroencephalogram (EEG) monitored for non-motor seizures. One should avoid neuroleptic phenothiazines and butyrophenone, which can lower the seizure threshold.

Hypertension and tachycardia are usually transient and can be managed by titration of diazepam. Nitroprusside can be used for hypertensive crisis at a maximum infusion rate of 10 µg/kg/min for 10 minutes followed with a lower infusion rate of 0.3 to 2 mg/kg/min. Myocardial ischemia is managed by oxygen, vascular access, benzodiazepines, and nitroglycerin. Aspirin and thrombolytics are not routinely recommended because of the danger of intracranial hemorrhage. It is important to distinguish between angina and true ischemia. Delayed hypotension can be treated with fluids and vasopressors if needed. Life-threatening tachydysrhythmias may respond to an α-blocker such as phentolamine (Regitin) 5 mg IV for adults or 0.1 mg/kg IV for children and a short-acting β-blocker such as esmolol (Brevibloc) 500 µg/kg IV over 1 minute for adults, or 300 to 500 µg/kg over 1 minute for children. Ventricular dysrhythmias may respond to lidocaine or, in a severely hemodynamically compromised patient, immediate synchronized electrical cardioversion.

Rhabdomyolysis and myoglobinuria are treated with fluids, alkaline diuresis, and diuretics. Hyperthermia is treated with external cooling and cool 100% humidified oxygen. More extensive therapy may be needed in severe cases. If focal neurologic symptoms are present, the possibility of a cerebrovascular accident should be considered and a CT scan of the head should be obtained.

Paranoid ideation and threatening behavior should be treated with rapid tranquilization using a benzodiazepine. One should observe for suicidal depression that may follow intoxication and may require suicide precautions.

Extracorporeal measures are of no benefit.

### Disposition

Symptomatic patients should be observed on a monitored unit until the symptoms resolve and then observed for a short time after resolution for relapse.

### Anticholinergic Agents

Drugs with anticholinergic properties include antihistamines (H<sub>1</sub> blockers), neuroleptics (phenothiazines), tricyclic antidepressants, antiparkinsonism drugs (trihexyphenidyl [Artane], benztropine [Cogentin]), ophthalmic products (atropine), and a number of common plants.

The antihistamines are divided into the sedating anticholinergic types and the nonsedating single daily dose types. The sedating types include ethanolamines (e.g., diphenhydramine [Benadryl],

dimenhydrinate [Dramamine], and clemastine [Tavist]), ethylenediamines (e.g., tripeleminamine [Pyribenzamine]), alkyl amines (e.g., chlorpheniramine [Chlor-Trimeton], brompheniramine [Dimetane]), piperazines (e.g., cyclizine [Marezine], hydroxyzine [Atarax], and meclizine [Antivert]), and phenothiazine (e.g., Phenergan). The nonsedating types include astemizole (Hismanal), terfenadine (Seldane), loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec).

The anticholinergic plants include jimsonweed (*Datura stramonium*), deadly nightshade (*Atropa belladonna*), henbane (*Hyoscyamus niger*), and antispasmodic agents for the bowel (atropine derivatives).

### Toxic Mechanism

By competitive inhibition, anticholinergics block the action of acetylcholine on postsynaptic cholinergic receptor sites. The toxic mechanism primarily involves the peripheral and CNS muscarinic receptors. H<sub>1</sub> sedating-type agents also depress or stimulate the CNS, and in large overdoses some have cardiac membrane-depressant effects (e.g., diphenhydramine [Benadryl]) and α-adrenergic receptor blockade effects (e.g., promethazine [Phenergan]). Nonsedating agents produce peripheral H<sub>1</sub> blockade but do not possess anticholinergic or sedating actions. The original agents terfenadine (Seldane) and astemizole (Hismanal) were recently removed from the market because of the severe cardiac dysrhythmias associated with their use, especially when used in combination with macrolide antibiotics and certain antifungal agents such as ketoconazole (Nizoral), which inhibit hepatic metabolism or excretion. The newer nonsedating agents, including loratadine (Claritin), fexofenadine (Allegra), and cetirizine (Zyrtec), have not been reported to cause the severe drug interactions associated with terfenadine and astemizole.

### Toxic Dose

The estimated toxic oral dose of atropine is 0.05 mg/kg in children and more than 2 mg in adults. The minimal estimated lethal dose of atropine is more than 10 mg in adults and more than 2 mg in children. Other synthetic anticholinergic agents are less toxic, and the fatal dose varies from 10 to 100 mg.

The estimated toxic oral dose of diphenhydramine (Benadryl) in a child is 15 mg/kg, and the potential lethal amount is 25 mg/kg. In an adult, the potential lethal amount is 2.8 g. Ingestion of five times the single dose of an antihistamine is toxic.

For the nonsedating agents, an overdose of 3360 mg of terfenadine was reported in an adult who developed ventricular tachycardia and fibrillation that responded to lidocaine and defibrillation. A 1500-mg overdose produced hypotension. Cases of delayed serious dysrhythmias (torsades de pointes) have been reported with doses of more than 200 mg of astemizole. The toxic doses of fexofenadine (Allegra), cetirizine, and loratadine (Claritin) need to be established.

### Kinetics

The onset of absorption of intravenous atropine is in 2 to 4 minutes. Peak effects on salivation after intravenous or intramuscular administration are at 30 to 60 minutes.

Onset of absorption after oral ingestion is 30 to 60 minutes, peak action is 1 to 3 hours, and duration of action is 4 to 6 hours, but symptoms are prolonged in cases of overdose or with sustained-release preparations.

The onset of absorption of diphenhydramine is in 15 minutes to 1 hour, with a peak of action in 1 to 4 hours. Volume distribution is 3.3 to 6.8 L/kg, and protein binding is 75% to 80%. Ninety-eight percent of diphenhydramine is metabolized via the liver by N-demethylation. Interactions with erythromycin, ketoconazole (Nizoral), and derivatives produce excessive blood levels of the antihistamine and ventricular dysrhythmias.

The half-life of diphenhydramine is 3 to 10 hours.

The chemical structure of nonsedating agents prevents their entry into the CNS. Absorption begins in 1 hour, with peak effects in 4 to 6 hours. The duration of action is greater than 24 hours.

These agents are metabolized in the gastrointestinal tract and liver. Protein binding is greater than 90%. The plasma half-life is 3.5 hours. Only 1% is excreted unchanged; 60% of that is excreted in the feces and 40% in the urine.

### Manifestations

Anticholinergic signs are hyperpyrexia (“hot as a hare”), mydriasis (“blind as a bat”), flushing of skin (“red as a beet”), dry mucosa and skin (“dry as a bone”), “Lilliputian type” hallucinations and delirium (“mad as a hatter”), coma, dysphagia, tachycardia, moderate hypertension, and rarely convulsions and urinary retention. Other effects include jaundice (cyproheptadine [Periactin]), dystonia (diphenhydramine [Benadryl]), rhabdomyolysis (doxylamine), and, in large doses, cardiotoxic effects (diphenhydramine).

Overdose with non-sedating agents produces headache and confusion, nausea, and dysrhythmias (e.g., torsades de pointes).

### Laboratory Investigations

Monitoring of ABG (in cases of respiratory depression), electrolytes, glucose, and the ECG should be undertaken. Anticholinergic drugs and plants are not routinely included on screens for substances of abuse.

### Management

For patients in respiratory failure, intubation and assisted ventilation should be instituted. Gastrointestinal decontamination can be instituted. Caution must be taken with emesis in cases of diphenhydramine (Benadryl) overdose because of the drug’s rapid onset of action and risk of seizures. If bowel sounds are present for up to 1 hour after ingestion, activated charcoal can be given. Seizures can be controlled with benzodiazepines (diazepam [Valium] or lorazepam [Ativan]).

The administration of physostigmine (Antilirium) is not routine and is reserved for life-threatening anticholinergic effects that are refractory to conventional treatments. It should be administered with adequate monitoring and resuscitative equipment available. The use of physostigmine should be avoided if a tricyclic antidepressant is present because of increased toxicity. Urinary retention should be relieved by catheterization to avoid reabsorption of the drug and additional toxicity.

Supraventricular tachycardia should be treated only if the patient is hemodynamically unstable. Ventricular dysrhythmias can be controlled with lidocaine or cardioversion. Sodium bicarbonate 1 to 2 mEq/kg IV may be useful for myocardial depression and QRS prolongation. Torsades de pointes, especially when associated with terfenadine and astemizole ingestion, has been treated with magnesium sulfate 4 g or 40 mL 10% solution intravenously over 10 to 20 minutes and countershock if the patient fails to respond.

Hyperpyrexia is controlled by external cooling. Hemodialysis and hemoperfusion are not effective.

### Disposition

**Antihistamine H<sub>1</sub> Antagonists.** Symptomatic patients should be observed on a monitored unit until the symptoms resolve, then observed for a short time (3 to 4 hours) after resolution for relapse.

**Nonsedating Agents.** All asymptomatic children who acutely ingest more than the maximum adult dose and all symptomatic children should be referred to a health care facility for a minimum of 6 hours’ observation as well as cardiac monitoring. Asymptomatic adults who acutely ingest more than twice the maximum adult daily dose should be monitored for a minimum of 6 hours. All symptomatic patients should be monitored for as long as there are symptoms present.

### Barbiturates

Barbiturates have been used as sedatives, anesthetic agents, and anticonvulsants, but their use is declining as safer, more effective drugs become available.

### Toxic Mechanism

Barbiturates are  $\gamma$ -aminobutyric acid (GABA) agonists (increasing the chloride flow and inhibiting depolarization). They enhance the CNS depressant effect of GABA and depress the cardiovascular system.

### Toxic Dose

The shorter-acting barbiturates (including the intermediate-acting agents) and their hypnotic doses are as follows: amobarbital (Amytal), 100 to 200 mg; aprobarbital (Alurate), 50 to 100 mg; butobarbital (Butisol), 50 to 100 mg; butalbital, 100 to 200 mg; pentobarbital (Nembutal), 100 to 200 mg; secobarbital (Seconal), 100 to 200 mg. They cause toxicity at lower doses than long-acting barbiturates and have a minimum toxic dose of 6 mg/kg; the fatal adult dose is 3 to 6 g.

The long-acting barbiturates and their doses include mephobarbital (Mebaral), 50 to 100 mg, and phenobarbital, 100 to 200 mg. Their minimum toxic dose is greater than 10 mg/kg, and the fatal adult dose is 6 to 10 g. A general rule is that an amount five times the hypnotic dose is toxic and an amount 10 times the hypnotic dose is potentially fatal. Methohexital and thiopental are ultrashort-acting parenteral preparations and are not discussed.

### Kinetics

The barbiturates are enzyme inducers. Short-acting barbiturates are highly lipid-soluble, penetrate the brain readily, and have shorter elimination times. Onset of action is in 10 to 30 minutes, with a peak at 1 to 2 hours. Duration of action is 3 to 8 hours. The volume distribution of short-acting barbiturate is 0.8 to 1.5 L/kg; pKa is about 8. Mean half-life varies from 8 to 48 hours.

Long-acting agents have longer elimination times and can be used as anticonvulsants. Onset of action is in 20 to 60 minutes, with a peak at 1 to 6 hours. In cases of overdose, the peak can be at 10 hours. Usual duration of action is 8 to 12 hours. Volume distribution is 0.8 L/kg, and half-life is 11 to 120 hours. The pKa of phenobarbital is 7.2. Alkalinization of urine promotes its excretion.

### Manifestations

Mild intoxication resembles alcohol intoxication and includes ataxia, slurred speech, and depressed cognition. Severe intoxication causes slow respirations, coma, and loss of reflexes (except pupillary light reflex).

Other manifestations include hypotension (vasodilation), hypothermia, hypoglycemia, and death by respiratory arrest.

### Laboratory Investigations

Most barbiturates are detected on routine drug screens and can be measured in most hospital laboratories. Investigation should include barbiturate level; ABG; toxicology screen, including acetaminophen; glucose, electrolyte, BUN, creatinine, and creatine kinase levels; and urine pH. The minimum toxic plasma levels are greater than 10  $\mu$ g/mL for short-acting barbiturates and greater than 40  $\mu$ g/dL for long-acting agents. Fatal levels are 30  $\mu$ g/mL for short-acting barbiturates and 80 to 150  $\mu$ g/mL for long-acting agents. Both short-acting and long-acting agents can be detected in urine 24 to 72 hours after ingestion, and long-acting agents can be detected up to 7 days.

### Management

Vital functions must be established and maintained. Intensive supportive care including intubation and assisted ventilation should dominate the management. All stuporous and comatose patients should have glucose (for hypoglycemia), thiamine (if chronically alcoholic), and naloxone (Narcan) (in case of an opioid ingestion) intravenously and should be admitted to the intensive care unit. Emesis should be avoided especially in cases of ingestion of the shorter-acting barbiturates. Activated charcoal followed by MDAC (0.5 g/kg) every 2 to 4 hours has been shown to reduce the serum half-life of phenobarbital by 50%, but its effect on clinical course is undetermined.

Fluids should be administered to correct dehydration and hypotension. Vasopressors may be necessary to correct severe hypotension, and hemodynamic monitoring may be needed. The patient must be observed carefully for fluid overload. Alkalinization (ion trapping) is used only for phenobarbital (pKa 7.2) but not for short-acting barbiturates. Sodium bicarbonate, 1 to 2 mEq/kg IV in 500 mL of 5% dextrose in adults or 10 to 15 mL/kg in children during the first hour, followed by sufficient bicarbonate to keep the urinary pH at 7.5 to 8.0, enhances excretion of phenobarbital and shortens the half-life by 50%. Diuresis is not advocated because of the danger of cerebral or pulmonary edema.

Hemodialysis shortens the half-life to 8 to 14 hours, and charcoal hemoperfusion shortens the half-life to 6 to 8 hours for long-acting barbiturates such as phenobarbital. Both procedures may be effective in patients with both long-acting and short-acting barbiturate ingestion. If the patient does not respond to supportive measures or if the phenobarbital plasma concentration is greater than 150 µg/mL, both procedures may be tried to shorten the half-life.

Bullae are treated as a local second-degree skin burn. Hypothermia should be treated.

### Disposition

All comatose patients should be admitted to the intensive care unit. Awake and oriented patients with an overdose of short-acting agents should be observed for at least 6 asymptomatic hours; overdose of long-acting agents warrants observation for at least 12 asymptomatic hours because of the potential for delayed absorption. In the case of an intentional overdose, psychiatric clearance is needed before the patient can be discharged. Chronic use can lead to tolerance, physical dependency, and withdrawal and necessitates follow-up.

### Benzodiazepines

Benzodiazepines are used as anxiolytics, sedatives, and relaxants.

### Toxic Mechanism

The GABA agonists produce CNS depression and increase chloride flow, inhibiting depolarization.

Flunitrazepam (Rohypnol; street name “roofies”) is a long-acting benzodiazepine agonist sold by prescription in more than 60 countries worldwide, but it is not legally available in the United States.

### Toxic Dose

The long-acting benzodiazepines (half-life >24 hours) and their maximum therapeutic doses are as follows: chlordiazepoxide (Librium), 50 mg; clorazepate (Tranxene), 30 mg; clonazepam (Klonopin), 20 mg; diazepam (Valium), 10 mg in adults or 0.2 mg/kg in children; flurazepam (Dalmane), 30 mg; and prazepam, 20 mg.

The short-acting benzodiazepines (half-life 10 to 24 hours) and their doses include the following: alprazolam (Xanax), 0.5 mg, and lorazepam (Ativan), 4 mg in adults or 0.05 mg/kg in children, which act similar to the long-acting benzodiazepines.

The ultrashort-acting benzodiazepines (half-life <10 hours) are more toxic and include temazepam (Restoril), 30 mg; triazolam (Halcion), 0.5 mg; midazolam (Versed), 0.2 mg/kg; and oxazepam (Serax), 30 mg.

In cases of overdose of short- and long-acting agents, 10 to 20 times the therapeutic dose (>1500 mg diazepam or 2000 mg chlordiazepoxide) have been ingested with resulting mild coma but without respiratory depression. Fatalities are rare, and most patients recover within 24 to 36 hours after overdose. Asymptomatic unintentional overdoses of less than five times the therapeutic dose can be seen. Ultrashort-acting agents have produced respiratory arrest and coma within 1 hour after ingestion of 5 mg of triazolam (Halcion) and death with ingestion of as little as 10 mg. Midazolam (Versed) and diazepam (Valium) by rapid intravenous injection have produced respiratory arrest.

### Kinetics

Onset of CNS depression is usually in 30 to 120 minutes; peak action usually occurs within 1 to 3 hours when ingestion is by the oral route. The volume distribution varies from 0.26 to 6 L/kg (LA, 1.1 L/kg); protein binding is 70% to 99%. For flunitrazepam, the onset of action is in 0.5 to 2 hours, oral peak is in 2 hours, and duration 8 hours or more. The half-life of flunitrazepam is 20 to 30 hours, volume distribution is 3.3 to 5.5 L/kg, and 80% is protein bound. Flunitrazepam can be identified in urine 4 to 30 days after ingestion.

### Manifestations

Neurologic manifestations include ataxia, slurred speech, and CNS depression. Deep coma leading to respiratory depression suggests the presence of short-acting benzodiazepines or other CNS depressants. In elderly persons, the therapeutic doses can produce toxicity and can have an additive effect with other CNS depressants. Chronic use can lead to tolerance, physical dependency, and withdrawal.

### Laboratory Investigations

Most benzodiazepines can be detected in urine drug screens. Quantitative blood levels are not useful. Some of the immunoassay urinary screens cannot detect all of the new benzodiazepines currently available. A consultation with the laboratory analyst is warranted if a specific case occurs in which the test result is negative but benzodiazepine use is suspected by the patient's history. Situations in which benzodiazepines may not be detected include ingestion of a low dose (e.g., <10 mg), rapid elimination, and a different or no metabolite. Some immunoassay methods can produce a false-positive finding for the benzodiazepines when non-steroidal antiinflammatory drugs (tolmetin [Tolectin], naproxen [Aleve], etodolac [Lodine], and fenoprofen [Nalfon]) are used. If this is a concern, the laboratory analyst should be consulted.

In cases in which “date rape” drugs such as flunitrazepam are suspected, a police crime or reference laboratory should be consulted for testing.

### Management

Emesis and gastric lavage should be avoided. Activated charcoal can be useful only if given early before the peak time of absorption occurs. Supportive treatment should be instituted but rarely requires intubation or assisted ventilation.

Flumazenil (Romazicon) is a specific benzodiazepine receptor antagonist that blocks the chloride flow and inhibitor of GABA neurotransmitters. It reverses the sedative effects of benzodiazepines, zolpidem (Ambien), and endogenous benzodiazepines associated with hepatic encephalopathy. It is not recommended to reverse benzodiazepine-induced hypoventilation. The manufacturer advises that flumazenil be used with caution in cases of overdose with possible benzodiazepine dependency (because it can precipitate life-threatening withdrawal), if cyclic antidepressant use is suspected, or if a patient has a known seizure disorder.

### Disposition

If the patient is comatose, he or she must be admitted to the intensive care unit. If the overdose was intentional, psychiatric clearance is needed before the patient can be discharged.

### β-Adrenergic Blockers (β-Blockers)

β-Blockers are used in the treatment of hypertension and of a number of systemic and ophthalmologic disorders. Properties of β-blockers include the factors listed in Table 12.

Lipid-soluble drugs have CNS effects, active metabolites, longer duration of action, and interactions (e.g., propranolol). Cardioselectivity is lost in overdose. Intrinsic partial agonist agents (e.g., pindolol) may initially produce tachycardia and hypertension. Cardiac membrane depressive effect (quinidine-like) occurs in cases of overdose but not at therapeutic doses (e.g., with metoprolol or sotalol). α-Blocking effect is weak (e.g., with labetalol or acebutolol).

**TABLE 12** Pharmacologic and Toxic Properties of  $\beta$ -Blockers

B-BLOCKER	MAXIMUM SOLUBILITY	THERAPEUTIC PLASMA LEVEL	LIPID SOLUBILITY	INTRINSIC SYMPATHOMIMETIC ACTIVITY (PARTIAL AGONIST)	MEMBRANE STABILIZING EFFECT		CARDIAC SELECTIVITY
					B-SELECTIVE		A-SELECTIVE
					B <sub>1</sub>	B <sub>2</sub>	
Acebutolol (Sectral)	800 mg	200–2000 ng/mL	Moderate	+	+	+	+
Alprenolol <sup>2</sup>	800 mg	50–200 ng/mL	Moderate	2+	+	–	–
Atenolol (Tenormin)	100 mg	200–500 ng/mL	Low	–	–	2+	–
Betaxolol (Kerlone)	20 mg	NA	Low	+	–	+	–
Carteolol (Cartrol)	10 mg	NA	No	+	–	–	–
Esmolol (Brevibloc) (Class II antidysrhythmic, IV only)			Low	–	–	+	–
Labetalol (Trandate)	800 mg	50–500 ng/mL	Low	+	+/-	–	+
Levobunolol (AKBeta eyedrop) (Eye drops 0.25% and 0.5%)	20 mg	NA	No	–	–	–	–
Metoprolol (Lopressor)			Moderate	–	–	2+	–
Nadolol (Corgard)	320 mg	20–40 ng/mL	Low	–	–	–	–
Oxyprenolol <sup>2</sup>	480 mg	80–100 ng/mL	Moderate	2+	+	–	–
Pindolol (Visken)	60 mg	50–150 ng/mL	Moderate	3+	+/-	–	–
Propranolol (Inderal) (Class II antidysrhythmic)	360 mg	50–100 ng/mL	High	–	2+	–	–
Sotalol (Betapace) (Class II antidysrhythmic)	480 mg	500–4000 ng/mL	Low	–	–	–	–
Timolol (Blocadren)	60 mg	5–10 ng/mL	Low	–	+/-	–	–

<sup>2</sup>Not available in the United States.

### Toxic Mechanism

$\beta$ -Blockers compete with the catecholamines for receptor sites and block receptor action in the bronchi, the vascular smooth muscle, and the myocardium.

### Toxic Dose

Ingestions of greater than twice the maximum recommended daily therapeutic dose are considered toxic (see Table 12). Ingestion of 1 mg/kg propranolol in a child may produce hypoglycemia. Fatalities have been reported in adults with 7.5 g of metoprolol. The most toxic agent is sotalol, and the least toxic is atenolol.

### Kinetics

Regular-release formulations usually cause symptoms within 2 hours. Propranolol's onset of action is 20 to 30 minutes and peak is at 1 to 4 hours, but it may be delayed by co-ingestants. The onset of action with sustained-release preparations may be delayed to 6 hours and the peak to 12 to 16 hours. Volume distribution is 1 to 5.6 L/kg. Protein binding is variable, from 5% to 93%.

### Metabolism

Atenolol (Tenormin), nadolol (Corgard), and sotalol (Betapace) have enterohepatic recirculation. The duration of action for regular-acting agents is 4 to 6 hours, but in cases of overdose

it may be 24 to 48 hours. The duration of action for sustained-release agents is 24 to 48 hours.

The regular preparation with the longest half-life is nadolol, at 12 to 24 hours, and the one with the shortest half-life is esmolol, at 5 to 10 minutes.

### Manifestations

See "Toxic Properties" and Table 12.

Highly lipid soluble agents produce coma and seizures. Bradycardia and hypotension are the major cardiac symptoms and may lead to cardiogenic shock. Intrinsic partial agonists initially may cause tachycardia and hypertension. ECG changes include atrioventricular conduction delay or asystole. Membrane-depressant effects produce prolonged QRS and QT interval, which may result in torsades de pointes. Sotalol produces a very prolonged QT interval. Bronchospasm may occur in patients with reactive airway disease with any  $\beta$ -blocker because the selectivity is lost in overdose. Other manifestations include hypoglycemia (because  $\beta$ -blockers block catecholamine counter-regulatory mechanisms) and hyperkalemia.

### Laboratory Investigations

Measurements of blood levels are not readily available or useful. ECG and cardiac monitoring should be maintained, and blood glucose and electrolytes, BUN, and creatinine levels should be monitored, as well as ABG if there are respiratory symptoms.

## Management

Vital functions must be established and maintained. Vascular access, baseline ECG, and continuous cardiac and blood pressure monitoring should be established. A pacemaker must be available. Gastrointestinal decontamination can be undertaken initially with activated charcoal up to 1 hour after ingestion. MDAC is no longer recommended, based on the latest guidelines. Whole-bowel irrigation can be considered in cases of large overdoses with sustained-release preparations, but there are no studies evaluating the efficacy of intervention.

If there are cardiovascular disturbances, a cardiac consultation should be obtained. Class IA antidysrhythmic agents (procainamide, quinidine) and III (bretylium) are not recommended. Hypotension is treated with fluids initially, although it usually does not respond. Frequently, glucagon and cardiac pacing are needed. Bradycardia in asymptomatic, hemodynamically stable patients requires no therapy. It is not predictive of the future course of the disease. If the patient is unstable (has hypotension or a high-degree atrioventricular block), atropine 0.02 mg/kg (up to 2 mg) in adults, glucagon, and a pacemaker can be used. In case of ventricular tachycardia, overdrive pacing can be used. A wide QRS interval may respond to sodium bicarbonate. Torsades de pointes (associated with sotalol) may respond to magnesium sulfate and overdrive pacing. Prophylactic magnesium for prolonged QT interval has been suggested, but there are no data. Epinephrine must not be used because an unopposed  $\alpha$  effect may occur.

Hypotension and myocardial depression are managed by correction of dysrhythmias, Trendelenburg position, fluids, glucagon, or amrinone (Inocor), or a combination of these. Hemodynamic monitoring with a Swan-Ganz catheter or arterial line may be necessary to manage fluid therapy.

Glucagon is the initial drug of choice. It works through adenylyl cyclase and bypasses catecholamine receptors; therefore, it is not affected by  $\beta$ -blockers. Glucagon increases cardiac contractility and heart rate. It is given as an intravenous bolus of 5 to 10 mg<sup>3</sup> over 1 minute and followed by a continuous infusion of 1 to 5 mg/h (in children, 0.15 mg/kg followed by 0.05 to 0.1 mg/kg/h). In large doses and in infusion therapy D<sub>5</sub>W, sterile water, or saline should be used as a dilutant to reconstitute glucagon in place of the 0.2% phenol diluent provided with some drugs. Effects are seen within minutes. It can be used with other agents such as amrinone.

Amrinone (Inocor) inhibits phosphodiesterase enzyme, which metabolizes cyclic AMP. It is administered as a bolus of 0.15 to 2 mg/kg (0.15 to 0.4 mL/kg) intravenously, followed by infusion of 5 to 10  $\mu$ g/kg/min.

Hypoglycemia should be treated with intravenous glucose. Life-threatening hyperkalemia is treated with calcium (avoid if digoxin is present), bicarbonate, and glucose or insulin. Convulsions can be controlled with diazepam or phenobarbital. If bronchospasm is present,  $\beta_2$  nebulized bronchodilators are given.

Extraordinary measures such as intra-aortic balloon pump support can be instituted. Extracorporeal measures can be undertaken. Hemodialysis for cases of atenolol, acebutolol, nadolol, and sotalol (low volume distribution, low protein binding) ingestion may be helpful, particularly when there is evidence of renal failure. Hemodialysis is not effective for propranolol, metoprolol, and timolol.

Prenalterol<sup>2</sup> has successfully reversed both bradycardia and hypotension but is not currently available in the United States.

## Disposition

Asymptomatic patients with history of overdose require baseline ECG and continuous cardiac monitoring for at least 6 hours with regular-release preparations and for 24 hours with sustained-release preparations. Symptomatic patients should be observed with cardiac monitoring for 24 hours. If seizures or abnormal

rhythm or vital signs are present, the patient should be admitted to the intensive care unit.

## Calcium Channel Blockers

Calcium channel blockers are used in the treatment of effort angina, supraventricular tachycardia, and hypertension.

### Toxic Mechanism

Calcium channel blockers reduce influx of calcium through the slow channels in membranes of the myocardium, the atrioventricular nodes, and the vascular smooth muscles and result in peripheral, systemic, and coronary vasodilation, impaired cardiac conduction, and depression of cardiac contractility. All calcium channel blockers have vasodilatory action, but only bepridil, diltiazem, and verapamil depress myocardial contractility and cause atrioventricular block.

### Toxic Dose

Any ingested amount greater than the maximum daily dose has the potential of severe toxicity. The maximum oral daily doses in adults and toxic doses in children of each are as follows: amlodipine (Norvasc), 10 mg for adults and more than 0.25 mg/kg for children; bepridil (Vascor), 400 mg for adults and more than 5.7 mg/kg for children; diltiazem (Cardizem), 360 mg for adults (toxic dose >2 g) and more than 6 mg/kg for children; felodipine (Plendil), 40 mg for adults and more than 0.56 mg/kg for children; isradipine (DynaCirc), 40 mg for adults and more than 0.4 mg/kg for children; nicardipine (Cardene), 120 mg for adults and more than 0.85 mg/kg for children; nifedipine (Procardia), 120 mg for adults and more than 2 mg/kg for children; nimodipine (Nimotop), 360 mg for adults and more than 0.85 mg/kg for children; nitrendipine (Baypress),<sup>1</sup> 80 mg for adults and more than 1.14 mg/kg for children; and verapamil (Calan), 480 mg for adults and 15 mg/kg for children.

### Kinetics

Onset of action of regular-release preparations varies: for verapamil it is 60 to 120 minutes, for nifedipine 20 minutes, and for diltiazem 15 minutes after ingestion. Peak effect for verapamil is 2 to 4 hours, for nifedipine 60 to 90 minutes, and for diltiazem 30 to 60 minutes, but the peak action may be delayed for 6 to 8 hours. Duration of action is up to 36 hours. The onset of action for sustained-release preparations is usually 4 hours but may be delayed, and peak effect is at 12 to 24 hours. In cases of massive overdose, concretions and prolonged toxicity can develop.

Volume distribution varies from 3 to 7 L/kg. Hepatic elimination half-life varies from 3 to 7 hours. Patients receiving digitalis and calcium channel blockers run the risk of digitalis toxicity, because calcium channel blockers increase digitalis levels.

### Manifestations

Cardiac manifestations include hypotension, bradycardia, and conduction disturbances occurring 30 minutes to 5 hours after ingestion. A prolonged PR interval is an early finding and may occur at therapeutic doses. Torsades de pointes has been reported. All degrees of blocks may occur and may be delayed up to 16 hours. Lactic acidosis may be present. Calcium channel blockers do not affect intraventricular conduction, so the QRS interval is usually not affected.

Hypocalcemia is rarely present. Hyperglycemia may be present because of interference in calcium-dependent insulin release. Mental status changes, headaches, seizures, hemiparesis, and CNS depression may occur.

### Laboratory Investigations

Specific drug levels are not readily available and are not useful. Monitor blood sugar, electrolytes, calcium, ABG, pulse oximetry, creatinine, and BUN, and also use hemodynamic monitoring, ECG, and cardiac monitoring.

<sup>2</sup>Not available in the United States.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

## Management

Vital functions must be established and maintained. Baseline ECG readings should be obtained and continuous cardiac and blood pressure monitoring maintained. A pacemaker should be available. Cardiology consultation should be sought.

Gastrointestinal decontamination with activated charcoal is recommended. If a large dose of a sustained-release preparation was ingested, whole-bowel irrigation can be considered, but its effectiveness has not been investigated.

If the patient is symptomatic, immediate cardiology consult must be obtained, because a pacemaker and hemodynamic monitoring may be needed. In the case of heart block, atropine is rarely effective and isoproterenol (Isuprel) may produce vasodilation. The use of a pacemaker should be considered early.

Hypotension and bradycardia can be treated with positioning, fluids, and calcium gluconate or chloride, glucagon, amrinone (Inocor), and ventricular pacing. Calcium salts must be avoided if digoxin is present. Calcium usually reverses depressed myocardial contractility but may not reverse nodal depression or peripheral vasodilation. Calcium chloride can be given in a 10% solution, 0.1 to 0.2 mL/kg up to 10 mL in an adult, or calcium gluconate in a 10% solution 0.3 to 0.4 mL/kg up to 20 mL in an adult. Administration is intravenous, over 5 to 10 minutes. One should monitor for dysrhythmias, hypotension, and the serum ionized calcium. The aim is to increase calcium 4 mg/dL to a maximum of 13 mg/dL. The calcium response lasts 15 minutes and may require repeated doses or a continuous calcium gluconate infusion 0.2 mL/kg/h up to maximum of 10 mL/h.

If calcium fails, glucagon can be tried for its positive inotropic and chronotropic effect, or both. Amrinone (Inocor), an inotropic agent, may reverse the effects of calcium channel blockers. An effective dose is 0.15 mg to 2 mg/kg (0.15–0.4 mL/kg) by intravenous bolus followed by infusion of 5 to 10 µg/kg/min.

In case of hypotension, fluids, norepinephrine (Levophed), and epinephrine may be required. Amrinone and glucagon have been tried alone and in combination. Dobutamine and dopamine are often ineffective.

Extracorporeal measures (e.g., hemodialysis and charcoal hemoperfusion) are not useful, but extraordinary measures such as intra-aortic balloon pump and cardiopulmonary bypass have been used successfully.

For cases of calcium channel blocker toxicity that fail to respond to aggressive management, recent studies demonstrate that insulin and glucose have therapeutic value. The suggested dose range for insulin is to infuse regular insulin at 0.5 IU/kg/h with a simultaneous infusion of glucose 1 g/kg/h, with glucose monitoring every 30 minutes for at least the first 4 hours of administration and subsequent glucose adjustment to maintain euglycemia (70 to 100 mg/dL). Potassium levels should be monitored regularly, as they may shift in response to the insulin.

## Disposition

Patients who have ingested regular-release preparations should be monitored for at least 6 hours and those who have ingested sustained-release preparations should be monitored for 24 hours after the ingestion. Intentional overdose necessitates psychiatric clearance. Symptomatic patients should be admitted to the intensive care unit.

## Carbon Monoxide

Carbon monoxide is an odorless, colorless gas produced from incomplete combustion; it is also an *in vivo* metabolic breakdown product of methylene chloride used in paint removers.

## Toxic Mechanism

Carbon monoxide's affinity for hemoglobin is 240 times greater than that of oxygen. It shifts the oxygen dissociation curve to the left, which impairs hemoglobin release of oxygen to tissues and inhibits the cytochrome oxidase enzymes.

## Toxic Dose and Manifestations

Table 13 describes the manifestations of carbon monoxide toxicity. Exposure to 0.5% for a few minutes is lethal. Sequelae correlate with the patient's level of consciousness at presentation. ECG abnormalities may be noted. Creatine kinase is often elevated, and rhabdomyolysis and myoglobinuria may occur.

The carboxyhemoglobin (CoHB) expresses in percentage the extent to which carbon monoxide has bound with the total hemoglobin. This may be misleadingly low in the anemic patient with less hemoglobin than normal. The patient's presentation is a more reliable indicator of severity than the CoHB level. The manifestations listed in Table 13 for each level are in addition to those listed at the level above. The CoHB may not correlate reliably with the severity of the intoxication, and linking symptoms to specific levels of CoHB frequently leads to inaccurate conclusions. A level of carbon monoxide greater than 40% is usually associated with obvious intoxication.

## Kinetics

The natural metabolism of the body produces small amounts of CoHB, less than 2% for nonsmokers and 5% to 9% for smokers.

Carbon monoxide is rapidly absorbed through the lungs. The rate of absorption is directly related to alveolar ventilation. Elimination also occurs through the lungs. The half-life of CoHB in room air (21% oxygen) is 5 to 6 hours; in 100% oxygen, it is 90 minutes; in hyperbaric pressure at 3 atmospheres oxygen, it is 20 to 30 minutes.

## Laboratory Investigations

An ABG reading may show metabolic acidosis and normal oxygen tension. In cases of significant poisoning, the ABG, electrolytes, blood glucose, serum creatine kinase and cardiac enzymes, renal function tests, and liver function tests should be monitored. A urinalysis and test for myoglobinuria should be obtained. Chest radiograph can be useful in cases of smoke inhalation or if the patient is being considered for hyperbaric chamber. ECG monitoring should be maintained, especially if the patient is older than 40 years, has a history of cardiac disease, or has moderate to severe symptoms. Which toxicology studies are used is based on symptoms and circumstances. CoHB should be monitored during and at the end of therapy. The pulse oximeter has two wavelengths and overestimates oxyhemoglobin saturation in carbon monoxide poisoning. The true oxygen saturation is determined

**TABLE 13** Carbon Monoxide Exposure and Possible Manifestations

COHB SATURATION (%)	MANIFESTATIONS
3.5	None
5	Slight headache, decreased exercise tolerance
10	Slight headache, dyspnea on vigorous exertion, may impair driving skills
10–20	Moderate dyspnea on exertion, throbbing, temporal headache
20–30	Severe headache, syncope, dizziness, visual changes, weakness, nausea, vomiting, altered judgment
30–40	Vertigo, ataxia, blurred vision, confusion, loss of consciousness
40–50	Confusion, tachycardia, tachypnea, coma, convulsions
50–60	Cheyne-Stokes, coma, convulsions, shock, apnea
60–70	Coma, convulsions, respiratory and heart failure, death

by blood gas analysis, which measures the oxygen bound to hemoglobin. The co-oximeter measures four wavelengths and separates out CoHB and the other hemoglobin binding agents from oxyhemoglobin. Fetal hemoglobin has a greater affinity for carbon monoxide than adult hemoglobin and may falsely elevate the CoHB as much as 4% in young infants.

### Management

The first step is to adequately protect the rescuer. The patient must be removed from the contaminated area, and his or her vital functions must be established.

The mainstay of treatment is 100% oxygen via a non-rebreathing mask with an oxygen reservoir or endotracheal tube. All patients receive 100% oxygen until the CoHB level is 5% or less. Assisted ventilation may be necessary. ABG and CoHB should be monitored and the present CoHB level determined. *Note:* A near-normal CoHB level does not exclude significant carbon monoxide poisoning, especially if the measurement is taken several hours after termination of exposure or if oxygen has been administered prior to obtaining the sample.

The exposed pregnant woman should be kept on 100% oxygen for several hours after the CoHB level is almost 0, because carbon monoxide concentrates in the fetus and oxygen is needed longer to ensure elimination of the carbon monoxide from fetal circulation. The fetus must be monitored, because carbon monoxide and hypoxia are potentially teratogenic.

Metabolic acidosis should be treated with sodium bicarbonate only if the pH is below 7.2 after correction of hypoxia and adequate ventilation. Acidosis shifts the oxygen dissociation curve to the right and facilitates oxygen delivery to the tissues.

The decision to use the hyperbaric oxygen chamber must be made on the basis of the ability to handle other acute emergencies that may coexist in the patient and of the severity of the poisoning. The standard of care for persons exposed to carbon monoxide has yet to be determined, but most authorities recommend using the hyperbaric oxygen chamber under any of the following conditions:

- If the patient is in a coma or has a history of loss of consciousness or seizures
- If there is cardiovascular dysfunction (clinical ischemic chest pain or ECG evidence of ischemia)
- If the patient has metabolic acidosis
- If symptoms persist despite 100% oxygen therapy
- In a child, if the initial CoHB is greater than 15%
- In symptomatic patients with preexisting ischemia
- If there are signs of maternal or fetal distress regardless of CoHB level (infants and fetus are a special problem because fetal hemoglobin has greater affinity for carbon monoxide)

Although controversial, a neurologic-cognitive examination has been used to help determine which patients with low carbon monoxide levels should receive more aggressive therapy. Testing should include the following: general orientation memory testing involving address, phone number, date of birth, and present date; and cognitive testing, involving counting by 7s, digit span, and forward and backward spelling of three-letter and four-letter words. Patients with delayed neurologic sequelae or recurrent symptoms up to 3 weeks may benefit from hyperbaric oxygen chamber treatment.

Seizures and cerebral edema must be treated.

### Disposition

Patients with no or mild symptoms who become asymptomatic after a few hours of oxygen therapy, have a carbon monoxide level less than 10%, and have normal physical and neurologic-cognitive examination findings can be discharged, but they should be instructed to return if any signs of neurologic dysfunction appear. Patients with carbon monoxide poisoning requiring treatment need follow-up neuropsychiatric examinations.

### Caustics and Corrosives

The terms *caustic* and *corrosive* are used interchangeably and can be divided into acids and alkalis. The U.S. Consumer Product

Safety Commission Labeling Recommendations on containers for acids and alkalis indicate the potential for producing serious damage, as follows:

- Caution—weak irritant
- Warning—strong irritant
- Danger—corrosive

Some common acids with corrosive potential include acetic acid, formic acid, glycolic acid, hydrochloric acid, mercuric chloride, nitric acid, oxalic acid, phosphoric acid, sulfuric acid (battery acid), zinc chloride, and zinc sulfate. Some common alkalis with corrosive potential include ammonia, calcium carbide, calcium hydroxide (dry), calcium oxide, potassium hydroxide (lye), and sodium hydroxide (lye).

### Toxic Mechanism

Acids produce mucosal coagulation necrosis and may be absorbed systemically; they do not penetrate deeply. Injury to the gastric mucosa is more likely, although specific sites of injury for acids and alkalis are not clearly defined.

Alkalis produce liquefaction necrosis and saponification and penetrate deeply. The esophageal mucosa is likely to be damaged. Oropharyngeal and esophageal damage is more frequently caused by solids than by liquids. Liquids produce superficial circumferential burns and gastric damage.

### Toxic Dose

The toxicity is determined by concentration, contact time, and pH. Significant injury is more likely with a substance that has a pH of less than 2 or greater than 12, with a prolonged contact time, and with large volumes.

### Manifestations

The absence of oral burns does not exclude the possibility of esophageal or gastric damage. General clinical findings are stridor; dysphagia; drooling; oropharyngeal, retrosternal, and epigastric pain; and ocular and oral burns. Alkali burns are yellow, soapy, frothy lesions. Acid burns are gray-white and later form an eschar. Abdominal tenderness and guarding may be present if perforation has happened.

### Laboratory Investigations

If acid ingestion has taken place, the patient's acid-base balance and electrolyte status should be determined. If pulmonary symptoms are present, a chest radiograph, ABG measurement, and pulse oximetry are called for.

### Management

It is recommended that the container be brought to the examination, as the substance must be identified and the pH of the substance, vomitus, tears, or saliva tested.

If the acid or alkali has been ingested, all gastrointestinal decontamination procedures are contraindicated except for immediate rinse, removal of substance from the mouth, and dilution with small amounts (sips) of milk or water. The examiner should check for ocular and dermal involvement. Contraindications to oral dilution are dysphagias, respiratory distress, obtundation, or shock. If there is ocular involvement one should immediately irrigate the eye with tepid water for at least 30 minutes, perform fluorescein stain of eye, and consult an ophthalmologist. If there is dermal involvement, one should immediately remove contaminated clothes and irrigate the skin with tepid water for at least 15 minutes. Consultation with a burn specialist is called for.

In cases of acid ingestion, some authorities advocate a small flexible nasogastric tube and aspiration within 30 minutes after ingestion.

Patients should receive only intravenous fluids following dilution until endoscopic consultation is obtained. Endoscopy is valuable to predict damage and risk of stricture. The indications are controversial, with some authorities recommending it in all cases of caustic ingestions regardless of symptoms, and others selectively using clinical features such as vomiting, stridor, drooling,

and oral or facial lesions as criteria. We recommend endoscopy for all symptomatic patients or patients with intentional ingestions. Endoscopy may be performed immediately if the patient is symptomatic, but it is usually done 12 to 48 hours postingestion.

The use of corticosteroids is considered controversial. Some feel they may be useful for patients with second-degree circumferential burns. They recommend starting with hydrocortisone sodium succinate (Solu-Cortef) intravenously 10 to 20 mg/kg/d within 48 hours and changing to oral prednisolone 2 mg/kg/d for 3 weeks before tapering the dose. We do not usually recommend using corticosteroids because they have not been shown to be effective.

Tetanus prophylaxis should be provided if the patient requires it for wound care. Antibiotics are not useful prophylactically. Contrast studies are not useful in the first few days and may interfere with endoscopic evaluation; later, they can be used to assess the severity of damage.

Emergency medical therapy includes agents to inhibit collagen formation and intraluminal stents. Esophageal and gastric outlet dilation may be needed if there is evidence of stricture. Bougienage of the esophagus, however, has been associated with brain abscess. Interposition of the colon may be necessary if dilation fails to provide an adequate-sized passage.

Management of inhalation cases requires immediate removal from the environment, administration of humid supplemental oxygen, and observation for airway obstruction and noncardiac pulmonary edema. Radiographic and ABG evaluation should be obtained when appropriate. Intubation and respiratory support may be required.

Certain caustics produce systemic disturbances. Formaldehyde causes metabolic acidosis, hydrofluoric acid causes hypocalcemia and renal damage, oxalic acid causes hypocalcemia, phenol causes hepatic and renal damage, and picric acid causes renal injury.

### Disposition

Infants and small children should be medically evaluated and observed. All symptomatic patients should be admitted. If they have severe symptoms or danger of airway compromise, they should be admitted to the intensive care unit. After endoscopy, if no damage is detected, the patient may be discharged when he or she can tolerate oral feedings. Intentional exposures require psychiatric evaluation before the patient can be discharged.

### Cocaine (Benzoylmethylecgonine)

Cocaine is derived from the leaves of *Erythroxylum coca* and *Truxillo coca*. “Body packing” refers to the placement of many small packages of contraband cocaine for concealment in the gastrointestinal tract or other areas for illicit transport. “Body stuffing” refers to spontaneous ingestion of substances for the purpose of hiding evidence.

### Toxic Mechanism

Cocaine directly stimulates the CNS presynaptic sympathetic neurons to release catecholamines and acetylcholine, while it blocks the presynaptic reuptake of the catecholamines; it blocks the sodium channels along neuronal membranes; and it increases platelet aggregation. Long-term use depletes the CNS of dopamine.

### Toxic Dose

The maximum mucosal local anesthetic therapeutic dose of cocaine is 200 mg or 2 mL of a 10% solution. Although CNS effects can occur at relatively low local anesthetic doses (50 to 95 mg), they are more common with doses greater than 1 mg/kg; cardiac effects can occur with doses greater than 1 mg/kg. The potential fatal dose is 1200 mg intranasally, but death has occurred with 20 mg parenterally.

### Kinetics

Cocaine is well absorbed by all routes, including nasal insufflation, and oral, dermal, and inhalation routes (Table 14). Protein binding is 8.7%, and volume distribution is 1.5 L/kg.

Cocaine is metabolized by plasma and liver cholinesterase to the inactive metabolites ecgonine methyl ester and benzoylecgonine. Plasma pseudocholinesterase is congenitally deficient in 3% of the population and decreased in fetuses, young infants, the elderly, pregnant people, and people with liver disease. These enzyme-deficient individuals are at increased risk for life-threatening cocaine toxicity.

Ten percent of cocaine is excreted unchanged. Cocaine and ethanol undergo liver synthesis to form cocaethylene, a metabolite with a half-life three times longer than that of cocaine. It may account for some of cocaine’s cardiotoxicity and appears to be more lethal than cocaine or ethanol alone.

### Manifestations

The CNS manifestations of cocaine ingestion are euphoria, hyperactivity, agitation, convulsions, and intracranial hemorrhage. Mydriasis and septal perforation can occur, as well as cardiac dysrhythmias, hypertension, and hypotension (with severe overdose). Chest pain is frequent, but only 5.8% of patients have true myocardial ischemia and infarction. Other manifestations include vasoconstriction, hyperthermia (because of increased metabolic rate), ischemic bowel perforation if the substance is ingested, rhabdomyolysis, myoglobinuria, and renal failure. In pregnant users, premature labor and abruptio placentae can occur.

Body cavity packing should be suspected in cases of prolonged toxicity.

Mortality can result from cerebrovascular accidents, coronary artery spasm, myocardial injury, or lethal dysrhythmias.

### Laboratory Investigations

Monitoring of the ECG and cardiac rhythms, ABG, oxygen saturation, electrolytes, blood glucose, BUN, creatinine, and creatine kinase levels should be maintained. One should monitor cardiac fraction if the patient has chest pain, as well as the liver profile, and the urine for myoglobin. Intravenous drug users should have HIV and hepatitis virus testing.

Urine should be tested for cocaine and metabolites and other substances of abuse, and abdominal radiographs or ultrasonogram should be ordered for body packers. If the urine sample was collected more than 12 hours after cocaine intake, it will contain little or no cocaine. If cocaine is present, cocaine has been used within the past 12 hours. Cocaine’s metabolite benzoylecgonine may be detected within 4 hours after a single nasal insufflation and for up to 114 hours. Cross-reactions with some herbal

**TABLE 14** Routes and Kinetics of Cocaine

TYPE	ROUTE	ONSET	PEAK (MIN)	HALF-LIFE (MIN)	DURATION (MIN)
Cocaine leaf	Oral, chewing	20–30 min	45–90	—	240–360
Hydrochloride	Insufflation	1–3 min	5–10	78	60–90
	Ingestion	20–30 min	50–90	54	Sustained
	Intravenous	30–120 sec	5–11	36	60–90
Freebase/crack	Smoking	5–10 sec	5–11	—	Up to 20
Coca paste	Smoking	Unknown	—	—	—

teas, lidocaine, and droperidol (Inapsine) may give false-positive results by some immunoassay methods.

### Management

Supportive care includes blood pressure, cardiac, and thermal monitoring and seizure precautions. Diazepam (Valium) is the drug of choice for treatment of cocaine toxicity agitation, seizures, and dysrhythmias; doses are 10 to 30 mg intravenously at 2.5 mg per minute for adults and 0.2 to 0.5 mg/kg at 1 mg per minute up to 10 mg for a child.

Gastrointestinal decontamination should be instituted, if the cocaine was ingested, by administration of activated charcoal. MDAC may adsorb cocaine leakage in body stuffers or body packers. Whole-bowel irrigation with polyethylene glycol solution (PEG) has been used in body packers and stuffers if the contraband is in a firm container. If the packages are not visible on plain radiographs of the abdomen, a contrast study or CT scan can help to confirm successful passage. Cocaine in the nasal passage can be removed with an applicator dipped in a non-water-soluble product (lubricating jelly) if this is done within a few minutes after application.

In body packers and stuffers, venous access must be secured, and drugs must be readily available for treating life-threatening manifestations until the contraband is passed in the stool. Surgical removal may be indicated if the packet does not pass the pylorus, in an asymptomatic body packer, or in the case of intestinal obstruction.

Hypertension and tachycardia are usually transient and can be managed by careful titration of diazepam. Nitroprusside may be used for severe hypertension. Myocardial ischemia is managed by oxygen, vascular access, benzodiazepines, and nitroglycerin. Aspirin and thrombolysis are not routinely recommended because of the danger of intracranial hemorrhage.

Dysrhythmias are usually supraventricular (SVT) and do not require specific management. Adenosine is ineffective. Life-threatening tachydysrhythmias may respond to phentolamine (Regitine) 5 mg IV bolus in adults or 0.1 mg/kg in children at 5- to 10-minute intervals. Phentolamine also relieves coronary artery spasm and myocardial ischemia. Electrical synchronized cardioversion should be considered for patients with hemodynamically unstable dysrhythmias. Lidocaine is not recommended initially but may be used after 3 hours for ventricular tachycardia. Wide complex QRS ventricular tachycardia may be treated with sodium bicarbonate 2 mEq/kg as a bolus.  $\beta$ -Adrenergic blockers are not recommended.

Anxiety, agitation, and convulsions can be treated with diazepam. If diazepam fails to control seizures, neuromuscular blockers can be used. The EEG should be monitored for nonmotor seizure activity. For hyperthermia, external cooling and cool humidified 100% oxygen should be administered. Neuromuscular paralysis to control seizures will reduce temperature. Dantrolene and antipyretics are not recommended. Rhabdomyolysis and myoglobinuria are treated with fluids, alkaline diuresis, and diuretics.

If the patient is pregnant, the fetus must be monitored and the patient observed for spontaneous abortion.

Paranoid ideation and threatening behavior should be treated with rapid tranquilization. The patient should be observed for suicidal depression that may follow intoxication and may require suicide precautions. If focal neurologic manifestations are present, one should consider the possibility of a cerebrovascular accident and obtain a CT scan.

Extracorporeal clearance techniques are of no benefit.

### Disposition

Patients with mild intoxication or a brief seizure that does not require treatment who become asymptomatic may be discharged after 6 hours with appropriate psychosocial follow-up. If cardiac or cerebral ischemic manifestations are present, the patient should be monitored in the intensive care unit. Body packers and stuffers require care in the intensive care unit until passage of the contraband.

### Cyanide

Hydrogen cyanide is a byproduct of burning plastic and wools in residential fires. Hydrocyanic acid is the liquefied form of hydrogen cyanide. Cyanide salts can be found in ore extraction. Nitriles, such as acetonitrile (artificial nail removers), are metabolized in the body to produce cyanide. Cyanogenic glycosides are present in some fruit seeds (such as amygdalin in apricots, peaches, and apples). Sodium nitroprusside, the antihypertensive vasodilator, contains five cyanide groups.

### Toxic Mechanism

Cyanide blocks the cellular electron transport mechanism and cellular respiration by inhibiting the mitochondrial ferricytochrome oxidase system and other enzymes. This results in cellular hypoxia and lactic acidosis. *Note:* Citrus fruit seeds form cyanide in the presence of intestinal  $\beta$ -glucosidase (the seeds are harmful only if the capsule is broken).

### Toxic Dose

The ingestion of 1 mg/kg or 50 mg of hydrogen cyanide can produce death within 15 minutes. The lethal dose of potassium cyanide is 200 mg. Five to 10 mL of 84% acetonitrile is lethal. Infusions of sodium nitroprusside in rates above 2  $\mu$ g/kg per minute may cause cyanide to accumulate to toxic concentrations in critically ill patients.

### Kinetics

Cyanide is rapidly absorbed by all routes. In the stomach, it forms hydrocyanic acid. Volume distribution is 1.5 L/kg. Protein binding is 60%. Cyanide is detoxified by metabolism in the liver via the mitochondrial thiosulfate-rhodanase pathway, which catalyzes the transfer of sulfur donor to cyanide, forming the less toxic irreversible thiocyanate that is excreted in the urine. Cyanide is also detoxified by reacting with hydroxocobalamin (vitamin B<sub>12a</sub>) to form cyanocobalamin (vitamin B<sub>12</sub>).

The cyanide elimination half-life from the blood is 1.2 hours. The elimination route is through the lungs.

### Manifestations

Hydrogen cyanide has the distinctive odor of bitter almonds or silver polish. Manifestations of cyanide intoxication include hypertension, cardiac dysrhythmias, various ECG abnormalities, headache, hyperpnea, seizures, stupor, pulmonary edema, and flushing. Cyanosis is absent or appears late.

### Laboratory Investigations

The examiner should obtain and monitor ABGs, oxygen saturation, blood lactate, hemoglobin, blood glucose, and electrolytes. Lactic acidemia, a decrease in the arterial-venous oxygen difference, and bright red venous blood occurs. If smoke inhalation is the possible source of cyanide exposure, CoHB and methemoglobin (MetHb) concentrations should be measured.

Cyanide levels in whole blood, red blood cells, or serum are not useful in the acute management because the determinations are not readily available. Specific cyanide blood levels are as follows: smokers have less than 0.5  $\mu$ g/mL; a patient with flushing and tachycardia has 0.5 to 1.0  $\mu$ g/mL, one with obtundation has 1.0 to 2.5  $\mu$ g/mL, and one in coma or who has died has more than 2.5  $\mu$ g/mL.

### Management

If the cyanide was inhaled, the patient must be removed from the contaminated atmosphere. Attendants should not administer mouth-to-mouth resuscitation. Rescuers and attendants must be protected. Immediate administration of 100% oxygen is called for and oxygen should be continued during and after administration of the antidote. The clinician must decide whether to use any or all components of the cyanide antidote kit.

The mechanism of action of the antidote kit is twofold: to produce methemoglobinemia and to provide a sulfur substrate for the detoxification of cyanide. The nitrites make methemoglobin,

which has a greater affinity for cyanide than does the cytochrome oxidase enzymes. The combination of methemoglobin and cyanide forms cyanomethemoglobin. Sodium thiosulfate provides a sulfur substrate for the rhodanese enzyme, which converts cyanide into the relatively nontoxic sodium thiocyanate, which is excreted by the kidney.

The procedure for using the antidote kit is as follows:

**Step 1:** Amyl nitrite inhalant perles is only a temporizing measure (forms only 2% to 5% methemoglobin) and it can be omitted if venous access is established. Alternate 100% oxygen and the inhalant for 30 seconds each minute. Use a new perle every 3 minutes.

**Step 2:** Sodium nitrite ampule is indicated for cyanide exposures, except for cases of residential fires, smoke inhalation, and nitroprusside or acetonitrile poisonings. It is administered intravenously to produce methemoglobin of 20% to 30% at 35 to 70 minutes after administration. A dose of 10 mL of 3% solution of sodium nitrite for adults and 0.33 mL/kg of 3% solution for children is diluted to 100 mL 0.9% saline and administered slowly intravenously at 5 mL/min. If hypotension develops, the infusion should be slowed.

**Step 3:** Sodium thiosulfate is useful alone in cases of smoke inhalation, nitroprusside toxicity, and acetonitrile toxicity and should not be used at all in cases of hydrogen sulfide poisoning. The administration dose is 12.5 g of sodium thiosulfate or 50 mL of 25% solution for adults and 1.65 mL/kg of 25% solution for children intravenously over 10 to 20 minutes.

If cyanide symptoms recur, further treatment with nitrites or the perles is controversial. Some authorities suggest repeating the antidotes in 30 minutes at half of the initial dose, but others do not advise this for lack of efficacy. The child dosage regimen on the package insert must be carefully followed.

One hour after antidotes are administered, the methemoglobin level should be obtained and should not exceed 20%. Methylene blue should not be used to reverse excessive methemoglobin.

Gastrointestinal decontamination of oral ingestion by activated charcoal is recommended but is not very effective because of the rapidity of absorption. Seizures are treated with intravenous diazepam. Acidosis should be treated with sodium bicarbonate if it does not rapidly resolve with therapy. There is no role for hyperbaric oxygen or hemodialysis or hemoperfusion.

Other antidotes include hydroxocobalamin (vitamin B<sub>12a</sub>) (Cyanokit), which has proven effective when given immediately after exposure in large doses of 4 g (50 mg/kg) or 50 times the amount of cyanide exposure with 8 g of sodium thiosulfate. Hydroxocobalamin has FDA orphan drug approval.

### Disposition

Asymptomatic patients should be observed for a minimum of 3 hours. Patients who ingest nitrile compounds must be observed for 24 hours. Patients requiring antidote administration should be admitted to the intensive care unit.

### Digitalis

Cardiac glycosides are found in cardiac medications, common plants, and the skin of the Bufo toad.

### Toxic Mechanism

Cardiac glycosides inhibit the enzyme sodium/potassium-adenosine triphosphatase (Na<sup>+</sup>,K<sup>+</sup>,ATPase), leading to intracellular potassium loss and increased intracellular sodium, and producing phase 4 depolarization, increased automaticity, and ectopy. There is increased intracellular calcium and potentiation of contractility. Pacemaker cells are inhibited, and the refractory period is prolonged, leading to atrioventricular blocks. There is increased vagal tone.

### Toxic Dose

Digoxin total digitalizing dose, the dose required to achieve therapeutic blood levels of 0.6 to 2.0 ng/mL, is 0.75 to 1.25 mg or 10 to 15 µg/kg for patients older than 10 years of age; 40 to 50 µg/kg

for patients younger than 2 years of age; and 30 to 40 µg/kg for patients 2 to 10 years of age.

The acute single toxic dose is greater than 0.07 mg/kg or greater than 2 or 3 mg in an adult, but 2 mg in a child or 4 mg in an adult usually produces only mild toxicity. One to 3 mg or more may be found in a few leaves of oleander or foxglove. Serious and fatal overdoses are more than 4 mg in a child and more than 10 mg in an adult.

Acute digitoxin ingestion of 10 to 35 mg has produced severe toxicity and death. Digitoxin therapeutic steady state is 15 to 25 ng/mL. In cases of chronic or acute-on-chronic ingestions in patients with cardiac disease, more than 2 mg may produce toxicity; however, toxicity can develop within therapeutic range on chronic therapy.

Patients at greatest risk of overdose include those with cardiac disease, those with electrolyte abnormalities (low potassium, low magnesium, low T<sub>4</sub>, high calcium), those with renal impairment, and those on amiodarone (Cordarone), quinidine, erythromycin, tetracycline, calcium channel blockers, and β-blockers.

### Kinetics

Digoxin is a metabolite of digitoxin. In cases of oral overdose, the typical onset is 30 minutes, with peak effects in 3 to 12 hours. Duration is 3 to 4 days. Intravenous onset is in 5 to 30 minutes; peak level is immediate, and peak effect is at 1.5 to 3 hours.

Volume distribution is 5 to 6 L/kg. The cardiac-to-plasma ratio is 30:1. After an acute ingestion overdose, the serum concentration is not reflective of tissue concentration for at least 6 hours or more, and steady state is 12 to 16 hours after last dose.

Sixty percent to 80% of the parent compound is excreted unchanged in the urine. The elimination half-life is 30 to 50 hours.

### Manifestations

Onset of manifestations is usually within 2 hours but may be delayed up to 12 hours.

Gastrointestinal effects of nausea and vomiting are frequently present in cases of acute ingestion but may also occur in cases of chronic ingestion. The “digitalis effect” on ECG is scooped ST segments and PR prolongation; in cases of overdose, any dysrhythmia or block is possible but none are characteristic. Bradycardia occurs in patients with acute overdose with healthy hearts; supraventricular tachycardia occurs in patients with existing heart disease or chronic overdose. Ventricular tachycardia is seen only in cases of severe poisoning.

The CNS effects include headaches, visual disturbances, and colored halo vision. Hyperkalemia occurs following acute overdose and correlates with digoxin level and outcome. Among patients with serum potassium levels of less than 5.0 mEq/L, all survive. If the level is 5 to 5.5, 50% survive, and if the level is greater than 5.5, all die. Hypokalemia is commonly seen with chronic intoxication. Patients with normal digitalis levels may have toxicity in the presence of hypokalemia.

Chronic intoxications are more likely to produce scotoma, color perception disturbances, yellow vision, halos, delirium, hallucinations or psychosis, tachycardia, and hypokalemia.

### Laboratory Investigations

Continuous monitoring of ECG, pulse, and blood pressure is called for. Blood glucose, electrolytes, calcium, magnesium, BUN, and creatinine levels should also be monitored. An initial digoxin level should be measured on patient presentation and repeated thereafter. Levels should be measured more than 6 hours post-ingestion because earlier values do not reflect tissue distribution. Digoxin clinical toxicity is usually associated with serum digoxin levels of greater than 3.5 ng/mL in adults.

An endogenous digoxin-like substance cross-reacts in most common immunoassays (not with high-pressure liquid chromatography) and values as high as 4.1 ng/mL have been reported in newborns, patients with chronic renal failure, patients with abnormal immunoglobulins, and women in the third trimester of pregnancy.

## Management

A cardiology consult should be obtained and a pacemaker should be readily available.

In undertaking gastrointestinal decontamination, excessive vagal stimulation should be avoided (e.g., emesis and gastric lavage). Activated charcoal should be administered, and if a nasogastric tube is required for the activated charcoal, pretreatment with atropine (0.02 mg/kg in children and 0.5 mg in adults) should be considered.

Digoxin-specific antibody fragments (Fab, Digibind) 38 mg binds 0.5 mg digoxin and then is excreted through the kidneys. The onset of action is within 30 minutes. Problems associated with Fab therapy are mainly from withdrawal of digoxin and worsening heart failure, hypokalemia, decrease in glucose (if the patient has low glycogen stores), and allergic reactions (very rare). Digitalis administered after Fab therapy is bound and may be inactivated for 5 to 7 days.

Absolute indications for Fab therapy include the following:

- Life-threatening malignant (hemodynamically unstable) dysrhythmias
- Ventricular dysrhythmias, unstable severe bradycardia, or second- or third-degree blocks unresponsive to atropine or rapid deterioration in clinical status
- Life-threatening digitoxin and oleander poisonings

Relative indications for Fab therapy include the following:

- Ingestions greater than 4 mg in a child and 10 mg in an adult
- Serum potassium level greater than 5.0 mEq/L
- Serum digoxin level greater than 10 ng/mL in adults or greater than 5 ng/mL in children 6 hours after an acute ingestion
- Digitalis delirium and thrombocytopenia response

Digoxin-specific Fab fragments therapy can be administered as a bolus through a 22- $\mu$ m filter if the case is a critical emergency. If the case is less urgent, then it can be administered over 30 minutes. An empiric dose is 10 vials in adults and 5 vials in a child for an unknown amount ingested in a symptomatic patient with history of a digoxin overdose.

To calculate the dose in the case of a known ingestion, the following equation is used:

$$\text{Amount (total mg)} \times (0.8) \text{ body burden}$$

If liquid capsules were taken or the substance was given intravenously the 80% bioavailability figure is not used. Instead, the body burden divided by 0.5 (0.5 mg digoxin is bound by 1 vial of 38 mg of Fab) equals the number of vials needed.

If the amount is unknown but the steady state serum concentration is known, the following equations are used:

For digoxin:

$$\begin{aligned} \text{Digitoxin ng/mL} \times (5.6 \text{ L/kg Vd}) \times (\text{wt kg}) &= \text{mg body burden} \\ \text{Body burden} \div 1000 &= \text{mg body burden} \\ \text{Body burden}/0.5 &= \text{number of vials needed} \end{aligned}$$

For digitoxin:

$$\begin{aligned} \text{Digitoxin ng/mL} \times (0.56 \text{ L/kg Vd}) \times (\text{wt kg}) &= \text{mg body burden} \\ \text{Body burden} \div 1000 &= \text{mg body burden} \\ \text{Body burden}/0.5 &= \text{number of vials needed} \end{aligned}$$

Antidysrhythmic agents or a pacemaker should be used only if Fab therapy fails. For ventricular tachydysrhythmias, electrolyte disturbances should be corrected by the administration of lidocaine or phenytoin. For torsades de pointes, magnesium sulfate 20 mL 20% IV can be given slowly over 20 minutes (or 25 to 50 mg/kg in a child), titrated to control the dysrhythmia. Magnesium should be discontinued if hypotension, heart block, or decreased deep tendon reflexes are present. Magnesium is used with caution if the patient has renal impairment.

Unstable bradycardia and second-degree and third-degree atrio-ventricular block should be treated by Fab first. A pacemaker should be available if necessary. Isoproterenol should be avoided because it causes dysrhythmias. Cardioversion is used with caution, starting at a setting of 5 to 10 joules. The patient

should be pretreated with lidocaine, if possible, because cardioversion may precipitate ventricular fibrillation or asystole.

Potassium disturbances are caused by a shift, not a change, in total body potassium. Hyperkalemia (>5.0 mEq/L) is treated with Fab only. Calcium must never be used, and insulin/glucose and sodium bicarbonate should not be used concomitantly with Fab because they may produce severe life-threatening hypokalemia. Sodium polystyrene sulfonate (Kayexalate) should not be used. Hypokalemia must be treated with caution because it may be cardioprotective. Treatment can be administered if the patient has ventricular dysrhythmias or a serum potassium level less than 3.0 mEq/L and atrioventricular block.

Extracorporeal procedures are ineffective. Hemodialysis is used for severe or refractory hyperkalemia.

One must never use antidysrhythmic types Ia (procainamide, quinidine, disopyramide [Norpace], amiodarone [Cordarone]), Ic (propafenone [Rythmol], flecainide [Tambocor]), II ( $\beta$ -blockers), or IV (calcium channel blockers). Class Ib drugs (lidocaine, phenytoin [Dilantin], mexiletine [Mexitil], and tocainide [Tonocard]) can be used.

## Disposition

Consultation with a poison control center and a cardiologist experienced with digoxin-specific Fab fragments is warranted. All patients with significant dysrhythmias, symptoms, elevated serum digoxin concentration, or elevated serum potassium level should be admitted to the intensive care unit.

## Ethanol

Table 15 lists the features of alcohols and glycols.

## Toxic Mechanism

Ethanol has CNS depressant and anesthetic effects. Ethanol stimulates the  $\gamma$ -aminobutyric acid (GABA) system. It promotes cutaneous vasodilation (contributes to hypothermia), stimulates secretion of gastric juice (gastritis), inhibits the secretion of the antidiuretic hormone, inhibits gluconeogenesis (hypoglycemia), and influences fat metabolism (lipidemia).

## Toxic Dose

A dose of 1 mL/kg of absolute ethanol (100% ethanol, or 200 proof) gives a blood ethanol concentration of 100 mg/dL. A potentially fatal dose is 3 g/kg for children or 6 g/kg for adults. Children are more prone to developing hypoglycemia than adults.

## Kinetics

Onset of action is 30 to 60 minutes after ingestion; peak action is 90 minutes on empty stomach. Volume distribution is 0.6 L/kg. The major route of elimination (>90%) is by hepatic oxidative metabolism. The first step is by the enzyme alcohol dehydrogenase, which converts ethanol to acetaldehyde. Alcohol dehydrogenase metabolizes ethanol at a constant rate of 12 to 20 mg/dL/h (12 to 15 mg/dL/h in nondrinkers, 15 to 30 mg/dL/h in social drinkers, 30 to 50 mg/dL/h in heavy drinkers, and 25 to 30 mg/dL/h in children). At very low blood ethanol concentration (>30 mg/dL), the metabolism is by first-order kinetics. In the second step, acetaldehyde is metabolized by acetaldehyde dehydrogenase to acetic acid, which is metabolized by the Krebs cycle to carbon dioxide and water. The enzyme steps are nicotinamide adenine dinucleotide-dependent, which interferes with gluconeogenesis. Less than 10% of ethanol is excreted unchanged by the kidneys. The relationship between blood ethanol concentration (BEC) and dose (amount ingested) can be calculated as follows:

$$\begin{aligned} \text{BEC (mg/dL)} &= \text{amount ingested (mL)} \times \\ &\% \text{ ethanol product} \times \text{SG (0.79)/Vd (0.6 L/kg)} \times \text{body wt (kg)} \\ \text{Dose (amount ingested)} &= \text{BEC (mg/dL)} \times \\ &\text{Vd (0.6)} \times \text{body wt (kg)/\% ethanol} \times \\ &\text{specific gravity (0.79)} \end{aligned}$$

**TABLE 15** Summary of Alcohol and Glycol Features

	METHANOL	ISOPROPANOL	ETHANOL	ETHYLENE GLYCOL
Principal uses	Gas line antifreeze, Sterno, windshield de-icer	Solvent jewelry cleaner, rubbing alcohol	Beverage, solvent	Radiator antifreeze, windshield de-icer
Specific gravity	0.719	0.785	0.789	1.12
Fatal dose	1 mL/kg 100%	3 mL/kg 100%	5 mL/kg 100%	1.4 mL/kg
Inebriation	±	2+	2+	1+
Metabolic change		Hyperglycemia	Hypoglycemia	Hypocalcemia
Metabolic acidosis	4+	0	1+	2+
Anion gap	4+	±	2+	4+
Ketosis	Ketobutyric	Acetone	Hydroxybutyric	None
Gastrointestinal tract	Pancreatitis	Hemorrhagic gastritis	Gastritis	
Osmolality*	0.337	0.176	0.228	0.190

\* 1 mEq/L of substances raises freezing point osmolality of serum. The validity of the correlation of osmolality with blood concentrations has been questioned.

### Manifestations

Table 16 lists the clinical signs of acute ethanol intoxication.

Chronic alcoholic patients tolerate higher blood ethanol concentration, and correlation with manifestations is not valid. Rapid interview for alcoholism is the CAGE questions:

- C—Have you felt the need to Cut down?
- A—Have others Annoyed you by criticism of your drinking?
- G—Have you felt Guilty about your drinking?
- E—Have you ever had a morning Eye-opening drink to steady your nerves or get rid of a hangover?

Two affirmative answers indicate probable alcoholism.

### Laboratory Investigations

The blood ethanol concentration should be specifically requested and followed. Gas chromatography or a breathalyzer test gives rapid reliable results if no belching or vomiting is present. Enzymatic methods do not differentiate between the alcohols. ABG, electrolytes, and glucose should be measured, the anion and osmolar gaps determined (measure by freezing point depression, not vapor pressure), and a check for ketosis made.

### Management

The examiner should inquire about trauma and disulfiram use. The patient must be protected from aspiration and hypoxia. Vital functions must be established and maintained. The patient may require intubation and assisted ventilation.

Gastrointestinal decontamination plays no role in the management of ethanol intoxication.

If the patient is comatose, glucose should be administered intravenously, 1 mL/kg 50% glucose in adults and 2 mL/kg 25% glucose in children. Thiamine, 100 mg intravenously, is administered if the patient has a history of chronic alcoholism, malnutrition, or suspected eating disorders to prevent Wernicke-Korsakoff syndrome. Naloxone (Narcan) has produced a partial inconsistent response but is not recommended for known alcoholics.

General supportive care includes administration of fluids to correct hydration and hypotension and correction of electrolyte abnormalities and acid-base imbalance. Vasopressors and plasma expanders may be necessary to correct severe hypotension. Hypomagnesemia is frequent in chronic alcoholics. In case of hypomagnesemia, a loading dose of 2 g magnesium sulfate 10% is administered by intravenous solution over 5 minutes in the intensive care unit with blood pressure and cardiac monitoring and calcium chloride 10% on hand in case of overdose. This is followed with constant infusion of 6 g of 10% solution over 3 to 4 hours. Caution must be taken with the use of magnesium if renal failure is present.

**TABLE 16** Clinical Signs in the Nontolerant Ethanol Drinker

ETHANOL BLOOD CONCENTRATION (MG/DL)*	MANIFESTATIONS
>25	Euphoria
>47	Mild incoordination, sensory and motor impairment
>50	Increased risk of motor vehicle accidents
>100	Ataxia (legal toxic level in many localities)
>150	Moderate incoordination, slow reaction time
>200	Drowsiness and confusion
>300	Severe incoordination, stupor, blurred vision
>500	Flaccid coma, respiratory failure, hypotension; may be fatal

\*Ethanol concentrations sometimes reported in %.

Note: mg% is not equivalent to mg/dL because ethanol weighs less than water (specific gravity 0.79). A 1% ethanol concentration is 790 mg/dL and 0.1% is 79 mg/dL. There is great variation in individual behavior at different blood ethanol levels. Behavior is dependent on tolerance and other factors.

Hypothermic patients should be warmed. See the section on disturbances caused by cold.

Hemodialysis can be used in severe cases when conventional therapy is ineffective (rarely needed).

Repeated or prolonged seizures should be treated with diazepam (Valium). The brief "rum fits" do not need long-term anticonvulsant therapy. Repeated seizures or focal neurologic findings may warrant skull radiographs, lumbar puncture, and CT scan of the head, depending on the clinical findings. Withdrawal is treated with hydration and large doses of chlordiazepoxide (Librium) 50 to 100 mg or diazepam (Valium) 2 to 10 mg intravenously; these doses may be repeated in 2 to 4 hours. Very large doses of benzodiazepines may be required for delirium tremens. Withdrawal can occur in presence of elevated blood ethanol concentration and can be fatal if left untreated.

Chest radiograph is warranted to determine whether aspiration pneumonia is present. Renal and liver function tests and bilirubin level measurement should be made.

### Disposition

Clinical severity (e.g., intubation, assisted ventilation, aspiration pneumonia) should determine the level of hospital care needed. Young children with significant unintentional exposure

to ethanol (calculated to reach a blood ethanol concentration of 50 mg/dL) should have blood ethanol concentration obtained and blood glucose levels monitored for hypoglycemia frequently for 4 hours after ingestion. Patients with acute ethanol intoxication seldom require admission unless a complication is present. However, intoxicated patients should not be discharged until they are fully functional (can walk, talk, and think independently), have suicide potential evaluated, have proper disposition environment, and have a sober escort.

### Ethylene Glycol

Ethylene glycol is found in solvents, de-icers, radiator antifreeze (95%), and air-conditioning units. Ethylene glycol is a sweet-tasting, colorless, water-soluble liquid with a sweet aromatic fragrance.

### Toxic Mechanism

Ethylene glycol is oxidized by alcohol dehydrogenase to glycolaldehyde, which is metabolized to glycolic acid and glyoxylic acid. Glyoxylic acid is metabolized to oxalic acid via a pyridoxine-dependent pathway to glycine and by thiamine and magnesium-dependent pathways to  $\alpha$ -hydroxy-ketoadipic acid. The metabolites of ethylene glycol produce a profound metabolic acidosis, increased anion gap, hypocalcemia, and oxalate crystals, which deposit in tissues (particularly the kidney).

### Toxic Dose

The ingestion of 0.1 mL/kg 100% ethylene glycol can result in a toxic serum ethylene glycol concentration of 20 mg/dL. Ingestion of 3.0 mL (less than 1 teaspoonful or swallow) of a 100% solution in a 10-kg child or 30 mL of 100% ethylene glycol in an adult produces a serum ethylene glycol concentration of 50 mg/dL, a concentration that requires hemodialysis. The fatal amount is 1.4 mL/kg of 100% solution.

### Kinetics

Absorption is via dermal, inhalation, and ingestion routes. Ethylene glycol is rapidly absorbed from the gastrointestinal tract. Onset is usually in 30 minutes but may be delayed by co-ingestion of food and ethanol. The usual peak level is at 2 hours. Volume distribution is 0.65 to 0.8 L/kg.

For metabolism, see *Toxic Mechanism*.

The half-life of ethylene glycol without ethanol is 3 to 8 hours; with ethanol, it is 17 hours, and with hemodialysis it is 2.5 hours. Renal clearance is 3.2 mL/kg/min. About 20% to 50% is excreted unchanged in the urine. The relationship between serum ethylene glycol concentration (SEGC) and dose (amount ingested) can be calculated as follows:

$$0.12 \text{ mL/kg of } 100\% = \text{SEGC } 10 \text{ mg/dL}$$

### Manifestations

**Phase I.** The onset of manifestations is 30 minutes to several hours longer after ingestion with concomitant ethanol ingestion. The patient may be inebriated. Hypocalcemia, tetany, and calcium oxalate and hippuric acid crystals in urine can be seen within 4 to 8 hours but are not always present. Early, before metabolism of ethylene glycol, an osmolal gap may be present (see *Laboratory Investigations*). Later, the metabolites of ethylene glycol produce changes starting 4 to 12 hours following ingestion, including an anion gap, metabolic acidosis, coma, convulsions, cardiac disturbances, and pulmonary and cerebral edema. Because fluorescein is added to some antifreeze, the presence of fluorescence may be a clue to ethylene glycol exposure. However, it has been shown that fluorescent urine is not a reliable indicator of ethylene glycol ingestion and should not be used as a screen.

**Phase II.** After 12 to 36 hours, cardiopulmonary deterioration occurs, with pulmonary edema and congestive heart failure.

**Phase III.** Phase III occurs 36 to 72 hours after ingestion, with pulmonary edema and oliguric renal failure from oxalate crystal deposition and tubular necrosis predominating.

**Phase IV.** Neurologic sequelae may occur rarely, especially in patients who fail to receive early antidotal therapy. The onset ranges from 6 to 10 days after ingestion. Findings include facial diplegia, hearing loss, bilateral visual disturbances, elevated cerebrospinal fluid pressure with or without elevated protein levels and pleocytosis, vomiting, hyperreflexia, dysphagia, and ataxia.

### Laboratory Investigations

Blood glucose and electrolytes should be monitored. Urinalysis should look for oxalate ("envelope") and monohydrate ("hemp seed") crystals. Urine fluorescence is not reliable as a screen. ABG, ethylene glycol, and ethanol levels, plasma osmolality (using freezing point depression method), calcium, BUN, and creatinine should be measured. A serum ethylene glycol concentration of 20 mg/dL is toxic (ethylene glycol levels are very difficult to obtain). If possible, a glycolate level should be obtained. Cross-reactions with propylene glycol, a vehicle in many liquids and intravenous medications (phenytoin [Dilantin], diazepam [Valium]), other glycols, and triglycerides, may produce spurious ethylene glycol levels. False-positive ethylene glycol values may occur with colorimetric or gas chromatography using an OV-17 column in the presence of propylene glycol.

The following equations can be used to calculate the osmolality, osmolal gap, and ethylene glycol level:

$$2(\text{Na} + \text{mEq/L}) + (\text{Blood glucose mg/dL})/20 + (\text{BUN mg/dL})/3 = \text{Total calculated osmolality (mOsm/L)}$$

Osmolar Gap = measured osmolality (by freezing point depression method) – calculate osmolality

A gap greater than 10 is abnormal. *Note:* if ethanol is involved, add ethanol level/4.6 to the calculated equation.

An increased osmolal gap is produced by the following common substances: acetone, dextran, dimethyl sulfoxide, diuretics, ethanol, ethyl ether, ethylene glycol, isopropanol, paraldehyde, mannitol, methanol, sorbitol, and trichloroethane. [Table 10](#) gives the conversion factors for these substances.

Although a specific blood level of ethylene glycol in milligrams per deciliter can be estimated using the equation below, this is not considered to be a reliable method and should not take the place of obtaining a measured ethylene glycol blood concentration.

$$\text{Osmolar gap} \times \text{conversion factor} = \text{serum concentration}$$

**Caution:** The accuracy of the ethylene glycol estimated decreases as the ethylene glycol levels decrease. The toxic metabolites are not osmotically active, and patients presenting late may show signs of severe toxicity without an elevated osmolar gap.

The anion gap can be calculated using the following equation:

$$\text{Na} - (\text{Cl} + \text{HCO}_3) = \text{anion gap}$$

The normal gap is 8 to 12. Potassium is not used because it is a small amount and may be hemolyzed. [Table 8](#) lists factors that may account for an increased or a decreased anion gap.

### Management

Vital functions should be established and maintained. The airway must be protected, and assisted ventilation can be used, if necessary. Gastrointestinal decontamination has a limited role. Only gastric aspiration can be used within 60 minutes after ingestion. Activated charcoal is not effective.

Baseline measurements of serum electrolytes and calcium, glucose, ABGs, ethanol, serum ethylene glycol concentration (may be difficult to obtain readily in some institutions), and methanol concentrations should be obtained. In the first few hours, the measured serum osmolality should be determined and compared to calculated osmolality (see osmolality equation, earlier). If seizures occur, one should measure serum calcium (preferably ionized calcium) and treat with intravenous diazepam. If the patient has hypocalcemic seizures, he or she should also be treated with 10 to 20 mL 10% calcium gluconate (0.2 to 0.3 mL/kg in children) slowly intravenously, with the dose repeated as needed. Metabolic acidosis should be corrected with intravenous sodium bicarbonate.

Ethanol therapy should be initiated immediately if fomepizole (Antizol) is unavailable (see next paragraph). Alcohol dehydrogenase has a greater affinity for ethanol than ethylene glycol. Therefore, ethanol blocks the metabolism of ethylene glycol. Ethanol therapy is called for if there is a history of ingestion of 0.1 mL/kg of 100% ethylene glycol, serum ethylene glycol concentration is greater than 20 mg/dL, there is an osmolar gap not accounted for by other alcohols or factors (e.g., hyperlipidemia), metabolic acidosis is present with an increased anion gap, or there are oxalate crystals in the urine. Ethanol should be administered intravenously (the oral route is less reliable) to produce a blood ethanol concentration of 100 to 150 mg/dL. The loading dose is 10 mL/kg of 10% ethanol intravenously, administered concomitantly with a maintenance dose of 10% ethanol of 1.0 mL/kg/h. This dose may need to be increased to 2 mL/kg/h in patients who are heavy drinkers. The blood ethanol concentration should be measured hourly and the infusion rate should be adjusted to maintain a blood ethanol concentration of 100 to 150 mg/dL.

Fomepizole (Antizol, 4-methylpyrazole) inhibits alcohol dehydrogenase more reliably than ethanol and it does not require constant monitoring of ethanol levels and adjustment of infusion rates. Fomepizole is available in 1 g/mL vials of 1.5 mL. The loading dose is 15 mg/kg (0.015 mL/kg) IV; maintenance dose is 10 mg/kg (0.01 mL/kg) every 12 hours for four doses, then 15 mg/kg every 12 hours until the ethylene glycol levels are less than 20 mg/dL. The solution is prepared by being mixed with 100 mL of 0.9% saline or D<sub>5</sub>W (5% dextrose in water). Fomepizole can be given to patients requiring hemodialysis but should be dosed as follows:

Dose at the beginning of hemodialysis:

- If <6 hours since last Antizol dose, do not administer dose
- If >6 hours since last dose, administer next scheduled dose

Dosing during hemodialysis:

- Dose every 4 hours

Dosing at the time hemodialysis is completed:

- If <1 hour between last dose and end of dialysis, do not administer dose at end of dialysis
- If 1 to 3 hours between last dose and end of dialysis, administer one half of next scheduled dose
- If >3 hours between last dose and end of dialysis, administer next scheduled dose

Maintenance dosing off hemodialysis:

- Give the next scheduled dose 12 hours from the last dose administered

Hemodialysis is indicated if the ingestion was potentially fatal; if the serum ethylene glycol concentration is greater than 50 mg/dL (some recommend at levels of >25 mg/dL); if severe acidosis or electrolyte abnormalities occur despite conventional therapy; or if congestive heart failure or renal failure is present. Hemodialysis reduces the ethylene glycol half-life from 17 hours on ethanol therapy to 3 hours. Therapy (fomepizole and hemodialysis) should be continued until the serum ethylene glycol concentration is less than 10 mg/dL, the glycolate level is nondetectable (not readily available), the acidosis has cleared, there are no mental disturbances, the creatinine level is normal, and the urinary output is adequate. This may require 2 to 5 days.

Adjunct therapy involving thiamine, 100 mg/d (in children, 50 mg), slowly over 5 minutes intravenously or intramuscularly and repeated every 6 hours and pyridoxine, 50 mg IV or IM every 6 hours, has been recommended until intoxication is resolved, but these agents have not been extensively studied. Folate, 50 mg IV (child 1 mg/kg), can be given every 4 hours for 6 doses.

### Disposition

All patients who have ingested significant amounts of ethylene glycol (calculated level above 20 mg/dL), have a history of a toxic dose, or are symptomatic should be referred to the emergency department and admitted. If the serum ethylene glycol concentration cannot be obtained, the patient should be followed for 12 hours, with monitoring of the osmolar gap, acid-base parameters, and electrolytes to exclude development of metabolic acidosis

with an anion gap. Transfer should be considered for fomepizole therapy or hemodialysis.

### Hydrocarbons

The lower the viscosity and surface tension of hydrocarbons or the greater the volatility, the greater the risk of aspiration. Volatile substance abuse has produced the “Sudden Sniffing’s Death Syndrome,” most likely caused by dysrhythmias.

### Toxicologic Classification and Toxic Mechanism

All systemically absorbed hydrocarbons can lower the threshold of the myocardium to dysrhythmias produced by endogenous and exogenous catecholamines.

Aliphatic hydrocarbons are branched straight chain hydrocarbons. A few aspirated drops are poorly absorbed from the gastrointestinal tract and produce no systemic toxicity by this route. However, aspiration of very small amounts can produce chemical pneumonitis. Examples of aliphatic hydrocarbons are gasoline, kerosene, charcoal lighter fluid, mineral spirits (Stoddard’s solvent), and petroleum naphtha. Mineral seal oil (signal oil), found in furniture polishes, is a low-viscosity and low-volatility oil with minimum absorption that never warrants gastric decontamination. It can produce severe pneumonia if aspirated.

Aromatic hydrocarbons are six carbon ring structures that are absorbed through the gastrointestinal tract. Systemic toxicity includes CNS depression and, in cases of chronic abuse, multiple organ effects such as leukemia (benzene) and renal toxicity (toluene). Examples are benzene, toluene, styrene, and xylene. The seriously toxic ingested dose is 20 to 50 mL in adults.

Halogenated hydrocarbons are aliphatic or aromatic hydrocarbons with one or more halogen substitutions (Cl, Br, Fl, or I). They are highly volatile and are abused as inhalants. They are well absorbed from the gastrointestinal tract, produce CNS depression, and have metabolites that can damage the liver and kidneys. Examples include methylene chloride (may be converted into carbon monoxide in the body), dichloroethylene (also causes a disulfiram [Antabuse] reaction known as “degreaser’s flush” when associated with consumption of ethanol), and 1,1,1-trichloroethane (Glamorene Spot Remover, Scotchgard, typewriter correction fluid). An acute lethal oral dose is 0.5 to 5 mL/kg.

Dangerous additives to the hydrocarbons can be summed up with the mnemonic CHAMP: C, camphor (demoting agent); H, halogenated hydrocarbons; A, aromatic hydrocarbons; M, metals (heavy); and P, pesticides. Ingestion of these substances may warrant gastric emptying with a small-bore nasogastric tube.

Heavy hydrocarbons have high viscosity, low volatility, and minimal gastrointestinal absorption, so gastric decontamination is not necessary. Examples are asphalt (tar), machine oil, motor oil (lubricating oil, engine oil), home heating oil, and petroleum jelly (mineral oil).

### Laboratory Investigations

The ECG, ABG, pulmonary function, serum electrolytes, and serial chest radiographs should be continuously monitored. Liver and renal function should be monitored in cases of inhalation of aromatic hydrocarbons.

### Management

Asymptomatic patients who ingested small amounts of aliphatic petroleum distillates can be followed at home by telephone for development of signs of aspiration (cough, wheezing, tachypnea, and dyspnea) for 4 to 6 hours. Inhalation of any hydrocarbon vapors in a closed space can produce intoxication. The victim must be removed from the environment, have oxygen administered, and receive respiratory support.

Gastrointestinal decontamination is not advised in cases of hydrocarbon ingestion that usually do not cause systemic toxicity (aliphatic petroleum distillates, heavy hydrocarbons). In cases of ingestion of hydrocarbons that cause systemic toxicity in small amounts (aromatic hydrocarbons, halogenated hydrocarbons),

the clinician should pass a small-bore nasogastric tube and aspirate if the ingestion was within 2 hours and if spontaneous vomiting has not occurred. Some toxicologists advocate ipecac-induced emesis under medical supervision instead of small-bore nasogastric gastric lavage; we do not.

Patients with altered mental status should have their airway protected because of concern about aspiration. The use of activated charcoal has been suggested, but there are no scientific data as to effectiveness and it may produce vomiting. Activated charcoal may, however, be useful in adsorbing toxic additives such as pesticides or co-ingestants.

The symptomatic patient who is coughing, gagging, choking, or wheezing on arrival has probably aspirated. The clinician should provide supportive respiratory care and supplemental oxygen, while monitoring pulse oximetry, ABG, chest radiograph, and ECG. The patient should be admitted to the intensive care unit. A chest radiograph for aspiration may be positive as early as 30 minutes after ingestion, and almost all are positive within 6 hours. Negative chest radiographs within 4 hours do not rule out aspiration.

Bronchospasm is treated with a nebulized  $\beta$ -adrenergic agonist and intravenous aminophylline if necessary. Epinephrine should be avoided because of susceptibility to dysrhythmias. Cyanosis in the presence of a normal arterial  $\text{PaO}_2$  may be a result of methemoglobinemia that requires therapy with methylene blue. Corticosteroids and prophylactic antimicrobial agents have not been shown to be beneficial. (Fever or leukocytosis may be produced by the chemical pneumonitis itself.)

Most infiltrations resolve spontaneously in 1 week; lipoid pneumonia may last up to 6 weeks. It is not necessary to surgically treat pneumatoceles that develop because they usually resolve. Dysrhythmias may require  $\alpha$ - and  $\beta$ -adrenergic antagonists or cardioversion.

There is no role for enhanced elimination procedures.

Methylene chloride is metabolized over several hours to carbon monoxide. See treatment of carbon monoxide poisoning. Halogenated hydrocarbons are hepatorenal toxins; therefore, hepatorenal function should be monitored. *N*-acetylcysteine therapy may be useful if there is evidence of hepatic damage.

Extracorporeal membrane oxygenation (ECMO) has been used successfully for a few patients with life-threatening respiratory failure. Surfactant used for hydrocarbon aspiration was found to be detrimental.

### Disposition

Asymptomatic patients with small ingestions of petroleum distillates can be managed at home. Symptomatic patients with abnormal chest radiographic, oxygen saturation, or ABG findings should be admitted. Patients who become asymptomatic and have normal oxygenation and a normal repeat radiograph can be discharged.

### Iron

There are more than 100 iron over-the-counter preparations for supplementation and treatment of iron deficiency anemia.

### Toxic Mechanism

Toxicity depends on the amount of elemental iron available in various salts (gluconate 12%, sulfate 20%, fumarate 33%, lactate 19%, chloride 21% of elemental iron), not the amount of the salt. Locally, iron is corrosive and may cause fluid loss, hypovolemic shock, and perforation. Excessive free unbound iron in the blood is directly toxic to the vasculature and leads to the release of vasoactive substances, which produces vasodilation. In cases of overdose, iron deposits injure mitochondria in the liver, the kidneys, and the myocardium. The exact mechanism of cellular damage is not clear but is thought to be related to free radical formation.

### Toxic Dose

The therapeutic dose is 6 mg/kg/d of elemental iron. An elemental iron dose of 20 to 40 mg/kg may produce mild self-limited

gastrointestinal symptoms, 40 to 60 mg/kg produces moderate toxicity, more than 60 mg/kg produces severe toxicity and is potentially lethal, and more than 180 mg/kg is usually fatal without treatment. Children's chewable vitamins with iron have between 12 and 18 mg of elemental iron per tablet or 0.6 mL of liquid drops. These preparations rarely produce toxicity unless very large quantities are ingested and have never caused death.

### Kinetics

Absorption occurs chiefly in the upper small intestine. Ferrous (+2) iron is absorbed into the mucosal cells, where it is oxidized to the ferric (+3) state and bound to ferritin. Iron is slowly released from ferritin into the plasma, where it binds to transferrin and is transported to specific tissues for production of hemoglobin (70%), myoglobin (5%), and cytochrome. About 25% of iron is stored in the liver and spleen. In cases of overdose, larger amounts of iron are absorbed because of direct mucosal corrosion. There is no mechanism for the elimination of iron (elimination is 1 to 2 mg/d) except through bile, sweat, and blood loss.

### Manifestations

Serious toxicity is unlikely if the patient remains asymptomatic for 6 hours and has a negative abdominal radiograph. Iron intoxication can produce five phases of toxicity. The phases may not be distinct from one another.

**Phase I.** Gastrointestinal mucosal injury occurs 30 minutes to 12 hours postingestion. Vomiting starts within 30 minutes to 1 hour of ingestion and is persistent; hematemesis and bloody diarrhea may occur; abdominal cramps, fever, hyperglycemia, and leukocytosis may occur. Enteric-coated tablets may pass through the stomach without causing symptoms. Acidosis and shock can occur within 6 to 12 hours.

**Phase II.** A latent period of apparent improvement occurs over 8 to 12 hours postingestion.

**Phase III.** Systemic toxicity phase occurs 12 to 48 hours postingestion with cardiovascular collapse and severe metabolic acidosis.

**Phase IV.** Two to 4 days postingestion, hepatic injury associated with jaundice, elevated liver enzymes, and prolonged prothrombin time occur. Kidney injury with proteinuria and hematuria occur. Pulmonary edema, disseminated intravascular coagulation, and *Yersinia enterocolitica* sepsis can occur.

**Phase V.** Four to 8 weeks postingestion, pyloric outlet or intestinal stricture may cause obstruction or anemia secondary to blood loss.

### Laboratory Investigations

Iron poisoning produces anion gap metabolic acidosis. Monitoring should include complete blood cell counts, blood glucose level, serum iron, stools and vomitus for occult blood, electrolytes, acid-base balance, urinalysis and urinary output, liver function tests, and BUN and creatinine levels. Blood type and match should be obtained.

Serum iron measurements taken at the proper time correlate with the clinical findings. The lavender top Vacutainer tube contains EDTA, which falsely lowers serum iron. One must obtain the serum iron measurement before administering deferoxamine. Serum iron levels of less than 350  $\mu\text{g/dL}$  at 2 to 6 hours predict an asymptomatic course; levels of 350 to 500  $\mu\text{g/dL}$  are usually associated with mild gastrointestinal symptoms; those greater than 500  $\mu\text{g/dL}$  have a 20% risk of shock and serious iron toxicity. A follow-up serum iron measurement after 6 hours may not be elevated even in cases of severe poisoning, but a serum iron measurement taken at 8 to 12 hours is useful to exclude delayed absorption from a bezoar or sustained-release preparation. The total iron-binding capacity is not necessary.

Adult iron tablet preparations are radiopaque before they dissolve by 4 hours postingestion. A "negative" abdominal radiograph more than 4 hours postingestion does not exclude iron poisoning.

Patients who develop high fevers and signs of sepsis following iron overdose should have blood and stool cultures checked for *Yersinia enterocolitica*.

## Management

Gastrointestinal decontamination should involve immediate induction of emesis in cases of ingestions of elemental iron of greater than 40 mg/kg if vomiting has not already occurred. Activated charcoal is ineffective. An abdominal radiograph should be obtained after emesis to determine the success of gastric emptying. Children's chewable vitamins and liquid iron preparations are not radiopaque. If radiopaque iron is still present, whole-bowel irrigation with polyethylene glycol solution should be considered. In extreme cases, removal by endoscopy or surgery may be necessary because coalesced iron tablets produce hemorrhagic infarction in the bowel and perforation peritonitis.

Deferoxamine (Desferal) in a dose of about 100 mg binds 8.5 to 9.35 mg of free iron in the serum. The deferoxamine infusion should not exceed 15 mg/kg/h or 6 g daily, but faster rates (up to 45 mg/kg) and larger daily amounts have been administered and tolerated in extreme cases of iron poisoning (>1000 mg/dL). The deferoxamine-iron complex is hemodialyzable if renal failure develops.

Indications for chelation therapy are any of the following:

- Very large, symptomatic ingestions
- Serious clinical intoxication (severe vomiting and diarrhea [often bloody], severe abdominal pain, metabolic acidosis, hypotension, or shock)
- Symptoms that persist or progress to more serious toxicity
- Serum iron level greater than 500 mg/dL

Chelation should be performed as early as possible within 12 to 18 hours to be effective. One should start the infusion slowly and gradually increase to avoid hypotension.

Adult respiratory distress syndrome has developed in patients with high doses of deferoxamine for several days; infusions longer than 24 hours should be avoided.

The end point of treatment is when the patient is asymptomatic and the urine clears if it was originally a positive "vin rosö" color.

For supportive therapy, intravenous bicarbonate may be needed to correct the metabolic acidosis. Hypotension and shock treatment may require volume expansion, vasopressors, and blood transfusions. The physician should attempt to keep the urinary output at greater than 2 mL/kg/h. Coagulation abnormalities and overt bleeding require blood products or vitamin K. Pregnant patients are treated in a fashion similar to any other patient with iron poisoning.

Hemodialysis and hemoperfusion are ineffective. Exchange transfusion has been used in single cases of massive poisonings in children.

## Disposition

The asymptomatic or minimally symptomatic patient should be observed for persistence and progression of symptoms or development of toxicity signs (gastrointestinal bleeding, acidosis, shock, altered mental state). Patients with mild self-limited gastrointestinal symptoms who become asymptomatic or have no signs of toxicity for 6 hours are unlikely to have a serious intoxication and can be discharged after psychiatric clearance, if needed. Patients with moderate or severe toxicity should be admitted to the intensive care unit.

## Isoniazid

Isoniazid is a hydrazide derivative of vitamin B<sub>3</sub> (nicotinamide) and is used as an antituberculosis drug.

## Toxic Mechanism

Isoniazid produces pyridoxine deficiency by increasing the excretion of pyridoxine (vitamin B<sub>6</sub>) and by inhibiting pyridoxal 5-phosphate (the active form of pyridoxine) from acting with L-glutamic acid decarboxylase to form  $\gamma$ -aminobutyric acid (GABA), the major CNS neurotransmitter inhibitor, resulting in seizures. Isoniazid also blocks the conversion of lactate to pyruvate, resulting in profound and prolonged lactic acidosis.

## Toxic Dose

The therapeutic dose is 5 to 10 mg/kg (maximum 300 mg) daily. A single acute dose of 15 mg/kg lowers the seizure threshold; 35 to 40 mg/kg produces spontaneous convulsions; more than 80 mg/kg produces severe toxicity. A fatal dose in adults is 4.5 to 15 g. The malnourished patients, those with a previous seizure disorder, alcoholic patients, and slow acetylators are more susceptible to isoniazid toxicity. In cases of chronic intoxication, 10 mg/kg/d produces hepatitis in 10% to 20% of patients but less than 2% at doses of 3 to 5 mg/kg/d.

## Kinetics

Absorption from intestine occurs in 30 to 60 minutes, and onset is in 30 to 120 minutes, with peak levels of 5 to 8  $\mu$ g/mL within 1 to 2 hours. Volume distribution is 0.6 L/kg, with minimal protein binding.

Elimination is by liver acetylation to a hepatotoxic metabolite, acetyl-isoniazid, which is then hydrolyzed to isonicotinic acid. In slow acetylators, isoniazid has a half-life of 140 to 460 minutes (mean 5 hours), and 10% to 15% is eliminated unchanged in the urine. Most (45% to 75%) whites and 50% of African blacks are slow acetylators, and, with chronic use (without pyridoxine supplements), they may develop peripheral neuropathy. In fast acetylators, isoniazid has a half-life of 35 to 110 minutes (mean 80 minutes), and 25% to 30% is excreted unchanged in the urine. About 90% of Asians and patients with diabetes mellitus are fast acetylators and may develop hepatitis on chronic use.

In patients with overdose and hepatic disease, the serum half-life may increase. Isoniazid inhibits the metabolism of phenytoin (Dilantin), diazepam, phenobarbital, carbamazepine (Tegretol), and prednisone. These drugs also interfere with the metabolism of isoniazid. Ethanol may decrease the half-life of isoniazid but increase its toxicity.

## Manifestations

Within 30 to 60 minutes, nausea, vomiting, slurred speech, dizziness, visual disturbances, and ataxia are present. Within 30 to 120 minutes, the major clinical triad of severe overdose includes refractory convulsions (90% of overdose patients have one or more seizures), coma, and resistant severe lactic acidosis (secondary to convulsions), often with a plasma pH of 6.8.

## Laboratory Investigations

Isoniazid produces anion gap metabolic acidosis. Therapeutic levels are 5 to 8  $\mu$ g/mL and acute toxic levels are greater than 20  $\mu$ g/mL. These levels are not readily available to assist in making decisions in acute overdose situations. One should monitor the blood glucose (often hyperglycemia), electrolytes (often hyperkalemia), bicarbonate, ABGs, liver function tests (elevations occur with chronic exposure), BUN, and creatinine.

## Management

Seizures must be controlled. Pyridoxine and diazepam should be administered concomitantly through different IV sites. Pyridoxine (vitamin B<sub>6</sub>) is given in a dose of 1 g for each gram of isoniazid ingested. If the dose ingested is unknown, at least 5 g of pyridoxine should be given intravenously. Pyridoxine is administered in 50 mL D<sub>5</sub>W or 0.9% saline over 5 minutes intravenously. It must not be administered in the same bottle as sodium bicarbonate. Intravenous pyridoxine is repeated every 5 to 20 minutes until the seizures are controlled. Total doses of pyridoxine up to 52 g have been safely administered; however, patients given 132 and 183 g of pyridoxine have developed a persistent crippling sensory neuropathy.

Diazepam is administered concomitantly with pyridoxine but at a different site. They work synergistically. Diazepam should be administered intravenously slowly, 0.3 mg/kg at a rate of 1 mg/min in children or 10 mg at a rate of 5 mg/min in adults. After the seizures are controlled, the remainder of the pyridoxine is administered (1 g/1 g isoniazid) or a total dose of 5 g.

Phenobarbital or phenytoin is ineffective and should not be used.

In asymptomatic patients or patients without seizures, pyridoxine has been advised by some toxicologists prophylactically in gram-for-gram doses in cases of large overdoses (<80 mg/kg per dose) of isoniazid, although there are no studies to support this recommendation. In comatose patients, pyridoxine administration may result in the patient's rapid regaining of consciousness. Correction of acidosis may occur spontaneously with pyridoxine administration and correction of the seizures. Sodium bicarbonate should be administered if acidosis persists.

Hemodialysis is rarely needed because of antidotal therapy and the short half-life of isoniazid, but it may be used as an adjunct for cases of uncontrollable acidosis and seizures. Hemoperfusion has not been adequately evaluated. Diuresis is ineffective.

### Disposition

Asymptomatic or mildly symptomatic patients who become asymptomatic can be observed in the emergency department for 4 to 6 hours. Larger amounts of isoniazid may warrant pyridoxine administration and longer periods of observation. Intentional ingestions necessitate psychiatric evaluation before the patient is discharged. Patients with convulsions or coma should be admitted to the intensive care unit.

### Isopropanol (Isopropyl Alcohol)

Isopropanol can be found in rubbing alcohol, solvents, and lacquer thinner. Coma has occurred in children sponged for fever with isopropanol. See Table 10 for ethanol features of alcohols and glycols.

### Toxic Mechanism

Isopropanol is a gastric irritant. It is metabolized to acetone, a CNS and myocardial depressant. It inhibits gluconeogenesis. Normal propyl alcohol is related to isopropyl alcohol but is more toxic.

### Toxic Dose

A toxic dose of 0.5 to 1 mg/kg of 70% isopropanol (1 mL/kg of 70%) produces a blood isopropanol plasma concentration of 70 mg/dL. The CNS depressant potency is twice that of ethanol.

### Kinetics

Onset of action is within 30 to 60 minutes, and peak is 1 hour postingestion. Volume distribution is 0.6 kg/L. Isopropyl alcohol metabolizes to acetone. Its excretion is renal.

*Note:* The serum isopropyl concentration and amount ingested can be estimated using the same equation as is used in ethanol kinetics and substituting the specific gravity of 0.785 for isopropyl alcohol.

### Manifestations

Ethanol-like inebriation occurs, with an acetone odor to the breath, gastritis, occasionally with hematemesis, acetonuria, and acetonemia without systemic acidosis.

Depression of the CNS occurs: lethargy at blood isopropyl alcohol levels of 50 to 100 mg/dL, coma at levels of 150 to 200 mg/dL, potentially death in adults at levels greater than 240 mg/dL.

Hypoglycemia and seizures may occur.

### Laboratory Investigation

Monitoring of blood isopropyl alcohol levels (not readily available in all institutions), acetone, glucose, and ABG should be maintained. The osmolal gap increases 1 mOsm per 5.9 mg/dL of isopropyl alcohol and 1 mOsm per 5.5 mg/dL of acetone. The absence of excess acetone in the blood (normal is 0.3 to 2 mg/dL) within 30 to 60 minutes or excess acetone in the urine within 3 hours excludes the possibility of significant isopropanol exposure.

### Management

The airway must be protected with intubation, and assisted ventilation administered if necessary. If the patient is hypoglycemic,

**TABLE 17** Occupations Associated With Lead Exposure

Lead production or smelting	Demolition of ships and bridges
Production of illicit whiskey	Battery manufacturing
Brass, copper, and lead foundries	Machining/grinding lead alloys
Radiator repair	Welding of old painted metals
Scrap handling	Thermal paint stripping of old buildings
Sanding of old paint	Ceramic glaze/pottery mixing
Lead soldering	
Cable stripping	
Worker or janitor at a firing range	

Modified from Rempel D: The lead-exposed worker. *JAMA* 262:533, 1989.

glucose should be administered. Supportive treatment is similar to that for ethanol ingestions.

Gastrointestinal decontamination has no role in the treatment of isopropanol ingestion. Hemodialysis is warranted in cases of life-threatening overdose but is rarely needed. A nephrologist should be consulted if the blood isopropanol plasma concentration is greater than 250 mg/dL.

### Disposition

Symptomatic patients with concentrations greater than 100 mg/dL require at least 24 hours of close observation for resolution and should be admitted. If the patient is hypoglycemic, hypotensive, or comatose, he or she should be admitted to the intensive care unit.

### Lead

Acute lead intoxication is rare and usually occurs by inhalation of lead, resulting in severe intoxication and often death. Lead fumes can be produced by burning of lead batteries or use of a heat gun to remove lead paint. Acute lead intoxication also occurs from exposure to high concentrations of organic lead (e.g., tetraethyl lead).

Chronic lead poisoning occurs most often in children 6 months to 6 years of age who are exposed in their environment and in adults in certain occupations (Table 17). In the United States, the prevalence in children aged 1 to 5 years with a venous blood lead greater than 10 µg/dL decreased from 88.2% in a 1976–1980 survey to 8.9% in a 1988–1991 survey as a consequence of measures to reduce lead in the environment, particularly leaded gasoline. However, an estimated 1.7 million children between 1 and 5 years of age and more than 1 million workers in over 100 different occupations still have blood lead levels greater than 10 µg/dL.

### Toxic Dose

In cases of chronic lead poisoning, a daily intake of more than 5 µg/kg/d in children or more than 150 µg/d in adults can give a positive lead balance. In 1991, the Centers for Disease Control and Prevention (CDC) recommended routine screening for all children younger than 6 years of age. In children a venous blood level greater than 10 µg/dL was determined to be a threshold of concern. The average venous blood level in the United States is 4 µg/dL. In cases of occupational exposure (see Table 17), a venous blood level greater than 40 µg/dL is indicative of increased lead absorption in adults.

### Toxic Mechanism

Lead affects the sulfhydryl enzyme systems, the immature CNS, the enzymes of heme synthesis, vitamin D conversion, the kidneys, the bones, and growth. Lead alters the tertiary structure of cell proteins by denaturing them and causing cell death. Risk factors are mouthing behavior of infants and children and excessive oral behavior (pica), living in the inner city, a poorly maintained home, and poor nutrition (e.g., low calcium and iron). The CDC

questionnaire given in Table 18 is recommended at every pediatric visit. If any answers to the CDC questionnaire are “positive,” a blood screening test for lead should be administered. To be more accurate, however, identifying lead exposure studies have suggested that the questionnaire will have to be modified for each individual community because it has had poor sensitivity (40%) and specificity (60%) as it stands.

Table 19 lists sources of lead. The number one source is deteriorating lead-based paint, which forms leaded dust. Lead concentrations in indoor paint were not reduced to safer (0.06%) levels until 1978. Lead can also be produced by improper interior or exterior home renovation (scraping or demolition). It is found in pre-1960 built homes. The use of leaded gasoline (limited in 1973) resulted in residue from leaded motor vehicle emissions. Lead persists in the soil near major highways and in deteriorating homes and buildings. Vegetables grown in contaminated soil may contain lead.

Oil refineries and lead-processing smelters produce lead residue. Food cans produced in Mexico contain lead solder (95% do not in the United States). Lead water pipes (until 1950) and lead solder (until 1986) deliver lead-containing drinking water (calcium deposits, however, may offer some protection). Water at a consumer’s tap should contain less than 15 parts per billion (ppb) of lead (Table 20).

For occupational exposure, see Table 17. The Occupational Safety and Health Administration (OSHA) standards require employers to provide showering and clothes changing facilities for personnel working with lead; however, businesses with fewer than 25 employees are exempt from the regulation. The OSHA lead standard of 1978 set a limit of 60 µg/dL for occupational exposure to lead. At a blood lead level of 60 µg/dL, a worker should be removed from lead exposure and not allowed back until his or her lead level is below 40 µg/dL. Many authorities believe that this level should be lower. The lead residue on the clothes of the workers may represent a hazard to the family. Other occupations that are potential sources of lead exposure include plumbers, pipe fitters, lead miners, auto repairers, shipbuilders, printers, steel welders and cutters, construction workers, and rubber product manufacturers.

Leaded pots to make molds for “kumusha” tea represent lead exposure. Imported pottery lined with ceramic glaze can leach large amounts of lead into acids (e.g., citrus fruit juices).

Hobbies associated with lead exposure are listed in Box 1. Some “traditional” folk remedies or cosmetics that contain lead include the following:

**TABLE 18** CDC Questionnaire: Priority Groups for Lead Screening

1. Children age 6–72 months (was 12–36 months) who live in or are frequent visitors to older, deteriorated housing built before 1960.
2. Children age 6–72 months who live in housing built prior to 1960 with recent, ongoing, or planned renovation or remodeling.
3. Children age 6–72 months who are siblings, housemates, or playmates of children with known lead poisoning.
4. Children age 6–72 months whose parents or other household members participate in a lead-related industry or hobby.
5. Children age 6–72 months who live near active lead smelters, battery recycling plants, or other industries likely to result in atmospheric lead release.

**TABLE 19** Sources of Lead

PRODUCT	LEAD CONTENT (%) BY DRY WEIGHT
Paint	0.06
Solder	0.6
Plastic additives	2.0
Priming inks	2.0
Plumbing fixtures	2.0
Pesticides	0.1
Stained glass panes	0.1
Wine bottle foils	0.1
Construction material	0.1
Fertilizers	0.1
Glazes, enamels	0.06
Toys/recreational games	0.1
Curtain weights	0.1
Fishing weights	0.1

**TABLE 20** Agency Regulations and Recommendations Concerning Lead Content

AGENCY	SPECIMEN	LEVEL	COMMENTS
CDC	Blood (child)	10 µg/dL	Investigate community
OSHA	Blood (adult)	60 µg/dL	Medical removal from work
OSHA	Air	50 µg/m <sup>3</sup>	PEL*
	Air	0.75 µg/m <sup>3</sup>	Tetraethyl or tetramethyl
ACGIH	Air	150 µg/m <sup>3</sup>	TWA†
EPA	Air	1.5 µg/m <sup>3</sup>	Three-month average
EPA	Water	15 µg/L (ppb)	5 ppb circulating
EPA	Food	100 µg/d	Advisory
FDA	Wine	300 ppm	Plan to reduce to 200 ppm
EPA	Soil/dust	50 ppm	
CPSC	Paint	600 ppm (0.06%) by dry weight	

\*PEL = permissible exposure limit (highest level over an 8-hour workday).

†TWA = time-weighted average (air concentration for 8-hour workday and 40-hour workweek).

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; CDC = Centers for Disease Control and Prevention; CPSC = Consumer Product Safety Commission; EPA = Environmental Protection Agency; FDA = Food and Drug Administration; OSHA = Occupational Safety and Health Administration.

- “Azarcon por empacho” (“Maria Louisa” 90% to 95% lead trioxide): a bright orange powder used in Hispanic culture, especially Mexican, for digestive problems and diarrhea.
- “Greta” (4% to 90% lead): a yellow powder “por empacho” (“empacho” refers to a variety of gastrointestinal symptoms), used in Hispanic cultures, especially Mexican.
- “Pay-loo-ah”: an orange-red powder used for rash and fever in Southeast Asian cultures, especially among Northern Laos Hmong immigrants.
- “Alkohol” (Al-kohl, kohl, suma 5% to 92% lead): a black powder used in Middle Eastern, African, and Asian cultures as a cosmetic and an umbilical stump astringent.
- “Farouk”: an orange granular powder with lead used in Saudi Arabian culture.
- “Bint Al Zahab”: used to treat colic in Saudi Arabian culture.
- “Surma” (23% to 26% lead): a black powder used in India as a cosmetic and to improve eyesight.
- “Bali goli”: a round black bean that is dissolved in “grippe water,” used by Asian and Indian cultures to aid digestion.

Cases of substance abuse involving lead poisoning have been reported, in which the patient sniffs leaded gasoline or uses improperly synthesized amphetamines.

### BOX 1 Hobbies Associated With Lead Exposure

Casting of ammunition  
 Collecting antique pewter  
 Collecting/painting lead toys (e.g., soldiers and figures)  
 Ceramics or glazed pottery  
 Refinishing furniture  
 Making fishing weights  
 Home renovation  
 Jewelry making, lead solder  
 Glass blowing, lead glass  
 Bronze casting  
 Print making and other fine arts (when lead white, flake white, chrome yellow pigments are involved)  
 Liquor distillation  
 Hunting and target shooting  
 Painting  
 Car and boat repair  
 Burning/engraving lead-painted wood  
 Making stained leaded glass  
 Copper enameling

### Kinetics

Absorption of lead is 10% to 15% of the ingested dose in adults; in children, up to 40% is absorbed, especially in cases of iron deficiency anemia. With inhalation of fumes, absorption is rapid and complete. Volume distribution in blood (0.9% of total body burden) is 95% in red blood cells. Lead passes through the placenta to the fetus and is present in breast milk.

Organic lead is metabolized in the liver to inorganic lead. Its half-life is 35 to 40 days in blood; in soft tissue, the half-life is 45 days and in bone (99% of the lead), the half-life is 28 years. The major elimination route is the stool, 80% to 90%, and then renal 10% (80 g/d) and hair, nails, sweat, and saliva. Nine percent of organic lead is excreted in the urine per day.

### Manifestations

Adverse health effects are given in Table 21 and include the following.

TABLE 21 Summary of Lead-Induced Health Effects in Adults and Children

BLOOD LEAD LEVEL (MG/DL)	AGE GROUP	HEALTH EFFECT
>100	Adult	Encephalopathic signs and symptoms
>80	Adult	Anemia
	Child	Encephalopathy Chronic nephropathy (e.g., aminoaciduria)
>70	Adult	Clinically evident peripheral neuropathy
	Child	Colic and other gastrointestinal symptoms
>60	Adult	Female reproductive effects CNS disturbance symptoms (i.e., sleep disturbances, mood changes, memory and concentration problems, headaches)
>50	Adult	Decreased hemoglobin production Decreased performance on neurobehavioral tests
	Adult	Altered testicular function Gastrointestinal symptoms (i.e., abdominal pain, constipation, diarrhea, nausea, anorexia)
	Child	Peripheral neuropathy*
>40	Adult	Decreased peripheral nerve conduction Hypertension, age 40–59 years Chronic neuropathy*
	Adult	Elevated erythrocyte protoporphyrin in males
15–25	Adult	Elevated erythrocyte protoporphyrin in females
>10	Child	Decreased intelligence and growth Impaired learning Reduced birth weight* Impaired mental ability
	Fetus	Preterm delivery

From Anonymous: Implementation of the Lead Contamination Control Act of 1988. *MMWR Morb Mortal Wkly Rep* 41:288, 1992.

\*Controversial.

**Hematologic.** Lead inhibits  $\gamma$ -aminolevulinic acid dehydratase (early in the synthesis of heme) and ferrochelatase (transfers iron to ferritin for incorporation of iron into protoporphyrin to produce heme). Anemia is a late finding. Decreased heme synthesis starts at  $>40 \mu\text{g/dL}$ . Basophilic stippling occurs in 20% of severe lead poisoning.

**Neurologic.** Segmental demyelination and peripheral neuropathy, usually of the motor type (wrist and ankle drop), occurs in workers. A venous blood level of lead greater than  $70 \mu\text{g/dL}$  (usually  $>100 \mu\text{g/dL}$ ), produces encephalopathy in children (symptom mnemonic “PAINT”: P, persistent forceful vomiting and papilledema; A, ataxia; I, intermittent stupor and lucidity; N, neurologic coma and refractory convulsions; T, tired and lethargic). Decreased cognitive abilities have been reported with a venous blood level of lead greater than  $10 \mu\text{g/dL}$ , including behavioral problems, decreased attention span, and learning disabilities. IQ scores may begin to decrease at  $15 \mu\text{g/dL}$ . Encephalopathy is rare in adults.

**Renal.** Nephropathy as a result of damaged capillaries and glomerulus can occur at a venous blood level of lead greater than  $80 \mu\text{g/dL}$ , but recent studies show renal damage and hypertension with low venous blood levels. A direct correlation between hypertension and venous blood level over  $30 \mu\text{g/dL}$  has been reported. Lead reduces excretion of uric acid, and high-level exposure may be associated with hyperuricemia and “saturnine gout,” Fanconi’s syndrome (aminoaciduria and renal tubular acidosis), and tubular fibrosis.

**Reproductive.** Spontaneous abortion, transient delay in the child’s development (catch up at age 5 to 6 years), decreased sperm count, and abnormal sperm morphology can occur with lead exposure. Lead crosses the placenta and fetal blood levels reach 75% to 100% of maternal blood levels. Lead is teratogenic.

**Metabolic.** Decreased cytochrome P450 activity alters the metabolism of medication and endogenously produced substances. Decreased activation of cortisol and decreased growth are caused by interference in vitamin conversion (25-hydroxyvitamin D to 1,25-hydroxyvitamin D) at venous blood levels of 20 to  $30 \mu\text{g/dL}$ .

**Other Manifestations.** Abnormalities of thyroid, cardiac, and hepatic function occur in adults. Abdominal colic is seen in children at doses greater than  $50 \mu\text{g/dL}$ . “Lead gum lines” at the dental border of the gingiva can occur in cases of chronic lead poisoning.

#### Laboratory Investigations

Serial venous blood lead measurements are taken on days 3 and 5 during treatment and 7 days after chelation therapy, then every 1 to 2 weeks for 8 weeks, and then every month for 6 months. Intravenous infusion should be stopped at least 1 hour before blood lead levels are measured. Table 22 gives a classification of blood lead concentrations in children.

One should evaluate CBC, serum ferritin, erythrocyte protoporphyrin ( $>35 \mu\text{g/dL}$  indicates lead poisoning as well as iron deficiency and other causes), electrolytes, serum calcium and phosphorus, urinalysis, BUN, and creatinine. Abdominal and long bone radiographs may be useful in certain circumstances to identify radiopaque material in bowel and “lead lines” in proximal tibia (which occur after prolonged exposure in association with venous blood lead levels greater than  $50 \mu\text{g/dL}$ ).

Neuropsychological tests are difficult to perform in young children but should be considered at the end of treatment, especially to determine auditory dysfunction.

#### Management

The basis of treatment is removal of the source of lead. Cases of poisoning in children should be reported to local health department and cases of occupational poisoning should be reported to OSHA. The source must be identified and abated and dust controlled by wet mopping. Cold water should be let to run for 2 minutes before being used for drinking. Planting shrubbery (not vegetables) in contaminated soil will keep children away.

**TABLE 22** Classification of Blood Lead Concentrations in Children

BLOOD LEAD (MG/DL)	RECOMMENDED INTERVENTIONS
<9	None
10–14	Community intervention Repeat blood lead in 3 months
15–19	Individual case management Environmental counseling Nutritional counseling Repeat blood lead in 3 months
20–44	Medical referral Environmental inspection/abatement Nutritional counseling Repeat blood lead in 3 months
45–69	Environmental inspection/abatement Nutritional counseling Pharmacologic therapy DMSA succimer oral or $\text{CaNa}_2\text{EDTA}$ parenteral Repeat every 2 weeks for 6–8 weeks, then monthly for 4–6 months
>70	Hospitalization in intensive care unit Environmental inspection/abatement Pharmacologic therapy Dimercaprol (BAL in oil) IM initial alone Dimercaprol IM and $\text{CaNa}_2\text{EDTA}$ together Repeat every week

Abbreviations: BAL = British anti-Lewisite;  $\text{CaNa}_2\text{EDTA}$  = edetate calcium disodium; DMSA = dimercaptosuccinic acid; IM = intramuscular.

Supportive care should be instituted, including measures to deal with refractory seizures (continued antidotal therapy, diazepam, and possibly neuromuscular blockers), with the hepatic and renal failure, and intravascular hemolysis in severe cases. Seizures are treated with diazepam followed by neuromuscular blockers if needed.

Lead does not bind to activated charcoal. One must not delay chelation therapy for complete gastrointestinal decontamination in severe cases. Whole-bowel irrigation has been used prior to treatment. Some authorities recommend abdominal radiographs followed by gastrointestinal decontamination if necessary before switching to oral therapy. Chelation therapy can be used for patients in whom venous blood level of lead is greater than  $45 \mu\text{g/dL}$  in children and greater than  $80 \mu\text{g/dL}$  in adults or in adults with lower levels who are symptomatic or who have a “positive” lead mobilization test result (not routinely performed at most centers) (Table 23).

Succimer (dimercaptosuccinic acid, DMSA, Chemet), a derivative of British anti-Lewisite (BAL), is an oral agent for chelation in children with a venous blood level of greater than  $45 \mu\text{g/dL}$ . The recommended dose is  $10 \text{ mg/kg}$  every 8 hours for 5 days, then every 12 hours for 14 days. DMSA is under investigation to determine its role in children with a venous blood level less than  $45 \mu\text{g/dL}$ . Although not approved for adults, it has been used in the same dosage. Monitoring should be maintained by CBC, liver transaminases, and urinalysis for adverse effects.

D-Penicillamine (Cuprimine) is another oral chelator that is given in doses of 20 to  $40 \text{ mg/kg/d}$  not to exceed  $1 \text{ g/d}$ . However, it is not FDA approved and has a 10% adverse reaction rate. Nevertheless, D-penicillamine has been used infrequently in adults and children with elevated venous blood lead levels.

Edetate calcium disodium (ethylene diaminetetra-acetic acid or  $\text{CaNa}_2\text{EDTA}$  Versenate) is a water-soluble chelator given intramuscularly (with 0.5% procaine) or intravenously. The calcium in the compound is displaced by divalent and trivalent heavy metals, forming a soluble complex, which is stable at physiologic pH (but not at acid pH) and enhances lead clearance in the urine. EDTA

**TABLE 23** Pharmacologic Chelation Therapy of Lead Poisoning

DRUG	ROUTE	DOSE	DURATION	PRECAUTIONS	MONITOR
Dimercaprol (BAL in oil)	IM	3–5 mg/kg q4–6h	3–5 days	G6PD deficiency Concurrent iron therapy	AST/ALT enzymes
CaNa <sub>2</sub> EDTA (calcium disodium versenate)	IM/IV	50 mg/kg per day	5 days	Inadequate fluid intake Renal impairment Penicillin allergy	Urinalysis, BUN Creatinine Urinalysis, BUN
D-Penicillamine (Cuprimine)	PO	10 mg/kg per day increase 30 mg/kg over 2 weeks	6–20 weeks	Concurrent iron therapy; lead exposure Renal impairment	Creatinine, CBC
2,3-Dimercaptosuccinic acid (DMSA; succimer)	PO	10 mg/kg per dose 3 times daily 10 mg/ kg per dose twice daily for 14 days	19 days	AST/ALT Concurrent iron therapy G6PD deficiency lead exposure	AST/ALT

*Abbreviations:* ALT = alanine aminotransferase; AST = aspartate transaminase; BAL = British anti-Lewisite; bid = twice daily; BUN = blood urea nitrogen; CBC = complete blood count; G6PD = glucose-6-phosphate dehydrogenase; IM = intramuscular; IV = intravenous; PO = oral; tid = three times daily.

usually is administered intravenously, especially in severe cases. It must not be administered until adequate urine flow is established. It may redistribute lead to the brain; therefore, BAL may be given first at a venous blood lead level of greater than 55 µg/dL in children and greater than 100 µg/dL in adults. Phlebitis occurs at a concentration greater than 0.5 mg/mL. Alkalinization of the urine may be helpful. CaNa<sub>2</sub>EDTA should not be confused with sodium EDTA (disodium edetate), which is used to treat hypercalcemia; inadvertent use may produce severe hypocalcemia.

Dimercaprol (BAL) is a peanut oil-based dithiol (two sulfhydryl molecules) that combines with one atom of lead to form a heterocyclic stable ring complex. It is usually reserved for patients in whom venous blood lead is greater than 70 µg/dL, and it chelates red blood cell lead, enhancing its elimination through the urine and bile. It crosses the blood-brain barrier. Approximately 50% of patients have adverse reactions, including bad metallic taste in the mouth, pain at the injection site, sterile abscesses, and fever.

A venous blood lead level greater than 70 µg/dL or the presence of clinical symptoms suggesting encephalopathy in children is a potentially life-threatening emergency. Management should be accomplished in a medical center with a pediatric intensive care unit by a multidisciplinary team including a critical care specialist, a toxicologist, a neurologist, and a neurosurgeon. Careful monitoring of neurologic status, fluid status, and intracranial pressure should be undertaken if necessary. These patients need close monitoring for hemodynamic instability. Hydration should be maintained to ensure renal excretion of lead. Fluids, renal and hepatic function, and electrolyte levels should be monitored.

While waiting for adequate urine flow, therapy should be initiated with intramuscular dimercaprol (BAL) only (25 mg/kg/d divided into 6 doses). Four hours later, the second dose of BAL should be given intramuscularly, concurrently with CaNa<sub>2</sub>EDTA 50 mg/kg/d as a single dose infused over several hours or as a continuous infusion. The double therapy is continued until the venous blood level is less than 40 µg/dL.

As long as the venous blood level is greater than 40 µg/dL, therapy is continued for 72 hours and followed by two alternatives: either parenteral therapy with two drugs (CaNa<sub>2</sub>EDTA and BAL) for 5 days or continuation of therapy with CaNa<sub>2</sub>EDTA alone if a good response is achieved and the venous blood level of lead is less than 40 µg/dL. If one cannot get the venous blood lead report back, one should continue therapy with both BAL and EDTA for 5 days. In patients with lead encephalopathy, parenteral chelation should be continued with both drugs until the patient is clinically stable before changing therapy. Mannitol and dexamethasone can reduce the cerebral edema, but their role in lead encephalopathy is not clear. Surgical decompression is not recommended to reduce cerebral edema in these cases.

If BAL and CaNa<sub>2</sub>EDTA are used together, a minimum of 2 days with no treatment should elapse before another 5-day

course of therapy is considered. The 5-day course is repeated with CaNa<sub>2</sub>EDTA alone if the blood lead level rebounds to greater than 40 µg/dL or in combination with BAL if the venous blood level is greater than 70 µg/dL. If a third course is required, unless there are compelling reasons, one should wait at least 5 to 7 days before administering the course.

Following chelation therapy, a period of equilibration of 10 to 14 days should be allowed and a repeat venous blood lead concentration should be obtained. If the patient is stable enough for oral intake, oral succimer 30 mg/kg/d in three divided doses for 5 days followed by 20 mg/kg/d in two divided doses for 14 days has been suggested, but there are limited data to support this recommendation. Therapy should be continued until venous blood lead level is less than 20 µg/dL in children or less than 40 µg/dL in adults.

Chelators combined with lead are hemodialyzable in the event of renal failure.

### Disposition

All patients with a venous blood lead level of greater than 70 µg/dL or who are symptomatic should be admitted. If a child is hospitalized, all lead hazards must be removed from the home environment before allowing the child to return. The source must be eliminated by environmental and occupational investigations. The local health department should be involved in dealing with children who are lead poisoned, and OSHA should be involved with cases of occupational lead poisoning. Consultation with a poison control center or experienced toxicologist is necessary when chelating patients. Follow-up venous blood lead concentrations should be obtained within 1 to 2 weeks and followed every 2 weeks for 6 to 8 weeks, then monthly for 4 to 6 months if the patient required chelation therapy. All patients with venous blood level greater than 10 µg/dL should be followed at least every 3 months until two venous blood lead concentrations are 10 µg/dL or three are less than 15 µg/dL.

### Lithium (Eskalith, Lithane)

Lithium is an alkali metal used primarily in the treatment of bipolar psychiatric disorders. Most intoxications are cases of chronic overdose. One gram of lithium carbonate contains 189 mg (5.1 mEq) of lithium; a regular tablet contains 300 mg (8.12 mEq) and a sustained-release preparation contains 450 mg or 12.18 mEq.

### Toxic Mechanism

The brain is the primary target organ of toxicity, but the mechanism is unclear. Lithium may interfere with physiologic functions by acting as a substitute for cellular cations (sodium and potassium), depressing neural excitation and synaptic transmission.

### Toxic Dose

A dose of 1 mEq/kg (40 mg/kg) of lithium will give a peak serum lithium concentration about 1.2 mEq/L. The therapeutic serum lithium concentration in cases of acute mania is 0.6 to 1.2 mEq/L, and for maintenance it is 0.5 to 0.8 mEq/L. Serum lithium concentration levels are usually obtained 12 hours after the last dose. The toxic dose is determined by clinical manifestations and serum levels after the distribution phase.

Acute ingestion of twenty 300-mg tablets (300 mg increases the serum lithium concentration by 0.2 to 0.4 mEq/L) in adults may produce serious intoxication. Chronic intoxication can be produced by conditions listed below that can decrease the elimination of lithium or increase lithium reabsorption in the kidney.

The risk factors that predispose to chronic lithium toxicity are febrile illness, impaired renal function, hyponatremia, advanced age, lithium-induced diabetes insipidus, dehydration, vomiting and diarrhea, and concomitant use of other drugs, such as thiazide and spironolactone diuretics, nonsteroidal antiinflammatory drugs, salicylates, angiotensin-converting enzyme inhibitors (e.g., captopril), serotonin reuptake inhibitors (e.g., fluoxetine [Prozac]), and phenothiazines.

### Kinetics

Gastrointestinal absorption of regular-release preparations is rapid; serum lithium concentration peaks in 2 to 4 hours and is complete by 6 to 8 hours. The onset of toxicity may occur at 1 to 4 hours after acute overdose but usually is delayed because lithium enters the brain slowly. Absorption of sustained-release preparations and the development of toxicity may be delayed 6 to 12 hours.

Volume distribution is 0.5 to 0.9 L/kg. Lithium is not protein bound. The half-life after a single dose is 9 to 13 hours; at steady state, it may be 30 to 58 hours. The renal handling of lithium is similar to that of sodium: glomerular filtration and reabsorption (80%) by the proximal renal tubule. Adequate sodium must be present to prevent lithium reabsorption. More than 90% of lithium is excreted by the kidney, 30% to 60% within 6 to 12 hours.

### Manifestations

The examiner must distinguish between side effects, acute intoxication, acute or chronic toxicity, and chronic intoxications. Chronic is the most common and dangerous type of intoxication.

Side effects include fine tremor, gastrointestinal upset, hypothyroidism, polyuria and frank diabetes insipidus, dermatologic manifestations, and cardiac conduction deficits. Lithium is teratogenic.

Patients with acute poisoning may be asymptomatic, with an early high serum lithium concentration of 9 mEq/L, and deteriorate as the serum lithium concentration falls by 50% and the lithium distributes to the brain and the other tissues. Nausea and vomiting may occur within 1 to 4 hours, but the systemic manifestations are usually delayed several more hours. It may take as long as 3 to 5 days for serious symptoms to develop. Acute toxicity and acute on chronic toxicity are manifested by neurologic findings, including weakness, fasciculations, altered mental state, myoclonus, hyperreflexia, rigidity, coma, and convulsions with limbs in hypertension. Cardiovascular effects are nonspecific and occur at therapeutic doses, flat T or inverted T waves, atrioventricular block, and prolonged QT interval. Lithium is not a primary cardiotoxin. Cardiogenic shock occurs secondary to CNS toxicity. Chronic intoxication is associated with manifestations at lower serum lithium concentrations. There is some correlation with manifestations, especially at higher serum lithium concentrations. Although the levels do not always correlate with the manifestations, they are more predictive in cases of severe intoxication. A serum lithium concentration greater than 3.0 mEq/L with chronic intoxication and altered mental state indicates severe toxicity. Permanent neurologic sequelae can result from lithium intoxication.

### Laboratory Investigations

Monitoring should include CBC (lithium causes significant leukocytosis), renal function, thyroid function (chronic intoxication),

ECG, and electrolytes. Serum lithium concentrations should be determined every 2 to 4 hours until levels are close to therapeutic range. Cross-reactions with green-top Vacutainer specimen tubes containing heparin will spuriously elevate serum lithium concentration 6 to 8 mEq/L.

### Management

Vital function must be established and maintained. Seizure precautions should be instituted and seizures, hypotension, and dysrhythmias treated. Evaluation should include examination for rigidity and hyperreflexia signs, hydration, renal function (BUN, creatinine), and electrolytes, especially sodium. The examiner should inquire about diuretic and other drug use that increase serum lithium concentration, and the patient must discontinue the drugs. If the patient is on chronic therapy, the lithium should be discontinued. Serial serum lithium concentrations should be obtained every 4 hours until serum lithium concentration peaks and there is a downward trend toward almost therapeutic range, especially in sustained-release preparations. Vital signs should be monitored, including temperature, and ECG and serial neurologic examinations should be undertaken, including mental status and urinary output. Nephrology consultation is warranted in case of a chronic and elevated serum lithium concentration (>2.5 mEq/L), a large ingestion, or altered mental state.

An intravenous line should be established and hydration and electrolyte balance restored. Serum sodium level should be determined before 0.9% saline fluid is administered in patients with chronic overdose because hyponatremia may be present from diabetes insipidus. Although current evidence supports an initial 0.9% saline infusion (200 mL/h) to enhance excretion of lithium, once hydration, urine output, and normonatremia are established, one should administer 0.45% saline and slow the infusion (100 mL/h) for all patients.

Gastric lavage is often not recommended in cases of acute ingestion because of the large size of the tablets, and it is not necessary after chronic intoxication. Activated charcoal is ineffective. For sustained-release preparations, whole-bowel irrigation may be useful but is not proven. Sodium polystyrene sulfonate (Kayexalate), an ion exchange resin, is difficult to administer and has been used only in uncontrolled studies. Its use is not recommended.

Hemodialysis is the most efficient method for removing lithium from the vascular compartment. It is the treatment of choice for patients with severe intoxication with an altered mental state, those with seizures, and anuric patients. Long runs are used until the serum lithium concentration is less than 1 mEq/L because of extensive re-equilibration. Serum lithium concentration should be monitored every 4 hours after dialysis for rebound. Repeated and prolonged hemodialysis may be necessary. A lag in neurologic recovery can be expected.

### Disposition

An acute asymptomatic lithium overdose cannot be medically cleared on the basis of single lithium level. Patients should be admitted if they have any neurologic manifestations (altered mental status, hyperreflexia, stiffness, or tremor). Patients should be admitted to the intensive care unit if they are dehydrated, have renal impairment, or have a high or rising lithium level.

### Methanol (Wood Alcohol, Methyl Alcohol)

The concentration of methanol in Sterno fuel is 4% and it contains ethanol, in windshield washer fluid it is 30% to 60%, and in gas-line antifreeze it is 100%.

### Toxic Mechanism

Methanol is metabolized by alcohol dehydrogenase to formaldehyde, which is metabolized to formate. Formate inhibits cytochrome oxidase, producing tissue hypoxia, lactic acidosis, and optic nerve edema. Formate is converted by folate-dependent enzymes to carbon dioxide.

### Toxic Dose

The minimal toxic amount is approximately 100 mg/kg. Serious toxicity in a young child can be produced by the ingestion of 2.5 to 5.0 mL of 100% methanol. Ingestion of 5-mL 100% methanol by a 10-kg child produces estimated peak blood methanol of 80 mg/dL. Ingestion of 15 mL 40% methanol was lethal for a 2-year-old child in one report. A fatal adult oral dose is 30 to 240 mL 100% (20 to 150 g). Ingestion of 6 to 10 mL 100% causes blindness in adults. The toxic blood concentration is greater than 20 mg/dL; very serious toxicity and potential fatality occur at levels greater than 50 mg/dL.

### Kinetics

Onset of action can start within 1 hour but may be delayed up to 12 to 18 hours by metabolism to toxic metabolites. It may be delayed longer if ethanol is ingested concomitantly or in infants. Peak blood methanol concentration is 1 hour. Volume distribution is 0.6 L/kg (total body water).

For metabolism, see *Toxic Mechanism*.

Elimination is through metabolism. The half-life of methanol is 8 hours; with ethanol blocking it is 30 to 35 hours; and with hemodialysis 2.5 hours.

### Manifestations

Metabolism creates a delay in onset for 12 to 18 hours or longer if ethanol is ingested concomitantly. Initial findings are as follows:

- 0 to 6 hours: Confusion, ataxia, inebriation, formaldehyde odor on breath, and abdominal pain can be present, but the patient may be asymptomatic. *Note:* Methanol produces an osmolar gap (early), and its metabolite formate produces the anion gap metabolic acidosis (see later). Absence of osmolar or anion gap does not always exclude methanol intoxication.
- 6 to 12 hours: Malaise, headache, abdominal pain, vomiting, visual symptoms, including hyperemia of optic disc, "snow vision," and blindness can be seen.
- More than 12 hours: Worsening acidosis, hyperglycemia, shock, and multiorgan failure develop, with death from complications of intractable acidosis and cerebral edema.

### Laboratory Investigation

Methanol can be detected on some chromatography drug screens if specified. Methanol and ethanol levels, electrolytes, glucose, BUN, creatinine, amylase, and ABG should be monitored every 4 hours. Formate levels correlate more closely than blood methanol concentration with severity of intoxication and should be obtained if possible.

### Management

One should protect the airway by intubation to prevent aspiration and administer assisted ventilation as needed. If needed, 100% oxygen can be administered. A nephrologist should be consulted early regarding the need for hemodialysis.

Gastrointestinal decontamination procedures have no role.

Metabolic acidosis should be treated vigorously with sodium bicarbonate 2 to 3 mEq/kg intravenously. Large amounts may be needed.

Antidote therapy is initiated to inhibit metabolism if the patient has a history of ingesting more than 0.4 mL/kg of 100% with the following conditions:

- Blood methanol level is greater than 20 mg/dL
- The patient has osmolar gap not accounted for by other factors
- The patient is symptomatic or acidotic with increased anion gap and/or hyperemia of the optic disc.

The ethanol or fomepizole therapy outlined below can be used.

**Ethanol Therapy.** Ethanol should be initiated immediately if fomepizole is unavailable (see *Fomepizole Therapy*). Alcohol dehydrogenase has a greater affinity for ethanol than ethylene glycol. Therefore, ethanol blocks the metabolism of ethylene glycol.

Ethanol should be administered intravenously (oral administration is less reliable) to produce a blood ethanol concentration of

100 to 150 mg/dL. The loading dose is 10 mL/kg of 10% ethanol administered intravenously concomitantly with a maintenance dose of 10% ethanol at 1.0 mL/kg/h. This dose may need to be increased to 2 mL/kg/h in patients who are heavy drinkers. The blood ethanol concentration should be measured hourly and the infusion rate should be adjusted to maintain a concentration of 100 to 150 mg/dL.

**Fomepizole Therapy.** Fomepizole (Antizol, 4-methylpyrazole) inhibits alcohol dehydrogenase more reliably than ethanol and it does not require constant monitoring of ethanol levels and adjustment of infusion rates. Fomepizole is available in 1 g/mL vials of 1.5 mL. The loading dose is 15 mg/kg (0.015 mL/kg) IV, maintenance dose is 10 mg/kg (0.01 mL/kg) every 12 hours for 4 doses, then 15 mg/kg every 12 hours until the ethylene glycol levels are less than 20 mg/dL. The solution is prepared by being mixed with 100 mL of 0.9% saline or D<sub>5</sub>W. Fomepizole can be given to patients requiring hemodialysis but should be dosed as follows:

Dose at the beginning of hemodialysis:

- If less than 6 hours since last Antizol dose, do not administer dose
- If more than 6 hours since last dose, administer next scheduled dose

Dosing during hemodialysis:

- Dose every 4 hours

Dosing at the time hemodialysis is completed:

- If less than 1 hour between last dose and end dialysis, do not administer dose at end of dialysis
- If 1 to 3 hours between last dose and end dialysis, administer one half of next scheduled dose
- If more than 3 hours between last dose and end dialysis, administer next scheduled dose

Maintenance dosing off hemodialysis:

- Give the next scheduled dose 12 hours from the last dose administered

Hemodialysis increases the clearance of both methanol and formate 10-fold over renal clearance. A blood methanol concentration greater than 50 mg/dL has been used as an indication for hemodialysis, but recently some toxicologists from the New York City Poison Center recommended early hemodialysis in patients with blood methanol concentration greater than 25 mg/dL because it may be able to shorten the course of intoxication if started early. One should continue to monitor methanol levels and/or formate levels every 4 hours after the procedure for rebound. Other indications for early hemodialysis are significant metabolic acidosis and electrolyte abnormalities despite conventional therapy and if visual or neurologic signs or symptoms are present.

A serum formate level greater than 20 mg/dL has also been used as a criterion for hemodialysis, although this is often not readily available through many laboratories. If hemodialysis is used, the infusion rate of 10% ethanol should be increased 2.0 to 3.5 mL/kg/h. The blood ethanol concentration and glucose level should be obtained every 2 hours.

Therapy is continued with both ethanol and hemodialysis until the blood methanol level is undetectable, there is no acidosis, and the patient has no neurologic or visual disturbances. This may require several days.

Hypoglycemia is treated with intravenous glucose. Doses of folic acid (Leucovorin) and folic acid have been used successfully in animal investigations to enhance formate metabolism to carbon dioxide and water. Leucovorin 1 mg/kg up to 50 mg IV is administered every 4 hours for several days.

An initial ophthalmologic consultation and follow-up are warranted.

### Disposition

All patients who have ingested significant amounts of methanol should be referred to the emergency department for evaluation and blood methanol concentration measurement. Ophthalmologic follow-up of all patients with methanol intoxications should be arranged.

## Monoamine Oxidase Inhibitors

Nonselective monoamine oxidase inhibitors (MAOIs) include the hydrazines phenelzine (Nardil) and isocarboxazid (Marplan), and the nonhydrazine tranylcypromine (Parnate). Furazolidone (Furoxone) and pargyline (Eutonyl) are also considered nonselective MAOIs. Moclobemide,<sup>22</sup> which is available in many countries but not the United States, is a selective MAO-A inhibitor. MAO-B inhibitors include selegiline (Eldepryl), an antiparkinsonism agent, which does not have similar toxicity to MAO-A and is not discussed. Selectivity is lost in an overdose. MAOIs are used to treat severe depression.

### Toxic Mechanism

Monoamine oxidase enzymes are responsible for the oxidative deamination of both endogenous and exogenous catecholamines such as norepinephrine. MAO-A in the intestinal wall also metabolizes tyramine in food. MAOIs permanently inhibit MAO enzymes until a new enzyme is synthesized after 14 days or longer. The toxicity results from the accumulation, potentiation, and prolongation of the catecholamine action followed by profound hypotension and cardiovascular collapse.

### Toxic Dose

Toxicity begins at 2 to 3 mg/kg and fatalities occur at 4 to 6 mg/kg. Death has occurred after a single dose of 170 mg of tranylcypromine in an adult.

### Kinetics

Structurally, MAOIs are related to amphetamines and catecholamines. The hydrazine peak levels are at 1 to 2 hours; metabolism is hepatic acetylation; and inactive metabolites are excreted in the urine. For the nonhydrazines, peak levels occur at 1 to 4 hours, and metabolism is via the liver to active amphetamine-like metabolites.

The onset of symptoms in a case of overdose is delayed 6 to 24 hours after ingestion, peak activity is 8 to 12 hours, and duration is 72 hours or longer. The peak of MAO inhibition is in 5 to 10 days and lasts as long as 5 weeks.

### Manifestations

Manifestations of an acute ingestion overdose of MAO-A inhibitors are as follows:

**Phase I.** An adrenergic crisis occurs, with delayed onset for 6 to 24 hours, and may not reach peak until 24 hours. The crisis starts as hyperthermia, tachycardia, tachypnea, dysarthria, transient hypertension, hyperreflexia, and CNS stimulation.

**Phase II.** Neuromuscular excitation and sympathetic hyperactivity occur with increased temperature greater than 40°C (104°F), agitation, hyperactivity, confusion, fasciculations, twitching, tremor, masseter spasm, muscle rigidity, acidosis, and electrolyte abnormalities. Seizures and dystonic reactions may occur. The pupils are mydriatic, sometimes nonreactive with “ping-pong gaze.”

**Phase III.** CNS depression and cardiovascular collapse occur in cases of severe overdose as the catecholamines are depleted. Symptoms usually resolve within 5 days but may last 2 weeks.

**Phase IV.** Secondary complications occur, including rhabdomyolysis, cardiac dysrhythmias, multiorgan failure, and coagulopathies.

Biogenic interactions usually occur while the patient is on therapeutic doses of MAOI or shortly after they are discontinued (30 to 60 minutes), before the new MAO enzyme is synthesized. The following substances have been implicated: indirect acting sympathomimetics such as amphetamines, serotonergic drugs, opioids (e.g., meperidine, dextromethorphan), tricyclic antidepressants, specific serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine [Prozac], sertraline [Zoloft], paroxetine [Paxil]), tyramine-containing foods (e.g., wine, beer, avocados, cheese, caviar, chocolate, chicken liver), and L-tryptophan. SSRIs should not be started for at least 5 weeks after MAOIs have been discontinued.

In mild cases, usually caused by foods, headache and hypertension develop and last for several hours. In severe cases, malignant hypertension and severe hyperthermia syndromes consisting of hypertension or hyperthermia, altered mental state, skeletal muscle rigidity, shivering (often beginning in the masseter muscle), and seizures may occur.

The serotonin syndrome, which may be a result of inhibition of serotonin metabolism, has similar clinical findings to those of malignant hyperthermia and may occur with or without hyperthermia or hypertension.

Chronic toxicity clinical findings include tremors, hyperhidrosis, agitation, hallucinations, confusion, and seizures and may be confused with withdrawal syndromes.

### Laboratory Investigations

Monitoring of the ECG, cardiac monitoring, CPK, ABG, pulse oximeter, electrolytes, blood glucose, and acid-base balance should be maintained.

### Management

In the case of MAOI overdose, ipecac-induced emesis should not be used. Only activated charcoal alone should be used.

If the patient is admitted to the hospital and is well enough to eat, a nontyramine diet should be ordered.

Extreme agitation and seizures can be controlled with benzodiazepines and barbiturates. Phenytoin is ineffective. Nondepolarizing neuromuscular blockers (not depolarizing succinylcholine) may be needed in severe cases of hyperthermia and rigidity. If the patient has severe hypertension (catecholamine mediated), phentolamine (Regitine), a parenteral  $\beta$ -blocking agent, 3 to 5 mg intravenously, or labetalol (Normodyne), a combination of an  $\alpha$ -blocking agent and a  $\beta$ -blocker, 20-mg intravenous bolus, should be given. If malignant hypertension with rigidity is present, a short-acting nitroprusside and benzodiazepine can be used. Hypertension is often followed by severe hypotension, which should be managed by fluid and vasopressors. *Caution:* Vasopressor therapy should be administered at lower doses than usual because of exaggerated pharmacologic response. Norepinephrine is preferred to dopamine, which requires release of intracellular amines.

Cardiac dysrhythmias are treated with standard therapy but are often refractory, and cardioversion and pacemakers may be needed.

For malignant hyperthermia, dantrolene (Dantrium), a non-specific peripheral skeletal relaxing agent, is administered, which inhibits the release of calcium from the sarcoplasm. Dantrolene is reconstituted with 60 mL sterile water without bacteriostatic agents. Glass equipment must not be used, and the drug must be protected from light and used within 6 hours. Loading dose is 2 to 3 mg/kg intravenously as a bolus, and the loading dose is repeated until the signs of malignant hyperthermia (tachycardia, rigidity, increased end-tidal CO<sub>2</sub>, and temperature) are controlled. Maximum total dose is 10 mg/kg to avoid hepatotoxicity.

When malignant hyperthermia has subsided, 1 mg/kg IV is given every 6 hours for 24 to 48 hours, then orally 1 mg/kg every 6 hours for 24 hours to prevent recurrence. There is a danger of thrombophlebitis following peripheral dantrolene, and it should be administered through a central line if possible. In addition one should administer external cooling and correct metabolic acidosis and electrolyte disturbances. Benzodiazepine can be used for sedation. Dantrolene does not reverse central dopamine blockade; therefore, bromocriptine mesylate (Parlodel) 2.5 to 10 mg should be given orally or through a nasogastric tube three times a day.

Rhabdomyolysis and myoglobinuria are treated with fluids. Urine alkalization should also be treated.

Hemodialysis and hemoperfusion are of no proven value.

Biogenic amine interactions are managed symptomatically, similar to cases of overdose. For the serotonin syndrome cyproheptadine (Periactin), a serotonin blocker, 4 mg orally every hour for three doses, or methysergide (Sansert), 2 mg orally every 6

hours for three doses, should be considered. The effectiveness of these drugs has not been proven.

### Disposition

All patients who have ingested more than 2 mg/kg of an MAOI should be admitted to the hospital for 24 hours of observation and monitoring in the intensive care unit because the life-threatening manifestations may be delayed. Patients with drug or dietary interactions that are mild may not require admission if symptoms subside within 4 to 6 hours and the patients remain asymptomatic. Patients with symptoms that persist or require active intervention should be admitted to the intensive care unit.

### Opioids (Narcotic Opiates)

Opioids are used for analgesia, as antitussives, and as antidiarrheal agents and are illicit agents (heroin, opium) used in substance abuse. Tolerance, physical dependency, and withdrawal may develop.

### Toxic Mechanism

At least four main opioid receptors have been identified. The  $\mu$  receptor is considered the most important for central analgesia and CNS depression. The  $\kappa$  and  $\delta$  receptors predominate in spinal analgesia. The  $\sigma$  receptors may mediate dysphoria. Death is a consequence of dose-dependent CNS respiratory depression or secondary to pulmonary aspiration or noncardiac pulmonary edema. The mechanism of noncardiac pulmonary edema is unknown.

Dextromethorphan can interact with MAOIs, causing severe hyperthermia, and may cause the serotonin syndrome (see *Selective Serotonin Reuptake Inhibitors*). Dextromethorphan inhibits

the metabolism of norepinephrine and serotonin and blocks the reuptake of serotonin. It is found as a component of a large number of non-prescription cough and cold remedies.

### Toxic Dose

The toxic dose depends on the specific drug, route of administration, and degree of tolerance. For therapeutic and toxic doses, see Table 24. In children, respiratory depression has been produced by 10 mg of morphine or methadone, 75 mg of meperidine, and 12.5 mg of diphenoxylate. Infants younger than 3 months of age are more susceptible to respiratory depression. The dose should be reduced by 50%.

### Kinetics

Oral onset of analgesic effect of morphine is 10 to 15 minutes; the action peaks in 1 hour and lasts 4 to 6 hours. With sustained-release preparations, the duration is 8 to 12 hours. Opioids are 90% metabolized in the liver by hepatic conjugation and 90% excreted in the urine as inactive compounds. Volume distribution is 1 to 4 L/kg. Protein binding is 35% to 75%. The typical plasma half-life of opiates is 2 to 5 hours, but that of methadone is 24 to 36 hours. Morphine metabolites include morphine-3-glucuronide (inactive) and morphine-6-glucuronide (active) and normorphine (active). Meperidine (Demerol) is rapidly hydrolyzed by tissue esterases into the active metabolite normeperidine, which has twice the convulsant activity of meperidine. Heroin (diacetylmorphine) is deacetylated within minutes to 6-monacetylmorphine and morphine. Propoxyphene (Darvon) has a rapid onset of action, and death has occurred within 15 to 30 minutes after a massive overdose. Propoxyphene is metabolized to norpropoxyphene, an active metabolite with convulsive, cardiac dysrhythmic,

**TABLE 24** Doses and Onset and Duration of Action of Common Opioids

DRUG	ADULT ORAL DOSE	CHILD ORAL DOSE	ONSET OF ACTION	DURATION OF ACTION	ADULT FATAL DOSE
Camphored tincture of opium	25 mL	0.25–0.50 mL/kg (0.4 mg/mL)	15–30 min	4–5 h	NA
Codeine	30–180 mg	0.5–1 mg/kg	15–30 min	4–6 h	800 mg
	>1 mg/kg is toxic in a child, above 200 mg in adult >5 mg/kg fatal in a child				
Dextromethorphan	15 mg 10 mg/kg is toxic	0.25 mg/kg	15–30 min	3–6 h	NA
Diacetylmorphine; street heroin is less than 10% pure	60 mg	NA	15–30 min	3–4 h	100 mg
Diphenoxylate atropine (Lomotil)	5–10 mg	NA	120–240 min	14 h	300 mg
	7.5 mg is toxic in a child, 300 mg is toxic in adult				
Fentanyl (Duragesic)	0.1–0.2 mg	0.001–0.002 mg/kg	7–8 min	Intramuscular: ½–2 h	1.0 mg
Hydrocodone with APAP (Lortab)	5–30 mg	0.15 mg/kg	30 min	3–4 h	100 mg
Hydromorphone (Dilaudid)	4 mg	0.1 mg/kg	15–30 min	3–4 h	100 mg
Meperidine (Demerol)	100 mg	1–1.5 mg/kg	10–45 min	3–4 h	350 mg
Methadone (Dolophine)	10 mg	0.1 mg/kg	30–60 min	4–12 h	120 mg
Morphine	10–60 mg	0.1–0.2 mg/kg	<20 min	4–6 h	200 mg
	Oral dose is 6 times parenteral dose, MS Contin sustained-release prep				
Oxycodone APAP (Percocet)	5 mg	NA	15–30 min	4–5 h	NA
Pentazocine (Talwin)	50–100 mg	NA	15–30 min	3–4 h	NA
Propoxyphene (Darvon)	65–100 mg	NA	30–60 min	2–4 h	700 mg

and heart block properties. Symptoms of diphenoxylate overdose appear within 1 to 4 hours. It is metabolized into the active metabolite difenoxin, which is five times more active as a regular respiratory depressant agent. Death has been reported in children after ingestion of a single tablet.

### Manifestations

Initially, mild intoxication produces miosis, dull face, drowsiness, partial ptosis, and “nodding” (head drops to chest then bobs up). Larger amounts produce the classic triad of miotic pupils (exceptions below), respiratory depression, and depressed level of consciousness (flaccid coma). The blood pressure, pulse, and bowel activity are decreased.

Dilated pupils do not exclude opioid intoxication. Some exceptions to the miosis effect include dextromethorphan (paralyzes iris), fentanyl, meperidine, and diphenoxylate (rarely). Physiologic disturbances including acidosis, hypoglycemia, hypoxia, and postictal state, or a co-ingestant may also produce mydriasis.

Usually, the muscles are flaccid, but increased muscle tone can be produced by meperidine and fentanyl (chest rigidity). Seizures are rare but can occur with ingestion of codeine, meperidine, propoxyphene, and dextromethorphan. Hallucinations and agitation have been reported.

Pruritus and urticaria are caused by histamine release by some opioids or by sulfite additives.

Noncardiac pulmonary edema may occur after an overdose, especially with intravenous heroin abuse. Cardiac effects include vasodilation and hypotension. A heart murmur in an intravenous addict suggests endocarditis. Propoxyphene can produce delayed cardiac dysrhythmias.

Fentanyl is 100 times more potent than morphine and can cause chest wall muscle rigidity. Some of its derivatives are 2000 times more potent than morphine.

### Laboratory Investigations

For patients with overdose, one should obtain and monitor ABG, blood glucose, and electrolyte levels; chest radiographs; and ECG. For drug abusers, one should consider testing for hepatitis B, syphilis, and HIV antibody (HIV testing usually requires consent). Blood opioid concentrations are not useful. They confirm diagnosis (morphine therapeutic dose, 65 to 80 ng/mL; toxic, <200 ng/mL), but are not useful for making a therapeutic decision. Cross-reactions can occur with Vick's Formula 44, poppy seeds, and other opioids (codeine and heroin are metabolized to morphine). Naloxone 4 mg IV was not associated with a positive enzyme multiplied immunoassay technique urine screen at 60 minutes, 6 hours, or 48 hours.

### Management

Supportive care should be instituted, particularly an endotracheal tube and assisted ventilation. Temporary ventilation can be provided by a bag-valve mask with 100% oxygen. The patient should be placed on a cardiac monitor, have intravenous access established, and have specimens for ABG, glucose, electrolytes, BUN, and creatinine levels, CBC, coagulation profile, liver function, toxicology screen, and urinalysis taken.

For gastrointestinal decontamination, emesis should not be induced, but activated charcoal can be administered if bowel sounds are present.

If it is suspected that the patient is an addict, he or she should be restrained first and then 0.1 mg of naloxone (Narcan) should be administered. The dose should be doubled every 2 minutes until the patient responds or 10 to 20 mg has been given. If the patient is not suspected to be an addict, then 2 mg every 2 to 3 minutes to total of 10 to 20 mg is administered.

It is essential to determine whether there is a complete response to naloxone (mydriasis, improvement in ventilation), because it is a diagnostic therapeutic test. A continuous naloxone infusion may be appropriate, using the “response dose” every hour. Repeat doses of naloxone may be necessary because the effects of many opioids can last much longer than naloxone does (30 to 60

minutes). Methadone ingestions may require a naloxone infusion for 24 to 48 hours. Half of the response dose may need to be repeated in 15 to 20 minutes, after the infusion has been started.

Acute iatrogenic withdrawal precipitated by the administration of naloxone to a dependent patient should not be treated with morphine or other opioids. Naloxone's effects are limited to 30 to 60 minutes (shorter than most opioids) and withdrawal will subside in a short time.

Nalmefene (Revex), an FDA-approved long-acting (4 to 8 hours) pure opioid antagonist, is being investigated, but its role in cases of acute intoxication is unclear and it could produce prolonged withdrawal. It may have a role in place of naloxone infusion.

Noncardiac pulmonary edema does not respond to naloxone, and the patient needs intubation, assisted ventilation, positive end-expiratory pressure, and hemodynamic monitoring. Fluids should be given cautiously in patients with opioid overdose because opioids stimulate the antidiuretic hormone.

If the patient is comatose, 50% glucose (3% to 4% of comatose opioid overdose patients have hypoglycemia) and thiamine should be given prior to naloxone. If the patient has seizures that are unresponsive to naloxone, one administers diazepam and examines for metabolic (hypoglycemia, electrolyte disturbances) causes and structural disturbances.

Hypotension is rare and should direct a search for another etiology. If the patient is agitated, hypoxia and hypoglycemia must be excluded before opioid withdrawal is considered as a cause. Complications to consider include urinary retention, constipation, rhabdomyolysis, myoglobinuria, hypoglycemia, and withdrawal.

### Disposition

If a patient responds to intravenous naloxone, careful observation for relapse and the development of pulmonary edema is required, with cardiac and respiratory monitoring for 6 to 12 hours. Patients requiring repeated doses of naloxone or an infusion, or those who develop pulmonary edema, require intensive care unit admission and cannot be discharged from the intensive care unit until they are symptom free for 12 hours. Intravenous overdose complications are expected to be present within 20 minutes after injection, and discharge after 4 symptom-free hours has been recommended. Adults with oral overdose have delayed onset of toxicity and require 6 hours of observation. Children with oral opioid overdose should be admitted to the hospital for observation because of delayed toxicity. Some toxicologists advise restraining a patient who attempts to sign out against medical advice after treatment with naloxone, at least until the patient receives psychiatric evaluation.

### Organophosphates and Carbamates

Cholinergic intoxication sources are insecticides (organophosphates or carbamates), some medications, and some mushrooms. Examples of organophosphate insecticides are malathion (low toxicity, median lethal dose [LD<sub>50</sub>] 2800 mg/kg), chlorpyrifos, which has been removed from market (moderate toxicity), and parathion (high toxicity, LD<sub>50</sub> 2 mg/kg). Carbamate insecticides include carbaryl (low toxicity, LD<sub>50</sub> 500 mg/kg), propoxur (moderate toxicity, LD<sub>50</sub> 95 mg/kg), and aldicarb (high toxicity, LD<sub>50</sub> 0.9 mg/kg). Pharmaceuticals with carbamate properties include neostigmine (Prostigmin) and physostigmine (Antilirium). Cholinergic compounds also include the “G” nerve war weapons tabun (GA), sarin (GB), soman (GB), and venom X (VX).

### Toxic Mechanism

Organophosphates phosphorylate the active site on red cell acetylcholinesterase and pseudocholinesterase in the serum, neuromuscular and parasympathetic neuroeffector junctions, and in the major synapses of the autonomic ganglia, causing irreversible inhibition. There are two types of organophosphate intoxication: (a) direct action by the parent compound (e.g., tetraethylpyrophosphate), or (b) indirect action by the toxic metabolite (e.g., parathoxon or malathoxon).

Carbamates (esters of carbonic acid) cause reversible carbamylation of the active site of the enzymes. When a critical amount, greater than 50%, of cholinesterase is inhibited, acetylcholine accumulates and causes transient stimulation at cholinergic synapses and sympathetic terminals (muscarinic effect), the somatic nerves, the autonomic ganglia (nicotinic effect), and CNS synapses. Stimulation of conduction is followed by inhibition of conduction.

The major differences between the carbamates and the organophosphates are as follows: (a) carbamate toxicity is less and the duration is shorter; (b) carbamates rarely produce overt CNS effects (poor CNS penetration); (c) carbamate inhibition of the acetylcholinesterase enzyme is reversible and activity returns to normal rapidly; (d) pralidoxime, the enzyme regenerator, may not be necessary in the management of mild carbamate intoxication (e.g., carbaryl).

#### Toxic Dose

Parathion's minimum lethal dose is 2 mg in children and 10 to 20 mg in adults. The lethal dose of malathion is greater than 1375 mg/kg and that of chlorpyrifos is 25 g; the latter compound is unlikely to cause death.

#### Kinetics

Absorption is by all routes. The onset of acute ingestion toxicity occurs as early as 3 hours, usually before 12 hours and always before 24 hours. Lipid-soluble agents absorbed by the dermal route (e.g., fenthion) may have a delayed onset of more than 24 hours. Inhalation toxicity occurs immediately after exposure. Massive ingestion can produce intoxication within minutes.

Metabolism is via the liver. With some pesticides (e.g., parathion, malathion), the effects are delayed because they undergo hepatic microsomal oxidative metabolism to their toxic metabolites, the -oxons (e.g., paroxon, malaaxon).

The half-life of malathion is 2.89 hours and that of parathion is 2.1 days. The metabolites are eliminated in the urine and the presence of *p*-nitrophenol in the urine is a clue up to 48 hours after exposure.

#### Manifestations

Many organophosphates produce a garlic odor on the breath, in the gastric contents, or in the container. Diaphoresis, excessive salivation, miosis, and muscle twitching are helpful clues to diagnosis.

Early, a cholinergic (muscarinic) crisis develops that consists of parasympathetic nervous system activity. DUMBELS is the mnemonic for defecation, cramps, and increased bowel motility; urinary incontinence; miosis (mydriasis may occur in 20%); bronchospasm and bronchorrhea; excess secretion; lacrimation; and seizures. Bradycardia, pulmonary edema, and hypotension may be present.

Later, sympathetic and nicotinic effects occur, consisting of MATCH: muscle weakness and fasciculation (eyelid twitching is often present), adrenal stimulation and hyperglycemia, tachycardia, cramps in muscles, and hypertension. Finally, paralysis of the skeletal muscles ensues.

The CNS effects are headache, blurred vision, anxiety, ataxia, delirium and toxic psychosis, convulsions, coma, and respiratory depression. Cranial nerve palsies have been noted. Delayed hallucinations may occur.

Delayed respiratory paralysis and neurologic and neurobehavioral disorders have been described following certain organophosphate ingestions or dermal exposure. The "intermediate syndrome" is paralysis of proximal and respiratory muscles developing 24 to 96 hours after the successful treatment of organophosphate poisoning. A delayed distal polyneuropathy has been described with ingestion of certain organophosphates, such as triorthocresyl phosphate, bromoleptophos, and methomidophos.

Complications include aspiration, pulmonary edema, and acute respiratory distress syndrome.

#### Laboratory Investigations

Monitoring should include chest radiograph, blood glucose (nonketotic hyperglycemia is frequent), ABG, pulse oximetry, ECG, blood coagulation status, liver function, hyperamylasemia (pancreatitis reported), and urinalysis for the metabolite alkyl phosphate paranitrophenol. Blood should be drawn for red blood cell cholinesterase determination before pralidoxime is given. The red blood cell cholinesterase activity roughly correlates with clinical severity. Mild poisoning is 20% to 50% of normal, moderate poisoning is 10% to 20% of normal, and severe poisoning is 10% of normal (>90% depressed). A postexposure rise of 10% to 15% in the cholinesterase level determined at least 10 to 14 days after the exposure confirms the diagnosis.

#### Management

Protection of health care personnel with clothing (masks, gloves, gowns, goggles) and respiratory equipment or hazardous material suits, as necessary, is called for. General decontamination consists of isolation, bagging, and disposal of contaminated clothing and other articles. Vital functions should be established and maintained. Cardiac and oxygen saturation monitoring are needed. Intubation and assisted ventilation may be needed. Secretions should be suctioned until atropinization drying is achieved.

Dermal decontamination involves prompt removal of clothing and cleansing of all affected areas of skin, hair, and eyes. Ocular decontamination involves irrigation with copious amounts of tepid water or 0.9% saline for at least 15 minutes. Gastrointestinal decontamination, if the ingestion was recent, involves the administration of activated charcoal.

Atropine sulfate can be given as an antidote. It is both a diagnostic and a therapeutic agent. Atropine counteracts the muscarinic effects but is only partially effective for the CNS effects (seizures and coma). Preservative-free atropine (no benzyl alcohol) should be used. If the patient is symptomatic (bradycardia or bronchorrhea), a test dose should be administered, 0.02 mg/kg in children or 1 mg in adults, intravenously. If no signs of atropinization are present (tachycardia, drying of secretions, and mydriasis), atropine should be administered immediately, 0.05 mg/kg in children or 2 mg in adults, every 5 to 10 minutes as needed to dry the secretions and clear the lungs. Beneficial effects are seen within 1 to 4 minutes and maximum effect in 8 minutes. The average dose in the first 24 hours is 40 mg, but 1000 mg or more has been required in severe cases. Glycopyrrolate (Robinul) can be used if atropine is not available. The maximum dose should be maintained for 12 to 24 hours, then tapered and the patient observed for relapse. Poisoning, especially with lipophilic agents (e.g., fenthion, chlorfenthion), may require weeks of atropine therapy. An alternative is a continuous infusion of atropine 8 mg in 100 mL 0.9% saline at rate of 0.02 to 0.08 mg/kg/h (0.25 to 1.0 mL/kg/h) with additional 1 to 5 mg boluses as needed to dry the secretions.

Pralidoxime chloride (Protopam) has both antinicotinic and antimuscarinic effects and possibly also CNS effects. Successful treatment with pralidoxime chloride may allow a reduction in the dose of atropine. Pralidoxime acts to reactivate the phosphorylated cholinesterases by binding the phosphate moiety on the esteritic site and displacing it. It should be given early before "aging" of phosphate bond produces tighter binding. However, recent reports indicate that pralidoxime chloride is beneficial even several days after the poisoning. Improvement is seen within 10 to 40 minutes. The initial dose of pralidoxime chloride is 1 to 2 g in 250 mL 0.89% saline over 5 to 10 minutes, maximum 200 mg/min, in adults or 25 to 50 mg/kg, maximum 4 mg/kg/min, in children younger than 12 years of age. The dose can be repeated every 6 to 12 hours for several days. An alternative is a continuous infusion of 1 g in 100 mL 0.89% saline at 5 to 20 mg/kg/h (0.5 to 12 mL/g/h) up to 500 mg/h and titrated to desired response. Maximum adult daily dose is 12 g. Cardiac and blood pressure monitoring is advised during and for several hours after the infusion. The end point is absence of fasciculations and return of muscle strength.

Contraindicated drugs include morphine, aminophylline, barbiturates, opioids, phenothiazine, reserpine-like drugs, parasympathomimetics, and succinylcholine.

Noncardiac pulmonary edema may require respiratory support. Seizures may respond to atropine and pralidoxime chloride but often require anticonvulsants. Cardiac dysrhythmias may require electrical cardioversion or antidysrhythmic therapy if the patient is hemodynamically unstable. Extracorporeal procedures are of no proven value.

### Disposition

Asymptomatic patients with normal examination findings after 6 to 8 hours of observation may be discharged. In cases of intentional poisoning, the patients require psychiatric clearance for discharge. Symptomatic patients should be admitted to the intensive care unit. Observation of milder cases of carbamate poisoning, even those requiring atropine, for 6 to 8 hours symptom-free may be sufficient to exclude significant toxicity. In cases of workplace exposure, OSHA should be notified.

### Phencyclidine (Angel Dust)

Phencyclidine is an arylcyclohexylamine related to ketamine and chemically related to the phenothiazines. Originally a “dissociative” anesthetic banned in United States since 1979, it is now an illicit substance, with at least 38 analogues. It is inexpensively manufactured by “kitchen chemists” and is mislabeled as other hallucinogens. Improper phencyclidine synthesis may release cyanide when heated or smoked and can cause explosions.

### Toxic Mechanism

The mechanism of phencyclidine is complex and not completely understood. It inhibits some neurotransmitters and causes a loss of pain sensation without depressing the CNS respiratory status. It stimulates  $\alpha$ -adrenergic receptors and may act as a “false neurotransmitter.” The effects are sympathomimetic, cholinergic, and cerebellar.

### Toxic Dose

The usual dose of phencyclidine mixed with marijuana joints is 100 to 400 mg of phencyclidine. Joints or leaf mixtures contain 0.24% to 7.9% of PCP, 1 mg of PCP/150 leaves. Tablets contain 5 mg (the usual street dose). CNS effects at doses of 1 to 6 mg include hallucinations and euphoria, 6 to 10 mg produces toxic psychosis and sympathetic stimulation, 10 to 25 mg produces severe toxicity, and more than 100 mg has resulted in fatalities.

### Kinetics

Phencyclidine is a lipophilic weak base, with a pKa of 8.5 to 9.5. It is rapidly absorbed when smoked and snorted, poorly absorbed from the acid stomach, and rapidly absorbed from the alkaline middle small intestine. It has an enterogastric secretion and is reabsorbed in the small intestine. The onset of action when smoked is 2 to 5 minutes, with a peak in 15 to 30 minutes. With oral ingestion, the onset is in 30 to 60 minutes and when taken intravenously it is immediate. Most adverse reactions in cases of overdose begin within 1 to 2 hours. Its duration of action at low doses is 4 to 6 hours and normality returns in 24 hours; in large overdoses, fluctuating coma may last 6 to 10 days.

Volume distribution is 6.2L/kg. Phencyclidine concentrates in brain and adipose tissue. Protein binding is 70%. The route of elimination is by gastric secretion, liver metabolism, and 10% urinary excretion of conjugates and free phencyclidine. Renal excretion may be increased 50% with urinary acidification. The half-life is 1 hour (in cases of overdose, it is 11 to 89 hours).

### Manifestations

The classic picture is bursts of horizontal, vertical, and rotary nystagmus, which is a clue to diagnosis (occurs in 50% of cases), miosis, hypertension, and fluctuating altered mental state. There is a wide spectrum of clinical presentations.

Mild intoxication with 1 to 6 mg produces drunken and bizarre behavior, agitation, rotary nystagmus, and blank stare. Violent behavior and sensory anesthesia make these patients insensitive to pain, self-destructive, and dangerous. Most are communicative within 1 to 2 hours, are alert and oriented in 6 to 8 hours, and recover completely in 24 to 48 hours.

Moderate intoxication with 6 to 10 mg produces excess salivation, hypertension, hyperthermia, muscle rigidity, myoclonus, and catatonia. Recovery of consciousness occurs in 24 to 48 hours and complete recovery in 1 week.

Severe intoxication with 10 to 25 mg results in opisthotonus, decerebrate rigidity, convulsions, prolonged fluctuating coma, and respiratory failure. Patients in this category have a high rate of medical complications. Recovery of consciousness occurs in 24 to 48 hours, with complete normality in a month. Medical complications include apnea, aspiration pneumonia, cardiac arrest, hypertensive encephalopathy, hyperthermia, intracerebral hemorrhage, psychosis, rhabdomyolysis and myoglobinuria, and seizures. Loss of memory and “flashbacks” last for months. Phencyclidine-induced depression and suicide have been reported.

Fatalities occur with ingestions of greater than 100 mg and with serum levels greater than 100 to 250 ng/mL.

### Laboratory Investigations

Marked elevation of creatine kinase level may occur. Values greater than 20,000 units have been reported. Urinalysis should be monitored and urine tested for myoglobin. One should monitor the blood for creatine kinase, uric acid (an early clue to rhabdomyolysis), BUN, creatinine, electrolytes (hyperkalemia), blood glucose (20% of patients have hypoglycemia), urinary output, liver function tests, ECG, and ABG if the patient has any respiratory manifestations. Measurement of phencyclidine in the gastric juice is called for because concentrations are 10 to 50 times higher than in blood or urine. Phencyclidine blood concentrations are not helpful. Phencyclidine may be detected in the urine of the average user for 10 days to 3 weeks after the last dose. In chronic users, it can be detected for over 1 month. The analogues of phencyclidine may not produce positive test results for phencyclidine in the urine. Cross-reactions with bleach and dextromethorphan may cause false-positive urine test results on immunoassay, and cross-reaction with doxylamine may produce a false-positive finding on gas chromatography.

### Management

The patient should be observed for violent, self-destructive, bizarre behavior, and paranoid schizophrenia. Patients should be placed in a low sensory environment and dangerous objects should be removed from the area.

Gastrointestinal decontamination is not effective because phencyclidine is rapidly absorbed from intestines. Overtreating the mild intoxication should be avoided. There is insufficient evidence to support the use of MDAC. In cases of severe toxicity (stupor or coma), continuous gastric suction can be tried (with protection of the airway) because the drug is secreted into the gastric juice. The value of this procedure is controversial because of limited data.

The patient must be protected from harming himself or herself or others. Physical restraints may be necessary, but they should be used sparingly and for the shortest time possible because they increase risk of rhabdomyolysis. Metal restraints such as handcuffs should be avoided. For behavioral disorders and toxic psychosis, diazepam is the agent of choice. Pharmacologic intervention includes diazepam (Valium) 10 to 30 mg orally or 2 to 5 mg intravenously initially and titrated upward to 10 mg; however, up to 30 mg may be required. “Talk down” technique is usually ineffective and dangerous. Phenothiazines and butyrophenones should be avoided in the acute phase because they lower the convulsive threshold; however, they may be needed later for psychosis. Haloperidol (Haldol) administration has been reported to produce catatonia.

Seizures and muscle spasm are managed with diazepam, from 2.5 mg up to 10 mg. Hyperthermia (>38.5°C [101.3°F]) is treated with external cooling measures. Hypertension is usually transient and does not require treatment. In the case of emergent hypertensive crisis (blood pressure >200/115 mm Hg) nitroprusside can be used in a dose of 0.3 to 2 µg/kg/min. Maximum infusion rate is 10 µg/kg/min for only 10 minutes.

Acid ion trapping diuresis is not recommended because of the danger of myoglobin precipitation in the renal tubules. Rhabdomyolysis and myoglobinuria are treated by correcting volume depletion and ensuring a urinary output of greater than 2 mL/kg/h. Alkalinization is controversial because of reabsorption of phencyclidine.

Hemodialysis is beneficial if renal failure occurs; otherwise, the extracorporeal procedures are not beneficial.

#### Disposition

All patients with coma, delirium, catatonia, violent behavior, aspiration pneumonia, sustained hypertension greater than 200/115 mm Hg, and significant rhabdomyolysis should be admitted to the intensive care unit until asymptomatic for at least 24 hours. If patients with mild intoxication are mentally and neurologically stable and become asymptomatic (except for nystagmus) for 4 hours, they may be discharged in the company of a responsible adult. All patients must be assessed for suicide risk before discharge. Drug counseling and psychiatric follow-up should be arranged. Patients should be warned that episodes of disorientation and depression may continue intermittently for 4 weeks or more.

## Phenothiazines and Nonphenothiazines (Neuroleptics)

### Toxic Mechanism

Neuroleptics have complex mechanisms of toxicity, including (a) block of the postsynaptic dopamine receptors; (b) block of peripheral and central α-adrenergic receptors; (c) block of cholinergic muscarinic receptors; (d) quinidine-like antidysrhythmic and myocardial depressant effect in cases of large overdose; (e) lowering of the convulsive threshold; (f) effect on hypothalamic temperature regulation (Table 25).

### Toxic Dose

Extrapyramidal reactions, anticholinergic effects, and orthostatic hypotension may occur at therapeutic doses. The toxic amount is not established, but the maximum daily therapeutic dose may result in significant side effects, and twice this amount may be potentially fatal. Chlorpromazine (Thorazine), the prototype, may produce serious hypotension and CNS depression at doses greater than 200 mg (17 mg/kg) in children and 3 to 5 g in an adult. Fatalities have been reported after 2.5 g of loxapine (Loxitane) and mesoridazine (Serentil) and 1.5 g of thioridazine (Mellaril).

### Kinetics

These agents are lipophilic and have unpredictable gastrointestinal absorption. Peak levels occur 2 to 6 hours postingestion and have enterohepatic recirculation.

The mean serum half-life in phase 1 is 1 to 2 hours and the biphasic half-life is 20 to 40 hours. Volume distribution is 10 to 40 L/kg; protein binding is 92% to 98%. Chlorpromazine taken

**TABLE 25** Neuroleptics and Properties

1+ = very low activity; 2+ = moderate activity; 3+ = very high activity.

orally has an onset of action in 30 to 60 minutes, peak in 2 to 4 hours, and duration of 4 to 6 hours. With sustained-release preparations, the onset is in 30 to 60 minutes and duration is 6 to 12 hours.

Elimination is by hepatic metabolism, which results in multiple metabolites (some are active). Metabolites can be detected in urine months after chronic therapy. Only 1% to 3% is excreted unchanged in the urine.

### Manifestations

In cases of phenothiazine overdose, anticholinergic symptoms may be present early but are not life-threatening. Miosis is usually present (80%) if the phenothiazine has strong  $\alpha$ -adrenergic blocking effect (e.g., chlorpromazine), but anticholinergic activity mydriasis may occur. Agitation and delirium rapidly progress into coma. Major problems are cardiac toxicity and hypotension. The cardiotoxic effects are seen more commonly with thioridazine and its metabolite mesoridazine. These agents have produced the largest number of fatalities in patients with phenothiazine overdose. Cardiac conduction disturbances include prolonged PR, QRS, and QTc intervals, U- and T-wave abnormalities, and ventricular dysrhythmias, including torsades de pointes. Seizures occur mainly in patients with convulsive disorders or with administration of loxapine. Sudden death in children and adults has been reported.

Idiosyncratic dystonic reactions are most common with the piperidine group. Reactions are not dose-dependent and consist of opisthotonos, torticollis, orolingual dyskinesia, or oculogyric crisis (painful upward gaze). These reactions are more frequent in children and women. Neuroleptic malignant syndrome occurs in patients on chronic therapy and is characterized by hyperthermia, muscle rigidity, autonomic dysfunction, and altered mental state. There is one case reported with acute overdose. The loxapine syndrome consists of seizures, rhabdomyolysis, and renal failure.

### Laboratory Investigations

Monitoring should include arterial blood gases, renal and hepatic function, electrolytes, blood glucose, and creatine kinase and myoglobinemia in neuroleptic malignant syndrome. Most of these agents are detected on routine screening. Quantitative serum levels are not useful in management. Cross-reactions with enzyme multiplied immunoassay technique tests occur with cyclic antidepressants. Phenothiazines give false-negative results on pregnancy urine tests using human chorionic gonadotropin as an indicator, and give false-positive results for urine porphyrins, indirect Coombs test, urobilinogen, and amylase.

### Management

Vital functions must be established and maintained. All overdose patients require venous access, 12-lead ECG (to measure intervals), cardiac and respiratory monitoring, and seizure precautions. One should monitor core temperature to detect poikilothermic effect. If the patient is comatose, intubation and assisted ventilation may be required, as well as 100% oxygen, intravenous glucose, naloxone (Narcan), and thiamine.

Emesis is not recommended. Activated charcoal can be administered if ingestion was within 1 hour. MDAC has not been proven beneficial. A radiograph of the abdomen may be useful, if the phenothiazine is radiopaque. Haloperidol (Haldol) and trifluoperazine (Stelazine) are most likely to be radiopaque. Whole-bowel irrigation may be useful when a large number of pills are visualized on radiograph or if sustained-release preparations were taken, but whole-bowel irrigation has not been evaluated in patients with phenothiazine overdose.

Convulsions are treated with diazepam or lorazepam (Ativan). Loxapine (Loxitane) overdose may result in status epilepticus. If nondepolarizing neuromuscular blockade is required, pancuronium (Pavulon) or vecuronium (Norcuron) should be used (not succinylcholine [Anectine], which may cause malignant hyperthermia), and EEG should be monitored during paralysis.

Patients with dysrhythmias should be monitored with serial ECGs. Unstable rhythms can be treated with electrical cardioversion. Class 1a antidysrhythmics (procainamide, quinidine, and disopyramide [Norpace]) must be avoided.

Hypokalemia predisposes to dysrhythmias and should be corrected aggressively. Supraventricular tachycardia with hemodynamic instability is treated with electrical cardioversion. The role of adenosine has not been defined. Calcium channel and  $\beta$ -blockers should be avoided.

Prolongation of the QRS interval is treated with sodium bicarbonate 1 to 2 mEq/kg by intravenous bolus over a few minutes. Torsades de pointes is treated with magnesium sulfate IV 20% solution 2 g over 2 to 3 minutes. If there is no response in 10 minutes, the dose is repeated and followed by a continuous infusion of 5 to 10 mg/min or given as an infusion of 50 mg/min for 2 hours followed by 30 mg/min for 90 minutes twice a day for several days, as needed. The dose in children is 25 to 50 mg/kg initially and maintenance dose is 30 to 60 mg/kg per 24 hours (0.25 to 0.50 mEq/kg per 24 hours) up to 1000 mg per 24 hours. Serum magnesium levels should be monitored.

To treat ventricular tachydysrhythmias in a stable patient, lidocaine is used. If the patient is unstable, electrical cardioversion is used. Patients with heart block with hemodynamic instability should be managed with temporary cardiac pacing.

Hypotension is treated with the Trendelenburg position and 0.9% saline. If the condition is refractory to treatment or there is a danger of fluid overload, vasopressors are administered. The vasopressor of choice is  $\alpha$ -adrenergic agonist norepinephrine (Levophed), titrated to response. Epinephrine and dopamine should not be used because  $\beta$ -receptor stimulation in the presence of  $\alpha$ -receptor blockade may provoke dysrhythmias and phenothiazines are antidopaminergic.

Hypothermia and hyperthermia are treated with external warming and cooling measures, respectively. Antipyretic drugs must not be used.

Management of the neuroleptic malignant syndrome includes the following actions:

- Immediately discontinuing the offending agent
- Hyperventilating the patient, using 100% humidified, cooled oxygen at high gas flows (at least 10L/min) because of rapid breathing
- Administering a benzodiazepine to control convulsions and facilitate cooling measures
- Initiating appropriate mechanical cooling measures, which may include intravenous cold saline (not lactated Ringer's), ice baths, cold lavage of the stomach, bladder, and rectum, and a hypothermic blanket
- Correcting acid-base and electrolyte disturbances and treating significant hyperkalemia with hyperventilation, calcium, sodium bicarbonate, intravenous glucose, and insulin; hemodialysis may be necessary

In addition, dysrhythmias usually respond to correction of the underlying acid-base disturbances and hyperkalemia. If antidysrhythmic agents are required, calcium channel blockers must be avoided because they may precipitate hyperkalemia and cardiovascular collapse. Dantrolene sodium (Dantrium), which is a phenytoin derivative, inhibits calcium release from the sarcoplasmic reticulum and results in decreased muscle contraction. Dantrolene acts peripherally and does not reverse the rigidity or psychomotor disturbances resulting from the central dopamine blockade; it therefore is often used in combination with bromocriptine. Bromocriptine mesylate (Parlodel) acts centrally as a dopamine agonist, as does amantadine hydrochloride (Symmetrel). Bromocriptine and dantrolene have been reported to be successful in combination with cooling and good supportive measures in malignant hyperthermia.

Dosing for these agents is as follows: dantrolene sodium at 2 to 3 mg/kg IV as a bolus, then 1 mg/kg/min to a maximum of 10 mg/kg or until the tachycardia, rigidity, increased end-tidal CO<sub>2</sub>, and temperature elevation are controlled. *Note:* Hepatotoxicity occurs with doses greater than 10 mg/kg. To prevent symptom

recurrence, 1 mg/kg should be administered every 6 hours for 24 to 48 hours after the episode. After that time, oral dantrolene can be used at a dose of 1 mg/kg every 6 hours for 24 hours as necessary. The patient should be observed for thrombophlebitis following intravenous dantrolene. It is best administered via a central line. Bromocriptine mesylate at 2.5 to 10 mg orally or via a nasogastric tube, three times a day, should be used in combination with dantrolene.

Idiosyncratic dystonic reaction can be treated with diphenhydramine (Benadryl) 1 to 2 mg/kg/dose intravenously over 5 minutes up to maximum of 50 mg intravenously; a response is noted within 2 to 5 minutes. This can be followed with oral doses for 4 to 6 days to prevent recurrence.

Extracorporeal measures (hemodialysis, hemoperfusion) are not effective in removing these agents.

### Disposition

Asymptomatic patients should be observed for at least 6 hours after gastric decontamination. Symptomatic patients with cardiotoxicity, hypotension, and convulsions should be admitted to the intensive care unit and monitored for 48 hours.

### Salicylates (Acetylsalicylic Acid, Salicylic Acid)

#### Toxic Mechanism

The primary toxic mechanisms include (a) direct stimulation of the medullary chemoreceptor trigger zone and respiratory center; (b) uncoupling oxidative phosphorylation; (c) inhibition of the Krebs cycle enzymes; (d) inhibition of vitamin K dependent and independent clotting factors; (e) alteration of platelet function; and (f) inhibition of prostaglandin synthesis.

#### Toxic Dose

Acute mild intoxication occurs at a dose of 150 to 200 mg/kg, moderate intoxication at 200 to 300 mg/kg, and severe intoxication at 300 to 500 mg/kg. Acute salicylate plasma concentration greater than 30 mg/dL (usually >40 mg/dL) may be associated with clinical toxicity. Chronic intoxication occurs at ingestions greater than 100 mg/kg/d for more than 2 days because of accumulation kinetics. Methyl salicylate (oil of wintergreen) is the most toxic form of salicylate. A dose of 1 mL of 98% contains 1.4 g of salicylate. Fatalities have occurred with ingestion of 1 teaspoonful in children and 1 ounce in adults. It is found in topical ointments and liniments (18% to 30%).

#### Kinetics

Acetylsalicylic acid and salicylic acid are weak acids with a pKa of 3.5 and 3.0, respectively. Acetylsalicylic acid is absorbed from the stomach, from the small bowel, and dermally. Onset of action is within 30 minutes. Methyl salicylate and effervescent tablets are absorbed more rapidly. Salicylate plasma concentration is detectable within 15 minutes after ingestion and peaks in 30 to 120 minutes. The peak may be delayed 6 to 12 hours in cases of large overdose, overdose with enteric-coated or sustained-release preparations, and development of concretions. The therapeutic duration of action is 3 to 4 hours but is markedly prolonged in cases of overdose.

Volume distribution is 0.13 L/kg for salicylic acid but increases as the salicylate plasma concentration increases. Protein binding is greater than 90% for salicylic acid at pH 7.4 and a salicylate plasma concentration of 20 to 30 mg/dL, 75% at a salicylate plasma concentration greater than 40 mg/dL, 50% at a salicylate plasma concentration of 70 mg/dL, and 30% at a salicylate plasma concentration of 120 mg/dL.

The half-life for salicylic acid is 3 hours after a 300 mg dose, 6 hours after a 1 g overdose, and greater than 10 hours after a 10 g overdose. Elimination includes Michaelis-Menten hepatic metabolism by three saturable pathways: (a) glycine conjugation to salicyluric acid (75%); (b) glucuronyl transferase to salicyl phenol glucuronide (10%); and (c) salicyl aryl glucuronide (4%). Nonsaturable pathways are hydrolysis to gentisic acid (<1%). Ten percent is excreted unchanged.

Acidosis increases the severity of the intoxication by increasing the non-ionized salicylate that can cross membranes and enter the brain cells. In kidneys, the unionized salicylic acid undergoes glomerular filtration, and the ionized portion undergoes tubular secretion in proximal tubules and passive reabsorption in the distal tubules. Renal excretion of salicylate is enhanced by alkaline urine.

#### Manifestations

The ingestion of concentrated topical salicylic acid preparations (e.g., wart remover) can cause mucosal caustic injury to the gastrointestinal tract. Occult salicylate overdose should be considered in any patient with unexplained acid-base disturbance.

The manifestations of acute overdose of salicylates are as follows:

**Minimal Symptoms.** Tinnitus, dizziness, and deafness may occur at high therapeutic salicylate plasma concentrations of 20 to 30 mg/dL. Nausea and vomiting may occur immediately because of local gastric irritation.

**Phase I.** Mild manifestations occur at 1 to 12 hours after ingestion with a 6-hour salicylate plasma concentration of 45 to 70 mg/dL. Nausea and vomiting followed by hyperventilation are usually present within 3 to 8 hours after acute overdose. Hyperventilation, an increase in both rate (tachypnea) and depth (hyperpnea), is present but it may be subtle. It results in a mild respiratory alkalosis with a serum pH greater than 7.4 and urine pH greater than 6.0. Some patients may have lethargy, vertigo, headache, and confusion. Diaphoresis may be noted.

**Phase II.** Moderate manifestations occur at 12 to 24 hours after ingestion with a 6-hour salicylate plasma concentration of 70 to 90 mg/dL. Serious metabolic disturbances, including a marked respiratory alkalosis with anion gap metabolic acidosis, dehydration, and urine pH less than 6.0, may occur. Other metabolic disturbances include hypoglycemia or hyperglycemia, hypokalemia, decreased ionized calcium, and increased BUN, creatinine, and lactate. Mental disturbances (confusion, disorientation, hallucinations) may occur. Hypotension and convulsions have been reported.

**Phase III.** Severe intoxication occurs more than 24 hours after ingestion with a 6-hour salicylate plasma concentration of 90 to 130 mg/dL. In addition to the above clinical findings, coma and seizures develop and indicate severe intoxication. Pulmonary edema may occur. Metabolic disturbances include metabolic acidemia (pH <7.4) and aciduria (pH <6.0). In adults, alkalosis may persist until terminal respiratory failure.

In children younger than 4 years of age, a mixed metabolic acidosis and respiratory alkalosis develop earlier (within 4 to 6 hours) than in adults because children have less respiratory reserve and accumulate lactate and other organic acids. Hypoglycemia is more common in children.

Fatalities occur at 6-hour salicylate plasma concentrations greater than 130 to 150 mg/dL and result from CNS depression, cardiovascular collapse, electrolyte imbalance, and cerebral edema.

Chronic salicylism is more serious than acute intoxication and the 6-hour salicylate plasma concentration does not correlate well with the manifestations in both acute and chronic cases of intoxication. Chronic intoxication usually occurs with therapeutic errors in young children or the elderly with underlying illness, and the diagnosis is delayed because it is not recognized. Noncardiac pulmonary edema is a frequent complication in the elderly. The mortality rate is about 25%. Chronic salicylate poisoning in children may mimic Reye syndrome. It is associated with exaggerated CNS findings (hallucinations, delirium, dementia, memory loss, papilledema, bizarre behavior, agitation, encephalopathy, seizures, and coma). Hemorrhagic manifestations, renal failure, and pulmonary and cerebral edema may occur. The metabolic picture is hypoglycemia and mixed acid-base derangements. A chronic salicylate plasma concentration greater than 60 mg/dL with metabolic acidosis and an altered mental state is very serious.

### Laboratory Investigations

All patients with intentional salicylate overdoses should have acetaminophen plasma level measured after 4 hours.

One should continuously monitor ECG, urine output, urine pH, and specific gravity. Every 2 to 4 hours in cases of severe intoxication, salicylate plasma concentration, glucose (in a case of salicylism, CNS hypoglycemia may be present despite normal serum glucose), electrolytes, ionized calcium, magnesium and phosphorus, anion gap, ABGs, and pulse oximeter should be monitored. Daily monitoring of BUN, creatinine, liver function tests, and prothrombin time should take place.

The therapeutic salicylate plasma concentration is less than 10 mg/dL for analgesia and 15 to 30 mg/dL for antiinflammatory effect. Cross-reaction with diflunisal (Dolobid) will give a falsely high salicylate plasma concentration. The Done nomogram is not considered accurate in evaluating acute or chronic salicylate intoxications.

### Management

Treatment is based on clinical and metabolic findings, not on salicylate levels. Continuous monitoring of the urine pH is essential for successful alkalization treatment. One should always obtain an acetaminophen plasma level.

Vital functions must be established and maintained. If the patient is in an altered mental state, glucose, naloxone, and thiamine are administered in standard doses. Depending on the severity, the initial studies include an immediate and a 6-hour postingestion salicylate plasma concentration, ECG and cardiac monitoring, pulse oximeter, urine (analysis, pH, and specific gravity), chest radiograph, ABGs, blood glucose, electrolytes and anion gap calculation, calcium (ionized), magnesium, renal and liver profiles, and prothrombin time. Gastric contents and stool should be tested for occult blood. Bismuth and magnesium salicylate preparations may be radiopaque on radiographs. Consultation with a nephrologist is warranted in cases of moderate, severe, or chronic intoxication.

For gastrointestinal decontamination, activated charcoal is useful (each gram of activated charcoal binds 550 mg of salicylic acid) if a toxic dose was ingested up to 4 hours postingestion. MDAC is not recommended for salicylate intoxication.

Concretions may occur with massive (usually >300 mg/kg) ingestions. If blood levels fail to decline, prompt contrast radiography

of the stomach may reveal concretions that have to be removed by repeated lavage, whole-bowel irrigation, endoscopy, or gastrostomy.

Fluids and electrolyte treatment of salicylate poisonings is given in Table 26. For shock, perfusion and vascular volume should be established with 5% dextrose in 0.9% saline, then the treatment can proceed with correction of dehydration and alkalization.

For cases of acute moderate or severe salicylism (see Table 26), adults should receive a bolus of 1 to 2 mEq/kg of sodium bicarbonate (NaHCO<sub>3</sub>) followed by an infusion of 100 to 150 mEq NaHCO<sub>3</sub> added to 500 to 1000 mL of 5% dextrose and administered over 60 minutes. Children should receive a bolus of 1 to 2 mEq/kg of NaHCO<sub>3</sub> followed by an infusion of 1 to 2 mEq/kg added to 20 mL/kg of 5% dextrose administered over 60 minutes. Potassium is added after the patient voids. The goal is to achieve a urine output of greater than 2 mL/kg/h and a urine pH of greater than 8. The initial infusion is followed by subsequent infusions (two to three times normal maintenance) of 200 to 300 mL/h in adults or 10 mL/kg/h in children. If the patient is acidotic and has a serum pH of less than 7.15, an additional 1 to 2 mEq/kg of NaHCO<sub>3</sub> is given over 1 to 2 hours; persistent acidosis may require 1 to 2 mEq/kg of bicarbonate every 2 hours. The infusion rate, the amount of bicarbonate, and the electrolytes should be adjusted to correct serum abnormalities and to maintain the targeted urine output and urinary pH. Diuresis is not as important as the alkalization. Careful monitoring for fluid overload should take place for patients at risk of pulmonary and cerebral edema (e.g., the elderly) and because of inappropriate secretion of the antidiuretic hormone.

In patients with mild intoxication who are not acidotic and have a urine pH greater than 6, 5% dextrose in 0.45% saline should be administered as maintenance to replace ongoing fluid loss. Some toxicologists may consider adding sodium bicarbonate 50 mEq/L or 1 mEq/kg in some cases.

To achieve alkalization, sodium bicarbonate is administered to produce a serum pH 7.4 to 7.5 and a urine pH greater than 8. Carbonic anhydrase inhibitors (acetazolamide [Diamox]) should not be used. If the patient is acidotic, additional bicarbonate may be required. About 2 mEq/kg raises the blood pH 0.1. In children, alkalization may be a difficult problem because of the organic acid production and hypokalemia. Hypokalemic and fluid-depleted patients cannot be adequately alkalized. Alkalization is usually discontinued in asymptomatic patients with

**TABLE 26** Fluid and Electrolyte Treatment of Salicylate Poisoning

TYPE OF SALICYLISM	METABOLIC DISTURBANCE	BLOOD PH	URINE PH	HYDRATING SOLUTION	AMOUNT OF NAHCO <sub>3</sub> (MEQ/L)	AMOUNT OF POTASSIUM (MEQ/L)
Mild	Respiratory alkalosis	>7.4	>6.0	5% Dextrose, 0.45% saline	50 (adult) 1 mEq/kg (child)	20
Moderate	Respiratory alkalosis	>7.4	<6.0	5% Dextrose in water	100 (adult) 1–2 mEq/kg (child)	40

Co-ingestant						

\*Correct hypoventilation.

Modified from Linden CH, Rumack BH: The legitimate analgesics, aspirin and acetaminophen. In Hansen Jr W (ed): *Toxic Emergencies*. New York, Churchill Livingstone, 1984.

a salicylate plasma concentration less than 30 to 40 mg/dL but is continued in symptomatic patients regardless of the salicylate plasma concentration. A decreased serum bicarbonate but normal or high blood pH indicates respiratory alkalosis predominating over metabolic acidosis, and the bicarbonate should be administered cautiously. An alkalemic pH of 7.40 to 7.50 is not a contraindication to bicarbonate therapy because these patients have a significant base deficit in spite of elevated blood pH.

Potassium is added, 20 to 40 mEq/L, to the infusion after the patient voids. In cases of severe, late, and chronic salicylism, 60 mEq/L of potassium may be needed. When the serum potassium is below 4.0 mEq/L, 10 mEq/L should be added over the first hour. If the patient has hypokalemia less than 3 mEq/L and flat T waves and U waves, 0.25 to 0.5 mEq/kg up to 10 mEq/h is administered. Potassium should be administered under ECG monitoring. Serum potassium is rechecked after each rapidly administered dose. A paradoxical urine acidosis (alkaline serum pH and acid urine pH) indicates that potassium is probably needed.

Convulsions are treated with diazepam or lorazepam, but hypoglycemia, low ionized calcium, cerebral edema, and hemorrhage should first be excluded with a CT scan. If tetany develops, the NaHCO<sub>3</sub> therapy is discontinued and calcium gluconate 0.1 to 0.2 mL/kg 10% administered.

Pulmonary edema management consists of fluid restriction, high FiO<sub>2</sub>, mechanical ventilation, and positive end-expiratory pressure.

Cerebral edema management consists of fluid restriction, elevation of the head, hyperventilation, osmotic diuresis, and administration of dexamethasone. Vitamin K<sub>1</sub> is administered parenterally to correct an increased prothrombin time (>20 seconds) and coagulation abnormalities. If the patient has active bleeding, fresh plasma and platelets are administered as needed. Hyperpyrexia is managed by external cooling measures, not antipyretics.

Hemodialysis is the choice for removal of salicylates because it corrects the acid-base, electrolyte, and fluid disturbances as well. The indications for hemodialysis include the following:

- Acute poisoning with salicylate plasma concentration greater than 100 mg/dL without improvement after 6 hours of appropriate therapy
- Chronic poisoning with cardiopulmonary disease and a salicylate plasma concentration as low as 40 mg/dL with refractory acidosis, severe CNS manifestations (coma and seizures), and progressive deterioration, especially in elderly patients
- Impairment of vital organs of elimination
- Clinical deterioration in spite of good supportive care and alkalization
- Severe refractory acid-base or electrolyte disturbances despite appropriate corrective measures

#### Disposition

There are limitations of salicylate plasma levels and patients are treated on the basis of clinical and laboratory findings. Patients who are asymptomatic should be monitored for a minimum of 6 hours, and longer if enteric-coated tablets or massive overdose was taken or if there is suspicion of concretions. Those who remain asymptomatic with a salicylate plasma concentration less than 35 mg/dL may be discharged following psychiatric evaluation, if indicated. Chronic salicylate-intoxicated patients with acidosis and an altered mental state should be admitted to the intensive care unit. Patients with acute ingestion and a salicylate plasma concentration less than 60 mg/dL and mild symptoms may be able to be treated in the emergency department. Patients with moderate and severe intoxications should be admitted to the intensive care unit.

#### Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are primarily prescribed as antidepressants. SSRIs include fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft).

#### Toxic Mechanism

The SSRIs interfere with the neuron reuptake of serotonin (5-hydroxytryptamine) at the presynaptic ganglia sites in the brain, increasing the activity of serotonin. SSRIs should not be used within 5 weeks of when a MAOI is given, nor should MAOI therapy be initiated or discontinued within 5 weeks of SSRI therapy.

#### Toxic Dose

The therapeutic oral dose of fluoxetine is 20 to 80 mg/d. No toxicity is seen in children with up to 3.5 mg/kg/dose orally. A fatal dose for adults is 6 g. The therapeutic dose for paroxetine is 20 to 50 mg/d. In 35 adult patients, none developed serious side effects after the ingestion of 10 to 1000 mg, and a study involving 35 children failed to demonstrate serious adverse effects at doses less than 180 mg. The therapeutic dose for sertraline is 50 mg to 200 mg/d. Patients have ingested up to 2.6 g without serious side effects. Overdose involving children who ingested less than 100 mg failed to cause adverse events.

#### Kinetics

Fluoxetine is well absorbed from the gastrointestinal tract and has a peak plasma concentration at 6 to 8 hours. Volume distribution is 20 to 42 L/kg; 95% is protein bound. The half-life is 4 days (for the demethylated active metabolite norfluoxetine, the half-life is 7 to 15 days). Elimination is 80% renal. Fluoxetine and other serotonin inhibitors are inhibitors of the cytochrome P450, CYP2D6 enzyme. Therefore interactions may occur with many other medications, such as antidysrhythmic class IC drugs (quinidine), phenytoin (Dilantin), haloperidol, lithium, tricyclic antidepressants (TCAs),  $\beta$ -blockers, codeine, and carbamazepine (Tegretol).

Paroxetine is almost completely absorbed from the gastrointestinal tract, with a peak in 2 to 8 hours. Protein binding is greater than 90%; volume distribution is 13 L/kg. Paroxetine undergoes extensive first-pass liver metabolism by oxidation and methylation to inactive metabolites. It inhibits the P450 system (see fluoxetine metabolism). The average half-life is 21 hours.

Sertraline peaks in 8 to 12 hours. Its volume distribution is 20 L/kg and protein binding is 98%. The average half-life of sertraline is 26 hours. It is metabolized to form a less-active metabolite, *N*-desmethylsertraline (half-life of 62 to 104 hours).

#### Manifestations

All SSRIs may cause serotonin syndrome, a potentially life-threatening reaction, if they are administered concurrently with an MAOI. Serotonin syndrome is caused by cerebral serotonergic stimulation and can cause severe hyperthermia, myoclonus, rhabdomyolysis, confusion, tremors, and a variety of psychological disturbances. In addition, cardiovascular complications and extrapyramidal side effects, including akathisia, dyskinesia, and Parkinson-like syndromes may occur. Also, increased suicidal ideation, seizures, sexual disorders, and hematologic disorders (platelet serotonin activity blockade leading to prolonged bleeding times) may develop. Inappropriate secretion of antidiuretic hormone resulting in hyponatremia may occur when SSRIs are administered to the elderly. This effect is usually seen within the first week of therapy.

Overdose effects are similar to the serotonin syndrome.

#### Laboratory Investigations

One should obtain a complete blood count (CBC), electrolytes, glucose levels, a coagulation profile, liver function tests, creatine kinase level, and an ECG.

#### Management

There is no specific antidote to SSRI intoxication.

Initial management consists of stabilizing vital functions, including thermoregulation. Supportive therapy and anticipation

of potential life-threatening manifestations (hypotension, hyperthermia, seizures, coma, disseminated intravascular coagulation, ventricular tachycardia, and metabolic acidosis) are essential. Vital signs, EEG, creatine kinase, and blood chemistry should be monitored.

Benzodiazepines are administered to prevent and control muscle hyperactivity (diazepam [Valium] for seizures, clonazepam [Klonopin] for myoclonus). If benzodiazepine therapy fails to control muscle activity or seizures, anesthesia or nondepolarizing neuromuscular blockade may be necessary.

Electrolyte abnormalities and acid-base balance should be corrected. Fluids are used to maintain a urine output of greater than 2 mL/kg/h if there is a risk of myoglobinuria.

There are no data to support the use of gastrointestinal decontamination, although activated charcoal may be used if an ingestion has occurred within 1 hour. Hemodialysis and charcoal hemoperfusion are unlikely to be beneficial. Haloperidol (Haldol), phenothiazines, and other highly protein-bound drugs are to be avoided.

Benzodiazepine and cooling therapy can be used for hyperthermia. Serotonin antagonists, such as cyproheptadine (Periactin), may be useful in treating serotonin syndrome, although there are no controlled data. Dantrolene (Dantrium) and bromocriptine (Parlodel) are not recommended and may actually precipitate serotonin syndrome.

### Disposition

Cases of ingestions in children up to 5 years of age of less than 180 mg of paroxetine (Paxil), less than 3.5 mg/kg of fluoxetine (Prozac), or less than 100 mg of sertraline (Zoloft) can be observed at home. Symptomatic patients should be admitted to the intensive care unit until asymptomatic for 24 hours. Asymptomatic patients should be observed for 6 hours. All patients should be assessed for risk of suicide before discharge. When taken chronically, SSRIs may increase cholesterol and triglycerides and decrease uric acid, so these test results should be followed.

### Theophylline

Theophylline (Slo-Phyllin) is a methylxanthine alkaloid similar to caffeine and theobromine. Aminophylline is 80% theophylline. Theophylline is used in the acute treatment of asthma, pulmonary edema, chronic obstructive pulmonary disease, and neonatal apnea.

### Toxic Mechanism

The proposed mechanisms of action include phosphodiesterase inhibition, adenosine receptor antagonism, inhibition of prostaglandins, and increase in serum catecholamines. Theophylline stimulates the central nervous, respiratory, and emetic centers and reduces the seizure threshold. It has positive cardiac inotropic and chronotropic effects, acts as a diuretic, relaxes smooth muscle, and causes peripheral vasodilation but cerebral vasoconstriction. Gastric secretions, gastrointestinal motility, lipolysis, glycogenolysis, and gluconeogenesis are all increased.

### Toxic Dose

A single dose of 1 mg/kg produces a theophylline plasma concentration of approximately 2 µg/mL. The therapeutic range usually is 10 to 20 µg/mL. An acute, single dose greater than 10 mg/kg causes mild toxicity, a dose greater than 20 mg/kg causes moderate toxicity, and a dose greater than 50 mg/kg causes serious, possibly fatal toxicity. Fatalities occur at lower doses in patients with chronic toxicity, especially those with risk factors (see *Kinetics*).

### Kinetics

The pKa is 9.5. Absorption from the stomach and upper small intestine is complete and rapid, with onset in 30 to 60 minutes.

**TABLE 27** Theophylline Blood Concentrations and Acute Toxicity

PLASMA CONCENTRATION (MG/ML)	TOXICITY DEGREE	MANIFESTATIONS
8–10	None	Bronchodilation
10–20	Mild	Therapeutic range: nausea, vomiting, nervousness, respiratory alkalosis, tachycardia
15–25		35% have mild manifestations of toxicity
20–40	Moderate	Gastrointestinal complaints and central nervous system stimulation Transient hypertension, tachypnea, tachycardia; 80% will have some manifestations of toxicity
60–100	Severe	Convulsions, dysrhythmias Hypokalemia, hyperglycemia Ventricular dysrhythmias, protracted convulsions, hypotension, acid-base abnormalities

Reprinted and modified from Linden CH, Rumack BH. In Hansen Jr W (ed): *Toxic Emergencies*. New York, Churchill Livingstone, 1984. With permission from Elsevier.

Peak theophylline plasma concentration occurs within 1 to 2 hours after ingestion of liquid preparations, 2 to 4 hours after ingestion of regular tablets, and 7 to 24 hours after ingestion of slow-release formulations. Volume distribution is 0.3 to 0.7 L/kg. Protein binding is 40% to 60% in adults, mainly to albumin (low albumin increases free active theophylline).

Elimination is 90% by hepatic metabolism to an active metabolite, 2-methyl xanthine. The half-life is 3.5 hours in a child and 4 to 6 hours in an adult. The half-life is shorter in smokers and patients taking enzyme-inducing drugs. Only 8% to 10% of the drug is excreted unchanged in the urine.

Risk factors that produce a longer half-life include age younger than 6 months or older than 60 years, use of enzyme-inhibitor drugs (calcium channel blockers, oral contraceptives, cimetidine [Tagamet], ciprofloxacin [Cipro], erythromycin, macrolide antibiotics, isoniazid), illness (persistent fever >38.9°C [>102°F]), viral illness, liver impairment, heart failure, chronic obstructive pulmonary disease, and influenza vaccination.

### Manifestations

Acute toxicity generally correlates with blood levels; chronic toxicity does not (Table 27).

In the case of an acute, single, regular-release overdose, vomiting and occasionally hematemesis occur at low theophylline plasma concentrations. CNS stimulation includes restlessness, muscle tremors, and protracted tonic-clonic seizures, but coma is rare. Convulsions are a sign of severe toxicity and usually are preceded by gastrointestinal symptoms (except with sustained-release and chronic intoxications). Cardiovascular disturbances include cardiac dysrhythmias (supraventricular tachycardia) and transient hypertension with mild overdoses, but hypotension and ventricular dysrhythmias with severe intoxications. Rhabdomyolysis and renal failure are occasionally seen. Children tolerate higher serum levels, and cardiac dysrhythmias and seizures occur at theophylline plasma concentrations greater than 100 µg/mL. Possible metabolic disturbances include hyperglycemia, pronounced

hypokalemia, hypocalcemia, hypomagnesemia, hypophosphatemia, increased serum amylase, and elevation of uric acid.

Chronic intoxication, defined as multiple doses of theophylline over 24 hours, or cases in which interacting drugs or illness interfere with theophylline metabolism are more serious and difficult to treat. Cardiac dysrhythmias and convulsions may occur at theophylline plasma concentrations of 40 to 60 µg/mL and there is no correlation with TPC. The seizures occur without warning and are protracted and repetitive and may produce status epilepticus. Vomiting and typical metabolic disturbances do not occur.

Differences with slow-release preparations are that few or no gastrointestinal symptoms occur, peak concentrations and convulsions may be delayed 12 to 24 hours postingestion, and convulsions occur without warning.

#### Laboratory Investigations

Monitoring includes vital signs, pulse oximeter, ABG, hemoglobin, hematocrit (for gastrointestinal hemorrhage), ECG and cardiac monitor, renal and hepatic function, electrolytes, blood glucose, acid-base balance, and serum albumin. Gastric contents and stools should be tested for occult blood. Samples for theophylline plasma concentration measurement should be drawn within 1 to 2 hours after ingestion of liquid preparations, 2 to 4 hours after ingestion of regular-release formulations, and 4 hours after ingestion of slow-release formulations. One should check the serum albumin level because a decrease in albumin levels may cause manifestations of toxicity despite normal theophylline plasma concentration. A single theophylline plasma concentration reading may be misleading; therefore, theophylline plasma concentration measurement should be repeated every 2 to 4 hours to determine the trend until a declining trend is reached and then monitored every 4 to 6 hours until it is below 20 µg/mL.

#### Management

Vital functions must be established and maintained. If the patient is in a coma or has convulsions or vomiting, he or she should be intubated immediately. The theophylline plasma concentration is obtained and repeated every 2 to 4 hours to determine peak absorption, and a theophylline bezoar should be considered if the theophylline plasma concentration fails to decline. Consultation with a nephrologist about charcoal hemoperfusion is recommended.

Gastrointestinal decontamination is warranted in the case of an acute overdose, but emesis must not be induced. Activated charcoal is the choice decontamination procedure in a dose of 1 g/kg to all patients, followed with MDAC 0.5 g/kg every 2 to 4 hours until the theophylline plasma concentration is less than 20 µg/mL. MDAC is effective in treating acute, chronic, and intravenous overdoses. Activated charcoal shortens the half-life of theophylline by about 50% and may be indicated up to 24 hours following ingestion.

Whole-bowel irrigation with polyethylene-electrolyte solution has been recommended for cases of massive overdose, possible concretions, and ingestion of sustained-release preparations. If intractable vomiting occurs, the antiemetic metoclopramide (Reglan) (0.1 mg/kg adult dose), droperidol (Inapsine) (2.5 to 10 mg IV), or ondansetron (Zofran) (8 to 32 mg IV) is administered. Ondansetron, however, inhibits metabolism of theophylline after a few doses.

Convulsions are controlled with lorazepam (Ativan) or diazepam (Valium) and phenobarbital. Phenytoin (Dilantin) is ineffective. The convulsions in patients with chronic intoxication are often refractory and may require, in addition to anticonvulsants, neuromuscular paralyzing agents, sedation, assisted ventilation, and EEG monitoring.

Hypotension is treated with fluids and vasopressors, if necessary. Norepinephrine (Levophed) 0.05 µg/kg/min is preferred as the vasopressor over dopamine.

Supraventricular tachycardia with hemodynamic instability requires cardioversion. Low-dose β-blockers may be used but should not be used in patients with reactive airway disease or hypotension. Adenosine (Adenocard) is ineffective. For ventricular dysrhythmias, electrolyte disturbances should be corrected. Lidocaine is the treatment of choice but has the potential to cause seizures at toxic concentrations. Cardioversion may be needed.

Hematemesis is managed with sucralfate (Carafate) 1 g four times daily and/or Maalox TC 30 mL every 2 hours and blood replacement, if necessary. H<sub>2</sub> antihistamine blockers that are enzyme inhibitors are not used.

Fluid and metabolic disturbances should be corrected. Hyperglycemia does not require insulin therapy. Hypokalemia should be corrected cautiously, as it may be largely an intracellular shift and not total body loss. Usually adding 40 mEq potassium to a liter of fluid will suffice. The serum potassium level must be monitored closely.

Charcoal hemoperfusion is the management of choice for patients with serious intoxications. Hemoperfusion can increase the clearance twofold to threefold over hemodialysis, but hemodialysis can be used if hemoperfusion is not available. Criteria for charcoal hemoperfusion are as follows:

- Life-threatening events such as convulsions or dysrhythmias
- Intractable vomiting refractory to antiemetics
- Acute intoxications with a theophylline plasma concentration greater than 80 µg/mL or greater than 70 µg/mL 4 hours after overdose with a sustained-release formulation and greater than 40 µg/mL in the case of chronic intoxication
- Acute or chronic overdoses with a theophylline plasma concentration greater than 40 µg/mL, especially if the patient has risk factors that lengthen the half-life of the drug (see Kinetics).

#### Disposition

Patients with mild symptoms and a theophylline plasma concentration less than 20 µg/mL can be treated in emergency department and discharged when asymptomatic for a few hours. Any patient with acute ingestion and a theophylline plasma concentration greater than 35 µg/mL should be admitted to a monitored bed with seizure precautions and suicide precautions, if needed. If neurologic or cardiotoxic effects or a theophylline plasma concentration greater than 50 µg/mL is present, the patient should be admitted to the intensive care unit. A patient with an overdose of a sustained-release preparation, regardless of symptoms or initial theophylline plasma concentration, requires admission, monitoring, activated charcoal, and MDAC. In patients on chronic therapy, toxicity may occur at a lower theophylline plasma concentration, and these patients should not be discharged until they are asymptomatic for several hours.

#### Tricyclic and Cyclic Antidepressants

Historically, tricyclic antidepressants are an important cause of pharmaceutical overdose fatalities. The mortality rate was reduced from 15% in the 1970s to less than 1% in the 1990s because of a better understanding of the pathophysiology of these agents and improvements in management (Table 28).

#### Toxic Mechanism

The major mechanisms of toxicity of the tricyclic antidepressants are (a) central and peripheral anticholinergic effects; (b) peripheral α-adrenergic blockade; (c) quinidine-like cardiac membrane stabilizing action blockade of the fast inward sodium channels; and (d) inhibition of synaptic neurotransmitter reuptake in the CNS presynaptic neurons. The tetracyclics, monocyclic aminoketones, and dibenzoxazepines possess convulsive activity and less cardiac toxicity in overdose than the older tricyclic antidepressants. Triazolopyridine has less serious cardiac and CNS toxicity.

**TABLE 28** Cyclic Antidepressants: Daily Dose and Their Major Properties

GENERIC NAME (TRADE NAME)	ADULT DAILY DOSE (MG)	THERAPEUTIC RANGE (NG/ML)	HALF-LIFE (HOURS)	TOXICITY		
				ANTICHOL	CNS	CARDIAC
<b>Tertiary Amines</b>						
Amitriptyline (Elavil)	75–300	120–250	31–46	3+	3+	3+
Imipramine (Tofranil)	75–300	125–250	9–24	3+	3+	2+
Doxepin (Sinequan)	75–300	30–150	8–24	3+	3+	2+
Trimipramine (Surmantil)	75–200	10–240	16–18	3+	3+	2+
<b>Secondary Amines</b>						
Nortriptyline (Pamelor)	75–150	50–150	18–93	2+	3+	3+
Desipramine (Norpramin)	75–200	75–160	14–62	1+	3+	3+
Protriptyline (Vivactil)	20–60	70–250	54–198	2+	3+	3+
<b>Newer Cyclic Antidepressants</b>						
Teracyclic			30–60	1+	2+	3+
Maprotiline (Ludomil)	75–300	—	30–60	1+	2+	3+
Trizolopyridine, a noncyclic, produces less serious cardiac and CNS toxicity						
Trazodone (Desyrel)	50–600	700	4–7	1+	1+	1+
<b>Monocyclic Aminoketones</b>						
Bupropion (Wellbutrin)	200–400	—	8–24	1+	3+	1+
Dibenzazepine						
Clomipramine (Anafranil)	100–250	200–500	21–32	2+	2+	2+
<b>Dibenzazepine</b>						
Amoxapine (Ascendin)	150–300	200–500	6–10	1+	3+	2+

*Abbreviations:* Antichol = anticholinergic effect; CNS = central nervous system effect primarily seizures; cardiac = cardiac effect.

Other drugs with similar structures are cyclobenzaprine, a muscle relaxant (similar to amitriptyline), and carbamazepine, an anticonvulsant (similar to imipramine); however, they cause less cardiac toxicity.

### Toxic Dose

The therapeutic dose of imipramine (Tofranil) is 1.5 to 5 mg/kg; a dose greater than 5 mg/kg may be mildly toxic; 10 to 20 mg/kg may be life threatening, although less than 20 mg/kg has produced few fatalities; greater than 30 mg/kg carries a 30% mortality rate; and at a dose greater than 70 mg/kg, patients rarely survive. In children 375 mg and in adults as little as 500 mg have been fatal. In adults, five times the maximum daily dose is toxic and 10 times is potentially fatal. Although major overdose symptoms are associated with plasma concentrations greater than 1 µg/mL (>1000 ng/mL), plasma tricyclic levels do not correlate well with toxicity; clinical signs and symptoms should guide therapy.

The relative dosage or potency equivalents are as follows: amitriptyline (Elavil) 100 mg = amoxapine (Ascendin) 125 mg = desipramine (Norpramin) 75 mg = doxepin (Sinequan) 100 mg = imipramine (Tofranil) 75 mg = maprotiline (Ludomil) 75 mg = nortriptyline (Pamelor) 50 mg = trazodone (Desyrel) 200 mg. This allows one to determine an equivalent dosage of an agent compared with another (see Table 28).

### Kinetics

The tricyclic and cyclic antidepressants are lipophilic. They are rapidly absorbed from the alkaline small intestine, but absorption may be prolonged and delayed in cases of massive overdose owing to anticholinergic action. Onset varies from less than 1 hour (30 to 40 minutes) to, rarely, 12 hours. The peak serum levels are reached in 2 to 8 hours and the peak effect

is in 6 hours but may be delayed 12 hours because of erratic absorption. The clinical effects correlate poorly with plasma levels.

Cyclic antidepressants are highly protein-bound to plasma glycoproteins, 98% at a pH 7.5 and 90% at 7.0. Volume distribution is 10 to 50 L/kg. The elimination route is by hepatic metabolism. The tertiary amines are metabolized into active demethylated secondary amine metabolites. The active secondary amine metabolites undergo a 15% enterohepatic recirculation and are metabolized over a period of days into nonactive metabolites. The intestinal bacterial flora may reconstitute the metabolites, which are active.

The half-life varies from 10 hours for imipramine to 81 hours for amitriptyline and 100 hours for nortriptyline. The active metabolites have longer half-lives.

Only 3% of the ingested dose is excreted in the urine unchanged.

### Manifestations

There are reports of asymptomatic patients who, upon arrival to an emergency department, suddenly have a seizure, develop hemodynamically unstable dysrhythmias, and die shortly thereafter from ingestion of a tricyclic antidepressant. Most patients with severe toxicity develop symptoms within 1 to 2 hours, but symptoms may be delayed 6 hours after overdose.

Small overdoses produce early anticholinergic effects, agitation, and transient hypertension, which are not life-threatening. Large

overdoses produce depression of the CNS and myocardium, convulsions, and hypotension. Death can occur within the first 2 to 6 hours following ingestion.

Some ECG screening tools for predicting cardiac or neurologic toxicity from ingestion of a tricyclic antidepressant have been developed: (a) a QRS greater than 0.10 second may produce seizures, and if greater than 0.16 second, 50% of patients may develop ventricular dysrhythmias (20% of these may be life-threatening) and seizures; (b) a terminal 40 msec of the QRS axis greater than 120 degrees in the right frontal plane may be associated with toxicity; or (c) a large R wave greater than 3 mm in ECG lead aVR may predispose the patient to toxicity. The quinidine cardiac membrane stabilizing effect produces depression of myocardium, conduction, and ECG changes. The peripheral  $\alpha$ -adrenergic blockade produces hypotension.

The secondary amines are metabolized to inactive metabolites. The tetracyclics produce a high incidence of cardiovascular disturbances and seizures. Monocyclic aminoketones produce seizures in doses greater than 600 mg. Dibenzoxazepines produce a syndrome of convulsions, rhabdomyolysis, and renal failure.

### Laboratory Investigations

If the patient has altered mental status or ECG abnormalities, ABG, ECG, chest radiograph, blood glucose, serum electrolytes, calcium, magnesium, blood urea nitrogen, and creatinine levels, liver profile, creatine kinase level, urine output, and, in severe cases, hemodynamic monitoring are indicated. Levels of the tricyclic and cyclic antidepressants less than 300 ng/mL are therapeutic; levels greater than 500 ng/mL indicate toxicity, and levels greater than 1000 ng/mL indicate serious poisoning and are associated with QRS widening.

### Management

Vital functions must be established and maintained. Even if the patient is asymptomatic, intravenous access should be established, vital signs and neurologic status monitored, and baseline 12-lead ECG and continuous cardiac monitoring obtained for at least 6 hours from admission or 8 to 12 hours postingestion. QRS interval should be measured on a limb lead ECG every 15 minutes for 6 hours postingestion.

For gastrointestinal decontamination, emesis should not be induced and gastric lavage should not be used. Activated charcoal is preferable. If the patient is in an altered mental state, the airway must be protected. Activated charcoal 1 g/kg is recommended up to 1 hour postingestion. Benefit from MDAC has not been demonstrated.

Alkalinization does not control seizures; diazepam or lorazepam should be used. Status epilepticus may require high-dose barbiturates or neuromuscular blockers with intravenous diazepam. If not successful, the patient can be paralyzed with short-term nondepolarizing neuromuscular blockers such as vecuronium (Norcuron), intubation, and assisted ventilation. A bolus of sodium bicarbonate is recommended as an adjunct to correct the acidosis produced by the seizures.

Sodium bicarbonate is administered in a dose of 1 to 2 mEq/kg undiluted as a bolus and repeated twice a few minutes apart, if needed, for "sodium loading" and alkalinization, which may increase protein binding from 90% to 98%. The sodium loading overcomes the sodium channel blockage and is more important than the alkalinization. Indications include (a) a QRS complex greater than 0.12 second, (b) ventricular tachycardia, (c) severe conduction disturbances, (d) metabolic acidosis, (e) coma, and (f) seizures. A continuous infusion of sodium bicarbonate is of limited usefulness for controlling dysrhythmias. Bolus therapy should be used as needed.

Hyperventilation alone has been recommended, but the pH elevation is not as instantaneous and there is compensatory renal

excretion of bicarbonate; therefore, we do not recommend it. The combination of hyperventilation and sodium bicarbonate has produced fatal alkalemia and is not recommended. One should monitor serum potassium level (the sudden increase in blood pH can aggravate or precipitate hypokalemia), serum sodium, and ionized calcium levels (hypocalcemia may occur with alkalinization) and blood pH.

Specific cardiovascular complications should be treated as follows: Hypotension is treated with norepinephrine, a predominantly  $\alpha$ -adrenergic drug, which is preferred over dopamine. Hypertension that occurs early rarely requires treatment. Sinus tachycardia usually does not require treatment. Supraventricular tachycardia in a patient who is hemodynamically unstable requires synchronized electrical cardioversion, starting at 0.25 to 1.0 watt-second per kilogram, after sedation. Ventricular tachycardia that persists after alkalinization requires intravenous lidocaine or countershock if the patient is hemodynamically unstable. Ventricular fibrillation should be treated with defibrillation. Torsades de pointes is treated with magnesium sulfate IV 20% solution, 2 g over 2 to 3 minutes, followed by a continuous infusion of 1.5 mL 10% solution or 5 to 10 mg per minute. For the treatment of bradydysrhythmias, atropine is contraindicated because of the anticholinergic activity. Isoproterenol 0.1  $\mu$ g/kg/min, used with caution, may produce hypotension. If the patient is hemodynamically unstable, a pacemaker is used.

Extraordinary measures, such as aortic balloon pump and cardiopulmonary bypass, have been successful.

Investigational treatments include FAB fragments specific for tricyclic antidepressant, which have been successful in animals. Prophylactic NaHCO<sub>3</sub> to prevent dysrhythmias is also being investigated.

Physostigmine has produced asystole, and flumazenil has produced seizures. Both are contraindicated.

### Disposition

A patient with an antidepressant overdose who meets any of the following criteria should be admitted to the intensive care unit for 12 to 24 hours: (a) ECG abnormalities except sinus tachycardia, (b) altered mental state, (c) seizures, (d) respiratory depression, and (e) hypotension. Low-risk patients include those in whom the above symptoms are absent at 6 hours postingestion, those who present with minor transient manifestations such as sinus tachycardia who subsequently become and remain asymptomatic for a 6-hour period, and asymptomatic patients who remain asymptomatic for 6 hours. These patients may be discharged if the ECG remains normal, they have normal bowel sounds, and they undergo psychiatric disposition.

Even if the patient is asymptomatic upon presentation to the health care facility, intravenous access should be established, vital signs and neurologic status monitored, a baseline 12-lead ECG obtained, and cardiac monitoring continued for at least 6 hours. *Caution:* In 25% of fatal cases, the patients were initially alert and awake at presentation. However, in most cases of fatality initially deemed as sudden cardiac death, the patient, upon reexamination, actually had symptoms that were missed.

Children younger than 6 years of age with non-intentional (accidental) exposures to amitriptyline (Elavil), desipramine (Norpramin), doxepin (Sinequan), imipramine (Tofranil), or nortriptyline (Aventyl) in a dose less than 5 mg/kg, who are asymptomatic and have what are deemed reliable caregivers, can be observed at home, with close poison control follow-up for 6 hours. Parents or caregivers should be given instructions regarding signs and symptoms to be alert for. Children who are symptomatic, or who ingested greater than 5 mg/kg, should be referred to the emergency department for monitoring, observation, and activated charcoal treatment.

## SPIDER BITES AND SCORPION STINGS

Method of

Anne-Michelle Ruha, MD

### CURRENT DIAGNOSIS

#### Black Widow Bite

- Target lesion, not always present
- Generalized pain and muscle cramps
- Hypertension, regional diaphoresis

#### Brown Recluse Bite

- Unlikely to occur outside of endemic areas
- Cyanotic or blistering wound within area of pallor surrounded by erythema
- Systemic loxoscelism associated with rash, fever, hemolysis, renal failure

#### Bark Scorpion Sting

- Absence of lesion or local inflammatory reaction
- Painful paresthesias
- Disconjugate, roving eye movements are characteristic
- Restlessness, agitation, and involuntary jerking of muscles

### CURRENT THERAPY

#### Black Widow Bite

- Opioid analgesics to control pain
- Benzodiazepines to control muscle cramping and anxiety
- Anti-*Latrodectus* antivenom (Antivenin) for persistent severe symptoms

#### Brown Recluse Bite

- General wound care
- If surgical excision is required, perform after 6 to 8 weeks
- Antibiotics only if infected

#### Bark Scorpion Sting

- Close attention to airway
- Opioid analgesics to control pain
- Benzodiazepines to control agitation
- *Centruroides* (scorpion) Immune F(ab')<sub>2</sub>

### Spider Bites

The majority of spiders native to the United States are incapable of envenomating humans. Important exceptions are *Latrodectus* and *Loxosceles* spiders, which produce clinical envenomations that, on rare occasion, are life-threatening.

#### Brown Recluse Spider

The most famous and abundant *Loxosceles* spider in the United States is *Loxosceles reclusa*, known as the brown recluse or fiddleback spider, due to the violin-shaped marking on its cephalothorax. The brown recluse inhabits the midwestern United States, with a range extending from east Texas to west Georgia and reaching north to southern Iowa. Bites from this nonaggressive spider are defensive, and they generally occur when spiders become trapped in clothes or bedsheets. The risk of a bite, even in heavily infested homes, appears to be very small. Most diagnoses of brown recluse bites, including many published in the medical literature, are likely erroneous, occurring in nonendemic areas without identification of the spider. Other *Loxosceles* species found in the United States are even less likely to bite because they avoid human dwellings. Evidence supporting an association between other native spider species and necrotic wounds is weak.

Although the majority of brown recluse bites do not produce significant injury, some result in loxoscelism, which ranges from minor dermonecrosis to, very rarely, life-threatening illness. The venom component thought responsible for loxoscelism is sphingomyelinase D, which affects platelets and cell membranes and activates inflammatory mediators. The first signs of dermonecrosis are often erythema, pruritus, and pain at the bite site. Over hours the site becomes pale and edematous. Erythema can progress and spread gravitationally. A vesicle can develop, form an eschar, and slough over days to weeks. In the first days after the bite, a sunken bluish wound surrounded by a ring of pallor and then erythema is characteristic. Some patients develop a generalized maculopapular rash. Although most necrotic lesions are not serious, some can enlarge to 40 cm and leave a significant scar. Obese persons are at risk for more-severe lesions.

Very rarely, systemic loxoscelism develops within 48 hours of the bite, characterized by fever, myalgias, and hemolysis. Vomiting and diarrhea can occur, and some patients develop a diffuse erythroderma. Renal failure, disseminated intravascular coagulation, and death can result. Death from massive hemolysis is rare and is more likely to occur in children.

Diagnosis of loxoscelism depends on recognition of signs and symptoms in combination with positive identification of the spider when possible. Alternative etiologies for necrotic wounds are much more common than necrotic arachnidism, especially in nonendemic areas. The differential diagnosis of brown recluse bite is large and includes infectious causes, neoplastic disease, and vascular disease.

Treatment is supportive. Most wounds heal without intervention, although a scar might remain. Early surgical excision, dapsone,<sup>1</sup> hyperbaric oxygen, or prophylactic antibiotics cannot be recommended owing to lack of convincing evidence. Patients should receive tetanus prophylaxis (Td) and general wound care. In severe cases, healing can take months and require surgical intervention, which should occur 6 to 8 weeks following the bite after the wound is fully demarcated.

#### Black Widow Spiders

*Latrodectus*, or widow, spiders are, medically, the most important group of spiders in the world. Native black widow spiders are shiny black with a red hourglass pattern on their ventral surface. They can reside in or near human structures, leading to contact with humans and subsequent bites.

$\alpha$ -Latrotoxin in venom causes neurotransmitters to be released from synaptic vesicles. This results in a combination of neuromuscular and autonomic effects unique to *Latrodectus* bites, termed *latrodectism*. Bites are inconsistently felt, and they might or might not leave visible puncture marks and a target-like lesion. Pain can progress locally or become generalized within several hours. Severe muscle pain, particularly involving the abdomen and back, is common. Other findings include hypertension, tachycardia, tremor, localized or diffuse diaphoresis, periorbital edema, and urinary retention. Less commonly, vomiting, fever, priapism, paresthesias, and fasciculations occur. Rhabdomyolysis can result from increased muscle activity. Rarely, acute cardiomyopathy, cardiac ischemia, and pulmonary edema occur. Deaths are uncommon but reported.

Diagnosis of latrodectism is based on history of a spider bite and consistent clinical findings. In the absence of a witnessed bite, diagnosis can be difficult. Sudden onset and rapid progression of symptoms should raise suspicion. Infectious and surgical etiologies must be considered in a febrile or vomiting patient. Similar neuromuscular and autonomic findings might also be seen with intoxication by stimulant drugs and scorpion envenomations, and these should be considered in the differential.

Latrodectism typically resolves within 2 to 7 days. Opioid analgesics are often required to treat pain. Severe symptoms require intravenous opioids for adequate pain control and benzodiazepines for muscle spasms and anxiety. If symptoms are life-threatening or not controlled with these therapies, antivenom (Antivenin [*Latrodectus mactans*, equine origin], Merck, Boston, Mass.) should be considered. One vial reverses symptoms of envenomation. This

<sup>1</sup>Not FDA approved for this indication.

whole-immunoglobulin product can produce acute hypersensitivity and should be administered in a monitored setting. Risks and benefits must be weighed before using this product. If antivenom is not an option or the patient is critically ill, care is supportive, including oxygen and airway support as needed, antihypertensives, antiemetics, and other symptomatic treatment.

### Tarantulas

Tarantulas are common pets and are generally harmless. Bites may be painful, but envenomation by native species has not been reported. Most injury to humans resulting from interaction with tarantulas is secondary to trauma and inflammation caused by barbed abdominal hairs that the spiders eject defensively when threatened. If the hairs embed in the skin, a rash and pruritus can result. They can also embed in the cornea or be transferred there by rubbing the eyes after handling a tarantula. Ophthalmia nodosa, iritis, and keratouveitis have all been reported following exposure to tarantula hairs.

Treatment of embedded corneal hairs entails referral to an ophthalmologist and removal of the hairs if possible. Topical steroids are generally recommended, and some authors also recommend topical antibiotics.

### Scorpion Stings

The bark scorpion, *Centruroides sculpturatus*, is the only native scorpion capable of producing a life-threatening envenomation. This small (<3 inches), yellowish-brown scorpion is found throughout Arizona and in bordering areas of surrounding states.

The scorpion seeks cool, dark environments and commonly enters homes. It injects venom by thrusting its stinger, located at the tip of its tail, toward the victim. The neurotoxic venom increases release of neurotransmitters that act at the neuromuscular junction and autonomic nerve endings.

Most stings are minor, producing local pain and paresthesias. Less than 5% of stings result in neurotoxicity, and the majority of these occur in children. Stings typically do not produce a visible skin lesion, although on rare occasion a small red mark is noted. Pain is immediate, and in a grade 1 envenomation remains local and resolves quickly. Grade 2 envenomations involve pain and paresthesias distal from the sting site, which can persist for days to weeks.

Most severe envenomations affect children younger than 5 years. Symptoms develop within 5 to 45 minutes and can progress for 4 hours. Infants and toddlers can exhibit sudden agitation and crying and transient vomiting, and they might rub their face and ears in response to paresthesias. If the child is verbal, complaints of burning pain and sensation of tongue swelling are common. Sinus tachycardia, hypertension, low-grade fever, and hypersalivation are common, and some children develop stridor. Restlessness, agitation, and twisting of the trunk with thrashing of the extremities is typical, as are tongue fasciculations and dysconjugate eye movements, or opsoclonus. Patients are conscious but often keep their eyes closed owing to diplopia. Presence of cranial nerve findings or neuromuscular agitation constitute a grade 3 envenomation; both are present in grade 4 envenomation. Severe envenomation may be associated with pulmonary edema, rhabdomyolysis, and aspiration pneumonia. Respiratory failure can occur due to several factors, including loss of tongue and respiratory muscle control, hypersalivation, and use of respiratory depressant medications.

Diagnosis often relies on recognition of symptoms, because children might not report a sting. Characteristic findings in regions inhabited by this scorpion usually make diagnosis straightforward. Differential diagnosis includes seizures or amphetamine toxicity. If a suspected envenomation does not follow the expected clinical course, a urine drug screen should be obtained.

Patients with grade 4 envenomation must be monitored for respiratory compromise in an emergency department or intensive care unit. If available, treatment with the antivenom *Centruroides* (Scorpion) Immune F(ab)<sup>2</sup> (Equine) Injection (Anascorp) should be considered. Anascorp reverses neurotoxicity within hours and often allows discharge home from the emergency department. In clinical trials Anascorp had an excellent safety profile; however, acute hypersensitivity reactions are possible, so antihistamines

and epinephrine (Adrenalin) must be accessible. Serum sickness can also develop up to 3 weeks after receiving antivenom.

If antivenom is not an option, longer-acting medications (morphine and lorazepam [Ativan]<sup>1</sup>) may be used to control pain and agitation. Intubation and mechanical ventilation is sometimes necessary owing to venom effects and respiratory depression from the medications used to control symptoms. While the patient is intubated, continuous infusion of sedative, analgesic, and muscle relaxing agents may be necessary until signs and symptoms of envenomation resolve. This typically occurs within 24 hours, although residual medication effects can require prolonged observation.

## VENOMOUS SNAKEBITE

Method of

Christopher Dion, DO; Anne-Michelle Ruha, MD; and †Steven Seifert, MD, MSc

### CURRENT DIAGNOSIS

#### Crotalinae (rattlesnake, copperhead, cottonmouth) bite

- One or two fang puncture marks
- Dry bites (non-envenomation) may occur in up to 20%; patients should be observed for at least 8 to 12 hours before declaring a dry bite
- Envenomation produces pain and progressive swelling
- Edema and functional deficits may take many weeks to completely resolve
- May include clear or hemorrhagic blisters
- May include ecchymosis
- Tissue necrosis and infection are rare and usually late (>2 days) complications
- Abnormalities in hematologic clotting elements (platelets, fibrinogen, PT/INR) are variable, may result in significant bleeding, and may persist for more than 2 weeks
- Typical findings in an endemic area are sufficient as an indication for antivenom treatment

#### Coral snake bite

- One or two fang puncture marks
- Dry bites (non-envenomation) may occur in up to 50%; patients should be observed for 24 hours
- Local effects, even with significant systemic envenomation, may be minimal to nil
- Neurologic effects (progressive, descending paralysis) predominate and may require airway support
- Motor effects may be poorly reversible once established and may persist for many weeks

## CURRENT THERAPY

### Crotalinae bite

- Opioid-level pain relief may be required
- If signs of envenomation, either Anavip or CroFab may be considered first-line treatment
- Allergic reactions are rare; no pretesting or pretreatments are needed
- Maintenance doses are recommended for CroFab
- Although the incidence of recurrent hematologic effects is low with Anavip, postdischarge hematologic monitoring is needed for all patients treated with CroFab or Anavip
- Wound care follow-up may be required for tissue necrosis
- Serum sickness incidence is low (<5%), and most symptoms are mild

### Coral snake bite

- Antivenom should be given at the earliest sign of envenomation to prevent progression

† Deceased.

Two families of significantly venomous snakes are native to the United States, Viperidae and Elapidae. The Viperidae family contains the sub-family Crotalinae, which contains all of the New World pit vipers. Native pit vipers from the United States and Canada are from three genera and contain more than 30 species of rattlesnakes, copperheads, and cottonmouths. The native Elapidae family (elapids) is composed of two genera and several species of coral snakes.

Each year, 5000 to 10,000 venomous snakebites by native species are reported to U.S. poison control centers, with fewer than 5 deaths. At least 97% of these bites are from crotalids.

Currently, there are two antivenoms that are effective against crotalid species: Crotalidae Polyvalent Immune Fab (ovine; CroFab, Boston Scientific/BTG, Farnham, UK) and Crotalidae Immune F(ab')<sub>2</sub> (equine; Anavip; Rare Disease Therapeutics, Inc., Franklin, TN). There is also a single antivenom, Coral Snake (*micrurus fulvius*) Immune Globulin Antivenin (equine; North American Coral Snake Antivenin [NACSA], Pfizer/Wyeth Laboratories, New York, NY) against coral snakes.

Approximately 50 additional bites per year occur from a wide variety of nonnative venomous species of snakes housed in zoos, academic institutions, serpentariums, and private collections. Identification of the biting species in these cases is usually not an issue.

## Diagnostic and Management Overview

### Initial Management

There are only a few actions that can be undertaken in the field to reduce morbidity and mortality from a venomous snakebite. Most “treatments” that have been advocated—cutting or sucking, applying tourniquets, heat, cold, or electricity—have no proven efficacy and are much more likely to result in additional tissue injury and delay of definitive therapy. Jewelry should be removed from the affected extremity. Immobilization and a non-constrictive splint in a position of extension may decrease local venom effects in Crotalinae envenomation, but application should not delay transport to a healthcare facility.

Definitive management for native venomous snakebites in the United States is achieved with appropriate local wound care and antivenom, which is composed of antibodies raised in a host animal (horse or sheep) against snake venom components. As native crotalids inhabit every state except Maine, Hawaii, and Alaska, most hospitals should stock or have ready access to one or both antivenoms.

Pfizer/Wyeth coral snake antivenom is not currently being manufactured at this time. Endemic areas such as Florida, Georgia, Texas, Alabama, and Louisiana have stockpiles; however, the stockpiles are currently being depleted. Pfizer has successfully applied for extensions for expiring lots of NACSA; however, new antivenom vials have not yet entered circulation. An experimental F(ab')<sub>2</sub> antivenom has completed a phase III clinical trial but is not currently available. Foreign-produced antivenoms against related coral snake species may also have efficacy against U.S. snakes but should be used only when a drug that is approved by the U.S. Food and Drug Administration (FDA) is not available and, ideally, with prior FDA approval.

An even more difficult situation results from exotic envenomations for which the appropriate antivenom (if one exists) is certain to be a non-FDA-approved product and must be located at a zoo or other non-healthcare source potentially distant from the location of the envenomation.

Antivenom, local wound care, and symptomatic and supportive care are the mainstays of envenomation management. A regional poison control center should be contacted for information and assistance in managing any venomous snake exposure, including locating an appropriate antivenom. Poison control centers have personnel who are experienced at assessing and managing envenomations and have access to the Antivenom Index, an updatable online database that lists sources of antivenoms for nonnative species. Poison control centers can be contacted from anywhere in the United States by calling 1-800-222-1222.

### Snake Identification

The major branch point in native North American snake envenomation is to determine whether the victim has been bitten by a coral snake or a crotalid. Identification of the specific species can help predict some species-specific challenges; however, more important is to determine if the envenomation was caused by a Crotalinae or Elapidae snake. Crotaline snakes are easily differentiated from coral snakes by virtue of the latter's distinctive color pattern of red, yellow, and black bands. It can be difficult to differentiate a coral snake from nonvenomous snakes that have similar markings. The rhyme “red touches yellow, kills a fellow; red touches black, venom lack,” which describes the red band being surrounded on either side by yellow or black, is accurate only for coral snakes in the United States and Canada. Mexican and South American coral snakes may have the opposite pattern. Crotalids, or pit vipers, can be distinguished from non-venomous snakes by the presence of vertically elliptical pupils, a triangular-shaped head, and the presence of temperature-sensing pits behind the nostrils.

Physical findings, laboratory evaluation, and geographic location of the envenomation is typically all that is required to determine that the snake is venomous and to guide therapy. Attempting to kill or capture the snake is unlikely to add additional information to treatment decisions and may result in further injury.

### Factors Affecting Toxicity and the Severity of Envenomation

Many factors govern whether an envenomation occurs after a bite, the signs and symptoms that develop, and the overall severity of the effects. Up to 25% of crotalid bites and up to 50% of elapid bites do not result in an envenomation. Barriers to fang penetration and other factors may result in no venom being injected. Patients must be watched for a sufficient length of time (i.e., 8 to 12 hours for a crotalid bite and 24 hours for a coral snakebite) to ensure that this is the case.

If an envenomation has occurred, the family and species of snake generally determines the spectrum of symptoms and signs. The amount of venom, specific venom components, and underlying health status of the victim determine severity.

## Crotalid Envenomations

### Epidemiology

Crotalid snakes are distributed throughout North America, with the exception of Maine, Alaska, and Hawaii. Bites are more

† The editors of *Conn's Current Therapy 2023* would like to recognize Dr. Steven Seifert's many years of contribution to this text and for sharing his national expertise on this subject. He passed in 2022.

common in southern states and during summer months, but they occur year-round and may occur at any time and in any location with captive collections. The various genera and species of crotalids in the United States have relatively stable geographic ranges, with much overlap. Many different species of venomous snakes may inhabit any given area. Nonvenomous or mildly venomous colubrid snakes are also native to the United States.

Pit vipers have large front, mobile fangs through which venom is injected into the victim. Because the fangs are curved, venom is usually injected subcutaneously rather than into deeper muscle compartments. Because of anatomic and other physical factors, bite wounds may appear as scratches or as one or more punctures. Envenomation may occur with any break in the skin.

Crotalid venom is complex, consisting of proteolytic enzymes, small peptides, phospholipases, and other elements responsible for the spectrum of clinical effects seen. There is great variability of venom composition among species, within species, and even within a single specimen over the course of a season and its entire life span.

### Clinical Effects

The spectrum of clinical effects is based on the specific genus or species of crotalid and is unpredictable, ranging from non-envenomation (a “dry bite”; up to 25% of bites) to life-threatening reactions. Crotalid snake envenomation typically results in tissue injury and hematologic effects. Local effects are typically pain and progressive swelling, and may include ecchymosis, tissue necrosis, or tissue loss. The complete absence of local effects cannot be used as a reliable marker of non-envenomation in a crotalid bite. We recommend a period of observation of 8 to 12 hours with serial blood draws to monitor for coagulopathy or thrombocytopenia.

Systemic effects including hematologic, neurologic, cardiovascular, and nonspecific findings may occur after crotalid envenomations. Rattlesnake (genera *Crotalus* and *Sistrurus*) envenomations are more likely to result in hematologic effects compared with copperhead or cottonmouth (genus *Agkistrodon*) envenomation. Hematologic abnormalities commonly include thrombocytopenia, hypofibrinogenemia, or prolonged prothrombin time (PT). Rattlesnake envenomations are much more likely to produce neurologic effects, such as muscle fasciculation or weakness, compared with copperhead or cottonmouth envenomations; however, these effects can be seen with any crotalid snake. Acute hypersensitivity can occur from any envenomation, which can result in hypotension, airway compromise, ECG changes, and/or coma. Nausea, vomiting, diaphoresis, anxiety, and other nonspecific effects may be seen.

### Duration of Clinical Effects

Local effects may develop rapidly or may not be apparent for many hours. Progression may occur for days, with resolution of tissue injury occurring over 1 to 6 weeks. Complications of tissue necrosis or infection have their own time frame of resolution. Hematologic effects usually begin within 1 to 2 hours of envenomation. If antivenom is given within this time frame, the detection of these effects may be masked and become apparent only after unbound antivenom has been eliminated from the body, usually within 1 week after treatment. Untreated or recurrent/delayed (after antivenom) hematologic effects may persist for up to 3 weeks after an envenomation. Neurologic and other systemic effects tend to occur within a few hours of envenomation and resolve over 24 to 36 hours.

### Severity of Envenomation

Untreated, local injury worsens over time, with proximal progression of tissue injury. Hematologic effects can be profound, resulting in spontaneous hemorrhage. Hypotension may be severe and can result in death. Neurologic and other systemic effects are rarely life-threatening events. As a result of changes in basic medical care and healthcare systems, it is not directly applicable to compare case-fatality rates before the introduction of antivenom (1950) with what can be expected today. Currently, there are approximately five deaths from crotalid snakebites per year in the United States.

## Management

### Determining Whether Envenomation Has Occurred and Its Severity

Because of the unpredictability of envenomation and the variability of possible clinical effects, each crotalid bite must be assessed and responded to individually (Box 1). It is important to determine whether an envenomation has occurred. If there are no signs or symptoms of envenomation, there is no indication for antivenom or other specific treatment. The severity of the envenomation helps determine the amount of antivenom required to counter and neutralize venom effects, but this may not be immediately apparent because envenomations tend to progress over time, and what may at first appear to be mild venom effects may progress to a severe envenomation.

### Initial Hospital Management

On arrival at the hospital, jewelry should be removed and the bitten extremity loosely splinted in an extended position. The wound should be cleansed (Box 2), and tetanus status should be updated if required. The extremity should be elevated to limit distal edema and pain. Patients often require opioid analgesics for pain relief.

At least one large intravenous line should be placed, avoiding the envenomated extremity, and crystalloid should be infused as required. Initial hospital therapy, including a first dose of antivenom, should be provided in an area capable of close monitoring of vital signs and capable of managing life-threatening reactions; this usually is an emergency department. Whether an intensive care unit or similar patient care area is used for subsequent management depends on the clinical situation.

#### BOX 1 Prehospital Management of Crotalid Envenomation

- Remove jewelry.
- Splint and elevate the extremity in extension.
- Expediently transport the patient to a healthcare facility.
- Obtain intravenous access in a non-envenomated extremity.
- Do not use cutting, sucking, tourniquets, heat, cold, or other local “therapies.”

#### BOX 2 Hospital Diagnosis and Initial Management of Crotalid Envenomation

- Remove jewelry.
- Obtain intravenous access in a non-envenomated extremity, and use crystalloid as indicated.
- Obtain CBC with platelet count, PT, and fibrinogen level every 6 to 12 hours until normalizing.
- Determine whether an envenomation has occurred.
- Determine severity based on the family or species of snake, age and health status of the victim, and development and rate of progression of signs and symptoms (e.g., local injury, hematologic abnormalities, hypotension, and other systemic effects).
- Determine the patient’s tetanus vaccination status, and update if necessary.
- Seek consultation from a poison control center: 1-800-222-1222.
- Determine whether antivenom is indicated, and administer per protocol.
- Provide basic wound care, and determine whether local injury requires specific management.
- Determine whether hematologic or other systemic effects require specific management.

### Indications for Antivenom

Because of the safety of the current FDA-approved antivenoms and their ability to stop proximal progression of local tissue injury, all patients with signs of progressive local envenomation effects as well as those with significant systemic effects are candidates for treatment with antivenom.

Depending on the original indication for treatment (local effects, systemic effects, or both), initial control of envenomation effects is the goal of the loading dose of antivenom. Currently, there are two FDA-approved crotalid antivenoms for North American pit viper envenomation: CroFab and Anavip. The incidence of acute hypersensitivity reactions with CroFab and Anavip are low and generally mild and were found to be similar between products in a comparative trial. Pretreatment sensitivity testing is not required or recommended. There are rare reports of IgE-mediated type I hypersensitivity reactions on repeat exposure in individuals who were previously treated with CroFab, but most people who have been previously treated do not develop an adverse reaction to subsequent administration. The incidence of type III hypersensitivity reaction ("serum sickness") with both antivenoms was approximately 2.5% in the comparative trial.

The half-life of CroFab is approximately 18 to 24 hours, which is considerably shorter than IgG or F(ab')<sub>2</sub> antivenoms, and it is believed to be responsible for increased late hemotoxicity compared with Anavip. Anavip has a longer half-life (approximately 133 hours) and a lower risk of late coagulopathy or thrombocytopenia.

For treatment of envenomations, antivenom is administered as an intravenous solution, with 4 to 6 vials of CroFab, or 10 vials of Anavip diluted into 250 mL of normal saline. The infusion should start at 25 to 50 mL/hour over the first 5 to 10 minutes, and then the rate is increased to finish by 1 hour if there is no reaction. Acute reactions are usually anaphylactoid (rate-related, not IgE-mediated) in nature, but they may reflect true anaphylaxis (IgE-mediated). Anaphylaxis is usually, but not always, more severe, and distinguishing between them is mostly based on a history of prior exposure or reaction.

If an acute hypersensitivity reaction occurs, the infusion should be slowed or stopped, depending on the severity, and appropriate symptomatic treatment should be started with H<sub>1</sub> and H<sub>2</sub> blockers, epinephrine, corticosteroids, and other supportive measures, as required. It should be determined whether antivenom is still required; if so, it should be restarted at a slower rate or higher dilution, or both, and consideration should be given to using an antivenom from a different source animal. CroFab is raised in sheep, and Anavip is raised in horses. Additionally, CroFab uses papain, an enzyme derived from papaya, during production, which may lead to an allergic reaction in those with papaya allergy.

### Treatment of Local Tissue Injury

Monitoring the circumference in three locations along the envenomated extremity is usually sufficient to document progressive local injury. If the antivenom is given exclusively for local findings, the envenomation is deemed to be controlled if measurements stabilize or decrease. Pain in the inguinal or axillary lymph nodes is indicative of spreading envenomation, which may be an indication for further doses of antivenom. There is often some redistribution of existing tissue edema, but uncontrolled proximal progression is usually seen as an indication that the envenomation is not under control. If antivenom is being given for hematologic effects, cessation of worsening or reversal should be seen. Often, thrombocytopenia rebounds dramatically. Hypofibrinogenemia may not rebound as quickly or merely stabilize because the liver must manufacture new fibrinogen. Although an elevated D-dimer value indicates fibrinolytic activity, it is not an independent indicator for antivenom treatment; therefore we do not recommend routinely obtaining this value.

Other systemic effects may serve as indicators for antivenom use, and they should show improvement by the end of the initial infusion. If initial control is not deemed to have occurred,

additional doses of antivenom should be administered until initial control is achieved. Most patients achieve initial control with 4 to 12 vials of Fab antivenom and 10 to 20 vials of F(ab')<sub>2</sub> antivenom.

### Maintenance Doses

A rapid decline of antivenom levels can occur when administering CroFab because of its large volume of distribution. After initial control is achieved, maintenance dosing of two vials every 6 hours for three doses is started. This usually maintains adequate antivenom serum levels to prevent early recurrence of local tissue injury progression; however, late onset of hemotoxicity occurs in about 30% of rattlesnake envenomations after treatment with CroFab. If progression of local effects or hemotoxicity does recur, an additional two vials of antivenom should be administered. Routine maintenance dosing with Anavip is not recommended, but the patient should be observed for an additional 18 hours to ensure that control is maintained. If reemergence of venom effects does occur, an additional four vials of Anavip should be given.

Although significant swelling of limbs may occur and limbs may appear tense, a true compartment syndrome secondary to rattlesnake envenomation is rare. Envenomated extremities may mimic compartment syndrome with symptoms such as paresthesias, swelling, and discoloration. In most cases, the treatment for increased pain, swelling, and other symptoms is more antivenom, as antivenom has been shown to reduce compartment pressure and limit venom-induced decreases in perfusion pressure. If compartment syndrome is suspected, compartment pressures must be directly measured to confirm the diagnosis. If pressures are found to be elevated, an initial trial of additional antivenom and elevation should be undertaken, but fasciotomy may be necessary in rare cases.

Bleb formation at the site of a bite is not an important sign in and of itself, although it may suggest the presence of underlying tissue necrosis. Bleb fluid may contain unneutralized venom. Envenomations to the fingers have significant potential for local necrosis. It is reasonable to unroof blebs at or near the bite site if under significant pressure or to debride obviously necrotic tissue, which usually becomes apparent several days after the bite. The incidence of infection in the United States from crotalid bites is very rare. There are no data to support the use of prophylactic antibiotics, and it is best to limit the opportunities for adverse drug effects. It is often difficult to distinguish inflammatory venom effects from infection.

### Long-Term Local Tissue Effects

The edema and tissue injury produced by most North American crotalid envenomations usually resolve within 1 to 4 weeks, and a return to normal function can be anticipated; however, tissue necrosis or deep tissue injury may result in longer-term or even permanent structural and functional disability. Loss of tissue may occur, including digits and other parts of the extremities, although this is rare and may be associated with prehospital application of tourniquets or other imprudent surgical interventions, delayed care, or complications such as infections. Early antivenom treatment is associated with faster recovery.

### Hematologic Abnormalities and Bleeding

One or more hematologic abnormalities may occur with native crotalid envenomation (Box 3). Significant decreases in platelet count or fibrinogen concentrations are independent indications for antivenom treatment. Isolated, mild prolongation of PT does not require antivenom treatment. Crotaline envenomation does not produce a true disseminated intravascular coagulopathy because there is no true intravascular coagulation. Sufficient platelets, fibrinogen, and thrombin are usually available for hemostasis, and clinically significant bleeding is rarely seen; however, severe depletion of individual clotting elements or a combination of hematologic abnormalities can result in bleeding.

The management of initial or persistent laboratory abnormalities is achieved with additional antivenom. Administration of blood products (e.g., fresh-frozen plasma, platelet concentrates,

- CroFab
  - Administer 4 to 6 vials of antivenom (ovine; Crotalidae Polyvalent Immune Fab [CroFab]) in crotalid envenomations for significant abnormalities of platelet count, PT, or fibrinogen.
- Anavip
  - Administer 10 vials of antivenom Crotalidae Immune F(ab')<sub>2</sub> (equine; Anavip) in crotalid envenomations for significant abnormalities of platelet count, PT, or fibrinogen.
- Administer additional antivenom in 4- to 6-vial (CroFab) or 10-vial (Anavip) increments until reversal of hematologic abnormalities occurs. Replacement of platelets, clotting factors, or fibrinogen may be gradual, and a positive trend indicates neutralization of venom or replacement in excess of venom effect.
- Patients treated with antivenom are at risk for recurrent hemotoxic effects 2 to 4 days after treatment and should be followed closely, with repeat laboratory tests on days 2 to 3 and days 5 to 7 with CroFab and on days 5 to 7 with Anavip.
- Consider treating recurrent hematologic abnormalities with additional antivenom. Indications include platelets <25,000/mm<sup>3</sup>; platelets <50,000/mm<sup>3</sup> with fibrinogen <80 mg/dL; or any evidence of bleeding or risk factors for bleeding.
- Consider readmission for severe abnormalities, other risk factors (e.g., uncontrolled hypertension, advanced age, other bleeding diatheses), or clinically significant bleeding.
- Administer blood products *plus* additional antivenom for significant bleeding.

other blood products) should be reserved for clinically significant (life-threatening) bleeding and given in conjunction with additional antivenom because transfused elements are similarly likely to be consumed by venom activity. Bleeding in damaged tissues, expansion of the vascular volume from crystalloid administration, and hemotoxic venom components may produce an anemia that may rarely require a red blood cell transfusion.

#### Late Hematologic Effects

Although both CroFab and Anavip have similar effects on early manifestations of envenomation, there are significant differences in risk of developing late hemotoxicity. Late hemotoxicity is generally defined as delayed onset or recurrence of thrombocytopenia and/or coagulopathy after completion of antivenom treatment and resolution of early venom toxicity. This usually occurs more than 48 hours after the snakebite occurs. Post-discharge hematologic abnormalities may be severe and may occur, even in patients who did not have initial hemotoxicity.

A study of data reported to a national snakebite registry found that 42% of patients who received CroFab developed late hemotoxicity, but only 4% of patients who received Anavip developed late hemotoxicity ( $P \leq .001$ ). One likely mechanism is recurrent unneutralized venomemia after elimination of unbound antivenom. Anavip has a longer half-life and will remain in circulation longer. As a result, Anavip appears to provide longer protection against recurrence. In the same study, 9% of CroFab patients were retreated with antivenom compared with no patients in the Anavip group ( $P = 0.049$ ).

Although the incidence of significant bleeding is low, even with profound laboratory abnormalities, it seems prudent to administer additional antivenom if the platelet count is less than 25,000/mm<sup>3</sup> in the setting of a normal fibrinogen; there is multicomponent hemotoxicity with fibrinogen less than 80 mg/dL and platelets less than 50,000/mm<sup>3</sup>; or there are underlying medical conditions that make hemorrhage more likely, such as pregnancy, advanced age, use of medications that increase risk of bleeding, or a bleeding diathesis.

#### Disposition

Patients may be discharged if their local effects are regressing, if their pain, hematologic effects, and other systemic effects are controlled and if they do not have complications such as infection or necrosis. Typically, this occurs between 36 and 48 hours after envenomation but may be delayed for up to 1 week. We currently recommend repeat CBC with platelets, PT, and fibrinogen values on days 2 to 3 and days 5 to 7 after envenomation for patients receiving CroFab and on days 5 to 7 in patients receiving Anavip. Ongoing pain relief may be required, with an effort to transition to nonopioid agents during the first week. Acetaminophen is a first-line agent, and in patients considered at low risk for late-onset, new-onset, or recurrent coagulopathy and thrombocytopenia, nonsteroidal antiinflammatory drugs (NSAIDs) may be recommended. Patients should be warned to watch for signs of serum sickness. Occupational or physical therapy should be arranged as needed to maximize return of function, and follow-up for local and systemic effects should be arranged.

#### Coral Snake Envenomations

##### Epidemiology

Each year, there are approximately 50 to 100 bites by coral snakes in the United States. Two genera and several species inhabit the United States, with the *Micrurus* genus responsible for bites in Florida, Texas, Georgia, Louisiana, Alabama, and some neighboring states. A smaller genus, *Micruroides*, is found in Arizona and New Mexico, but it is responsible for very few bites, and there have been no reports of serious envenomations. Bites are more common during the warmer months.

Coral snakes belong to the elapid family and have fixed, relatively short fangs, which may decrease the rate of envenomation. Factors that increase the risk of envenomation include more than one puncture, a deep puncture, and a prolonged time of bite with a sensation of “Velcro” as the snake is taken off.

##### Clinical Effects

Envenomation by the coral snake primarily produces neurologic toxicity from presynaptic toxins, initially producing bulbar muscle weakness, ptosis, diplopia, and dysphagia. These effects can begin within 15 to 30 minutes or may be delayed up to 24 hours after an envenomation. Muscle weakness and paralysis progress to include respiratory muscles, and they can result in respiratory arrest and death. Typical of presynaptic toxins, effect progression can be arrested with the use of antivenom, but the effects are not rapidly reversed. Typically, there is little or no local tissue injury, and the absence of local injury cannot be used to exclude envenomation. Likewise, there is usually no effect on hematologic function, and other systemic effects are rare. Patients cannot be assumed to have received a dry bite by a coral snake because of lack of symptoms on presentation. Presumed coral snake bites should be observed for at least 24 hours before concluding that an envenomation has not occurred.

Because of changes in basic medical care and healthcare systems, it is not directly applicable to compare case-fatality rates before the introduction of antivenom (1967) with what can be expected today; however, at that time, the case-fatality rate was approximately 10%.

##### Management

Coral snake envenomation has the potential for rapid progression of motor paralysis and respiratory compromise without significant local tissue injury. It is reasonable to attempt to slow the venom's progression into the circulation in a prehospital setting if the patient will have a prolonged transport time. A pressure immobilization band (i.e., elastic bandage wrapped from an extremity's tip to the trunk with the degree of tension used for sprains) is used for this purpose for elapid envenomations elsewhere in the world (Boxes 4 and 5). In Australian studies, a pressure immobilization bandage has been shown to slow venom absorption. We do not recommend application of pressure immobilization bandages for coral snake envenomation unless there will be a significant delay

**BOX 4** Prehospital Management of Elapid Envenomation

- Remove jewelry.
- Expediently transport the patient to a healthcare facility.
- Apply a pressure immobilization bandage (e.g., 3- to 4-inch crepe bandage at lymphatic pressure from the tip of the extremity to the trunk) or a lymphatic constriction band (e.g., wide rubber band or blood pressure cuff at 15 to 25 mm Hg proximal to the bite site) only if there will be a significant delay to hospital care.
- Do not delay transport to apply a constriction band.
- Obtain intravenous access in a non-envenomated extremity.
- Do not use cutting, sucking, heat, cold, or other local “therapies.”

**BOX 5** Hospital Diagnosis and Initial Management of Elapid Envenomation

- Remove jewelry.
- If an arterial or a venous tourniquet has been placed, remove the tourniquet.
- Obtain intravenous access in a non-envenomated extremity, and use crystalloid as indicated.
- Determine whether an envenomation has occurred.
- Determine severity based on the family or species of snake, age and health status of the victim, and development and rate of progression of signs or symptoms (e.g., paralysis and other neurologic effects).
- Determine the patient’s tetanus vaccination status, and update if necessary.
- Seek consultation from a poison control center: 1-800-222-1222.
- If a pressure immobilization band or lymphatic constriction band has been placed, remove the band.
- Determine whether antivenom is indicated, and administer per protocol.
- Provide basic wound care, and determine whether local injury requires specific management.
- Determine whether hematologic or other systemic effects require specific management.

to antivenom administration. We do not recommend routine placement of pressure immobilization bandages once a patient has presented to a hospital.

Standard wound care should be performed, including cleansing the wound and updating the tetanus status, if required. Wound infection is uncommon, and prophylactic antibiotics are not recommended.

Coral snake envenomation can result in progressive neurotoxicity, which may require mechanical ventilation. We recommend the use of antivenom if the patient exhibits any signs of envenomation. North American Coral Snake Antivenin (NACSA) is the only FDA-approved antivenom available for use in the United States. NACSA is equine-derived whole-IgG antivenom that is effective only against two of the North American coral snakes: eastern coral snakes (*Micrurus fulvius*), and Texas coral snakes (*Micrurus tener*). The antivenom is not effective against *Micruroides euryxanthus*, the Arizona coral snake; however, this snake does not have any reported medically significant envenomations or deaths reported. At this time, NACSA still remains in short supply, and production has not resumed. Practitioners in coral snake endemic areas have become more conservative with NACSA use. Studies have shown that delaying NACSA use until the patient shows signs of neurotoxicity was not associated with poor outcomes. Recent case series of Texas coral snake envenomation

reported to the North American Snakebite Registry over a 5-year period demonstrated that a “wait and see” approach for NACSA administration was acceptable as no patients received antivenom, and all patients recovered. NACSA stockpiles still exist; however, it does not appear that any new doses of antivenom have been produced. Pfizer has applied to extend the expiration date on lots of antivenom with the FDA.

When paralysis has progressed to significant airway compromise, complete or partial reversal with antivenom may not be possible. Aggressive respiratory support, including intubation and ventilation, may be needed for days or weeks. If an FDA-approved coral snake antivenom is not readily available, there are reports of coral snake antivenoms from Mexico, Costa Rica, and Brazil, and of tiger snake antivenom from Australia, reversing the neurotoxicity of *M. tener*. The use of foreign non-FDA-approved antivenoms should be reserved for circumstances in which an FDA-approved product is not available in a timely manner and, if possible, with prior approval by the FDA Center for Biologics Evaluation and Research (240-402-8020; after-hours emergency: 866-300-4374; 301-796-8240; email is [industry.biologics@fda.hhs.gov](mailto:industry.biologics@fda.hhs.gov)). Because these drugs are imported into the United States as Investigational New Drugs, institutional investigational review boards will also have notification requirements.

**Exotic Snakebite****Epidemiology and Clinical Effects**

In the United States, most exotic snake envenomations occur in private collections. These are not usually known to authorities or healthcare providers until an envenomation occurs, and they may involve the collection owner or family members, including children. They may occur in any locale, and victims may present to any healthcare facility.

Crotalid and elapid snakes, which account for the bulk of venomous bites worldwide, have patterns of venom activity similar to those of their North American counterparts, with some variation and with generally greater toxicity for some non-U.S. species. Some nonnative elapids, such as cobras, mambas, black snakes, or taipans, produce much higher rates of respiratory paralysis and may produce much greater local tissue injury than U.S. coral snakes. Similarly, envenomation from some nonnative crotalids, such as *Bothrops*, *Echis*, or *Bitis* species, or from an African colubrid, such as the boomslang, results in a greater risk of bleeding. Some of these species may directly activate prothrombin (e.g., *Echis* species, *Bothrops* species) and factor X (e.g., *Vipera* species, *Dispholidus* species), leading to a venom-induced consumptive coagulopathy with intravascular thrombosis, marked organ dysfunction, and, potentially, death.

**Management**

The specific management of exotic envenomations is beyond the scope of this chapter. Not all venomous exotic snakes have antivenoms. Even for snakes with antivenoms, they may not be available in the United States, although zoos stock antivenoms for snakes in their collections. As discussed earlier, the Antivenom Index lists these antivenoms and is accessible to regional poison control centers. For information on exotic antivenoms and assistance in managing an exotic snake envenomation, the regional poison control center should be contacted.

## IMMUNIZATION PRACTICES

Method of

Beth A. Damitz, MD

### CURRENT DIAGNOSIS

- Single-agent and poly-agent variety vaccines are available in the United States.
- Vaccine-preventable diseases are occurring in the United States despite efforts.
- Vaccine registries and office-based strategies can increase vaccination rates.

### CURRENT THERAPY

- Vaccination schedules are available through various sources such as the Centers for Disease Control and Prevention (CDC), including catch-up dosing.
- Vaccines can prevent diseases that are still occurring in the United States.
- Vaccination registry participation can increase vaccination rates.
- Each office visit should be used as an opportunity to review and offer vaccines.
- Providers need to be aware of special populations such as breast-feeding and pregnant women, immunosuppressed persons, and healthcare workers who could need different vaccines.

### Definitions and Background

Vaccination is one of the most successful and cost-effective ways to prevent infectious diseases. Immunization is the process of inducing immunity artificially by either active immunization or passive immunization. It also occurs naturally through transplacental transmission of antibodies to a fetus, which provides protection against many infectious diseases for the first few months of life.

### Physiology of Vaccines

Vaccines prevent disease in the people who receive them and protect those who come into contact with unvaccinated individuals such as children too young to receive vaccines, those who cannot be immunized for medical reasons, and those who cannot make an adequate response to vaccination. Vaccines are preparations of proteins, polysaccharides, or nucleic acids of pathogens that are delivered to the immune system as single entities, as part of complex particles, or by live, attenuated agents to induce specific responses that inactivate, destroy, or suppress the pathogen.

### Immunization Recommendations

The Advisory Committee on Immunization Practices (ACIP) sponsored by the Centers for Disease Control and Prevention

(CDC; <https://www.cdc.gov/vaccines/schedules/hcp/index.html>), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP) work together to issue a national schedule for routinely recommended vaccinations. They recommend routine vaccination to prevent 17 vaccine-preventable diseases that occur in infants, children, adolescents, or adults. These recommendations are reviewed and revised periodically. These immunization schedules give ranges of target ages for vaccines to be given (Figures 1–3). They include single and combination vaccine products. Catch-up dosing and special-population schedules are also available (updated immunization schedules are available at <https://www.cdc.gov/vaccines/schedules/index.html>).

### Disease Prevention

Since the development of vaccines, we have seen a dramatic decrease in both cases and deaths from vaccine-preventable diseases. For example, in 1950, there were 319,124 cases and 468 deaths from measles. This dramatically decreased to 43 cases and zero deaths in 2007. Obviously, decrease in disease and death is paramount, but it is also important to decrease the cost burden to our healthcare system. For every \$1 spent on measles, mumps, and rubella (MMR) vaccine, \$21 is saved in direct medical costs of treating a case of measles.

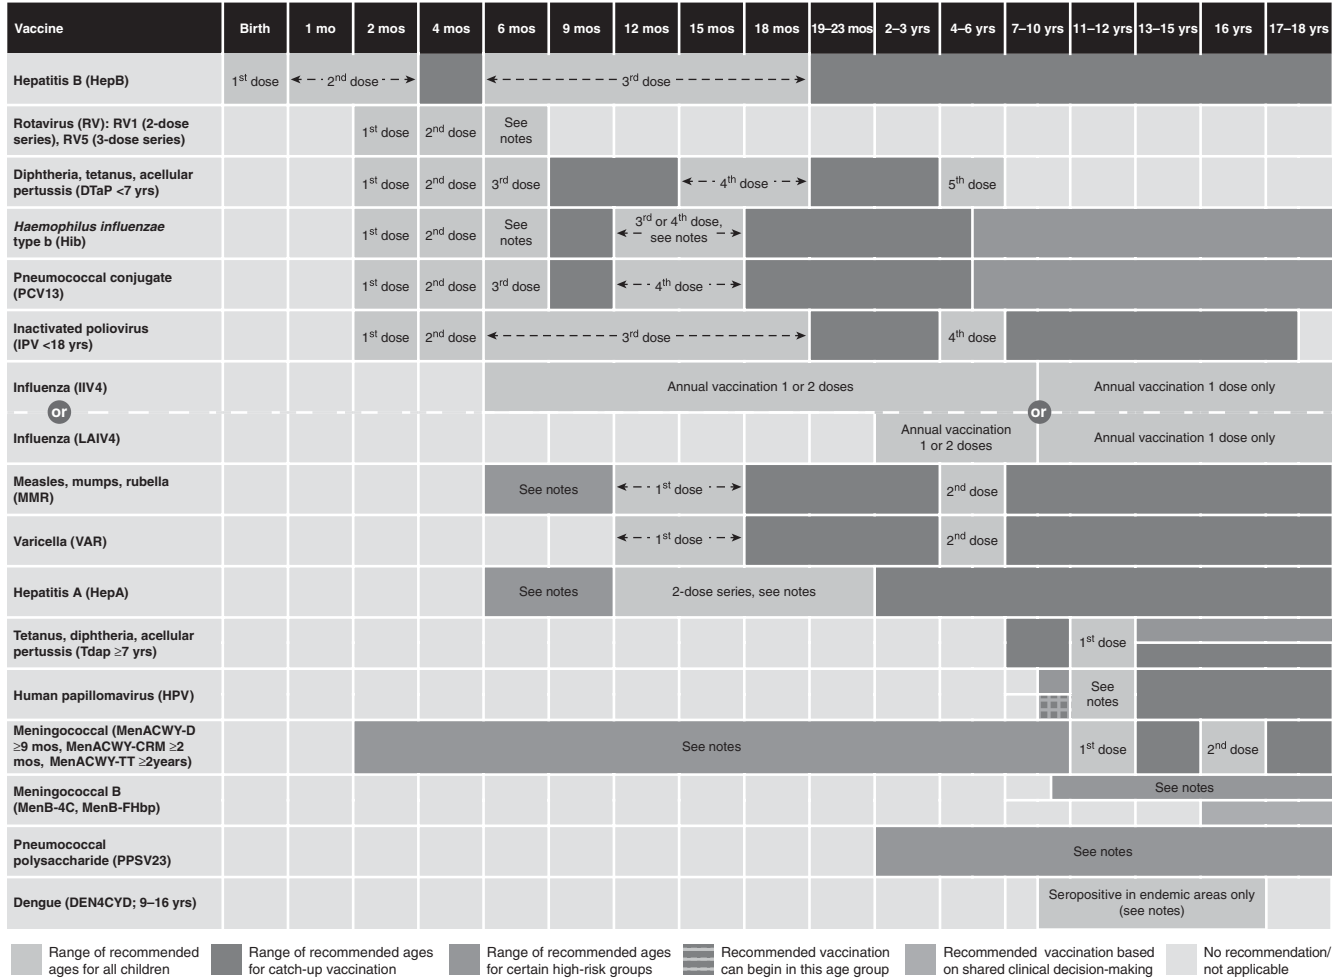

### COVID-19 Vaccines

COVID-19 is a respiratory disease caused by SARS-CoV-2, a virus in the Coronavirus family, that was discovered first in China in December of 2019. It spread rapidly across the world, causing a pandemic. Pharmaceutical companies immediately pursued the development of vaccines to COVID-19. Within the next year, several COVID-19 vaccines were authorized for emergency use. Currently, three vaccines are available in the United States from these manufacturers: Pfizer-BioNTech, Moderna, and Johnson & Johnson/Janssen. The Pfizer and Moderna vaccines are mRNA-derived vaccines. The Pfizer-BioNTech vaccine (Comirnaty) is FDA approved for 16 years and older and is administered in a two-dose series, 21 days apart. The Pfizer-BioNTech vaccine has also received an Emergency Use Authorization (EUA) for children 5 to 15 years of age, as a two-dose series, 3 weeks apart. The Moderna vaccine (Spikevax) is approved for ages 6 months and older and is delivered in a two-shot series 28 days apart. At this time a booster dose is only recommended for those 18 years and older. The Johnson & Johnson/Janssen vaccine is a viral vector–derived vaccine. It has been granted an EUA for use in those 18 years and older and is a one-shot regimen. All three vaccines have been granted EUA for booster dosing, but Pfizer-BioNTech or Moderna are preferred. For people who are moderately or severely immunocompromised, it is recommended they receive a second dose of either the Pfizer or Moderna vaccine 4 weeks after receiving the Johnson & Johnson vaccine. See Figures 4 and 5 for COVID vaccine immunization schedules.

All three vaccines can have side effects. Common side effects are minor and include injection site redness, swelling and pain, fever, headaches, fatigue, muscle pain, and nausea. More severe reactions are rare. There have been reports of thrombosis with thrombocytopenia syndrome with the Johnson & Johnson vaccine. Women under the age of 50 seem to be at a higher risk. In addition, there have been reports of myocarditis and pericarditis after the second doses of the mRNA vaccines (Pfizer and Moderna). These reactions are rare, and the CDC has recommended

## Recommended child and adolescent immunization schedule for ages 18 years or younger, United States, 2022

These recommendations must be read with the notes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule (table 2).

**Figure 1** Recommended immunization schedule for children and adolescents aged 18 years or younger—United States, 2022. All notes may be accessed at: <https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html#birth-15>. From the Centers for Disease Control and Prevention.

to continue to offer these vaccines as the benefits outweigh the risks. As with many viruses, COVID-19 can and does mutate. At this time there have been several variants identified. Studies demonstrate that the available vaccines are effective against them. Of note, since COVID-19 is evolving, new information is constantly being obtained. It is advised to explore other resources such as <https://www.cdc.gov> for the most up-to-date information.

### Pneumococcal Vaccine Update

On October 20, 2021, the Advisory Committee on Immunization Practices (ACIP) updated their recommendations for Pneumococcal vaccination to provide expanded serotype coverage. For adults 65 years and older who have never received a pneumococcal vaccine or whose vaccination status is unknown, it is recommended they receive one dose of the pneumococcal conjugate vaccine 20 (PCV20) or one dose of the pneumococcal conjugate vaccine 15 (PCV15) followed by a dose of the pneumococcal polysaccharide vaccine 23 (PPSV23) 1 year or later. Adults 65 years and older with a previous PPSV23 history only should receive either the PCV15 or PCV20 given 1 year or later after they received the PPSV23 with no further doses needed. For adults 65 years and older with a previous pneumococcal conjugate vaccine 13 (PCV13) history or a PCV13 and PPSV23 history, they should complete the PPSV23 series as previously recommended. For adults 19 to 64 years of age with certain medical conditions or risk factors (see following figures) who

have no or unknown PCV history, they should receive either one dose of the PCV20 or one dose of the PCV15 followed by a dose of the PPSV23 in 1 year.

### Immunization Responsibility

Appropriate vaccination is the responsibility of the healthcare team and patient (and parents). Education is critical. This can be done through various dissemination techniques such as one-on-one counseling, posters in the office, health fairs, and handouts at school and work. An office-based strategy consists of nursing and physician education of updates and changes in vaccines, the ability to track patient immunization records through registries, sending reminder letters to patients that there are recommended vaccines, and adopting standing orders to take advantage of appropriate office visits to maximize vaccination opportunities.

There are many sources for keeping current on immunizations and vaccines including the CDC's *Morbidity and Mortality Weekly Report* (MMWR). For parents and patients, the vaccine information statement (VIS), which is made available by the CDC to inform patients about the risks and benefits of immunizations, is very helpful and by law must be distributed before administering any vaccine. After the patient reads the VIS, the physician can then give any further information or answer questions before administering the vaccine. This discussion should be documented in the patient's medical record, including the refusal to receive certain vaccines (i.e., informed refusal).

## Recommended adult immunization schedule by age group, United States 2022

Vaccine	19–26 years	27–49 years	50–64 years	≥65 years
Influenza inactivated (IIV4) or Influenza recombinant (RIV4) <small>or</small>	1 dose annually			
Influenza live, attenuated (LAIV4)	1 dose annually			
Tetanus, diphtheria, pertussis (Tdap or Td)	1 dose Tdap each pregnancy; 1 dose Td/Tdap for wound management (see notes)			
	1 dose Tdap, then Td or Tdap booster every 10 years			
Measles, mumps, rubella (MMR)	1 or 2 doses depending on indication (if born in 1957 or later)			
Varicella (VAR)	2 doses (if born in 1980 or later)		2 doses	
Zoster recombinant (RZV)	2 doses for immunocompromising conditions (see notes)		2 doses	
Human papillomavirus (HPV)	2 or 3 doses depending on age at initial vaccination or condition	27 through 45 years		
Pneumococcal (PCV15, PCV20, PPSV23)	1 dose PCV15 followed by PPSV23 OR 1 dose PCV20 (see notes)			1 dose PCV15 followed by PPSV23 OR 1 dose PCV20
Hepatitis A (HepA)	2 or 3 doses depending on vaccine			
Hepatitis B (HepB)	2, 3, or 4 doses depending on vaccine or condition			
Meningococcal A, C, W, Y (MenACWY)	1 or 2 doses depending on indication, see notes for booster recommendations			
Meningococcal B (MenB)	19 through 23 years	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations		
Haemophilus influenzae type b (Hib)	1 or 3 doses depending on indication			

Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended vaccination for adults with an additional risk factor or another indication

Recommended vaccination based on shared clinical decision-making

No recommendation/not applicable

**Figure 2** Recommended immunization schedule for adults aged 19 years and older—United States, 2022. All notes may be accessed at: <https://www.cdc.gov/vaccines/schedules/hcp/imz/child-adolescent.html#birth-15>. From the Centers for Disease Control and Prevention.

### General Principles for Vaccine Scheduling

Optimal response to a vaccine depends on several factors, including the type of vaccine, age of the recipient, and immune status of the recipient. Simultaneous administration of vaccines increases the probability that a patient will be vaccinated fully by the appropriate age. Simultaneous administration of all age-appropriate doses of vaccines is recommended by the MMWR for children for whom no specific contraindications exist at the time of the visit. The use of combination vaccine preparations greatly reduces the overall number of injections a child or patient will receive. However, care must be taken to ensure that the individual vaccine entities are not administered too early and too many are not administered at once. This can be a challenge when patients switch clinics or in times of vaccine shortages.

More often, dosing intervals longer than recommended are encountered in the office. With the exception of oral live typhoid vaccine (Vivotif Berna), an interruption in the vaccination schedule does not require restarting the entire series of a vaccine or toxoid or addition of extra doses. When an unknown or uncertain vaccination status is encountered, every effort should be made to access records. If this cannot be done in a reasonable amount of time, these persons should be considered susceptible and started on the age-appropriate vaccination schedule. Serologic testing for immunity is an alternative to vaccination; however, commercial serologic testing might not always be sufficiently sensitive or standardized for detection of vaccine-induced immunity, and research laboratory testing might not be readily available.

### Route of Administration

There are three orally administered vaccines in the United States: rotavirus, cholera (Vaxchora), and typhoid vaccines. Rotavirus (Rotatrix, RotaTeq) is licensed for infants and does not need to be repeated if the vaccine is spit up or vomited. Typhoid vaccine

capsules (Vivotif) should be taken as directed by the manufacturer. Live, attenuated influenza vaccine (LAIV4, FluMist) is the only intranasal vaccine available. It does not need to be repeated if the person coughs or sneezes immediately after administration. Except for bacille Calmette-Guerin (BCG) vaccine and smallpox vaccine,<sup>a</sup> injectable vaccines are administered by the intramuscular or subcutaneous route.

### Storage

In general, vaccines need to be stored in a refrigerator or freezer. When vaccines are inappropriately stored, they can lose potency. Refrigerator and freezer storage units must be properly monitored and maintained to ensure vaccine integrity. Temperature logs should be maintained for 3 years unless state or local authorities require a longer time. Vaccines that have been stored at inappropriate temperatures should not be administered. An office protocol should be established for handling inappropriately stored vaccines, procedures for follow-up when these vaccines are inadvertently given, emergency vaccine retrieval and storage, handling vaccine shipments, maintaining a vaccine inventory log, and rotating vaccine stock to avoid expiration. Care should be taken to store similar vaccine products (sound-alike or look-alike) away from each other (on different shelves) or by color-coding labels. Diphtheria toxoid-, tetanus toxoid-, and acellular pertussis-containing vaccines are easily confused.

### Vaccine Safety

Vaccines in the United States undergo extensive safety and efficacy evaluations through the FDA licensing process. Despite this rigorous process, adverse reactions can and do occur. Adverse

<sup>a</sup>Available in the United States from the Centers for Disease Control and Prevention.

Recommended adult immunization schedule by medical condition and other indications, United States, 2022

Vaccine	Pregnancy	Immuno-compromised (excluding HIV infection)	HIV infection CD4 percentage and count		Asplenia, complement deficiencies	End-stage renal disease, or on hemodialysis	Heart or lung disease; alcoholism <sup>1</sup>	Chronic liver disease	Diabetes	Health care personnel <sup>2</sup>	Men who have sex with men
			<15% or <200 mm <sup>3</sup>	≥15 and ≥200 mm <sup>3</sup>							
IIV4 or RIV4 <b>or</b>	1 dose annually										
LAIV4	Contraindicated					Precaution			1 dose annually		
Tdap or Td	1 dose Tdap each pregnancy	1 dose Tdap, then Td or Tdap booster every 10 years									
MMR	Contraindicated*	Contraindicated	1 or 2 doses depending on indication								
VAR	Contraindicated*	Contraindicated	2 doses								
RZV	2 doses at age ≥19 years		2 doses at age ≥50 years								
HPV	Not recommended*	3 doses through age 26 years		2 or 3 doses through age 26 years depending on age at initial vaccination or condition							
Pneumococcal (PCV15, PCV20, PPSV23)	1 dose PCV15 followed by PPSV23 OR 1 dose PCV20 (see notes)										
HepA			2 or 3 doses depending on vaccine								
HepB	3 doses (see notes)		2, 3, or 4 doses depending on vaccine or condition								
MenACWY	1 or 2 doses depending on indication, see notes for booster recommendations										
MenB	Precaution	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations									
Hib	3 doses HSCT <sup>3</sup> recipients only				1 dose						

  Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection
   Recommended vaccination for adults with an additional risk factor or another indication
   Recommended vaccination based on shared clinical decision-making
   Precaution—vaccination might be indicated if benefit of protection outweighs risk of adverse reaction
   Contraindicated or not recommended—vaccine should not be administered.
   No recommendation/ not applicable

\*Vaccinate after pregnancy.

1. Precaution for LAIV4 does not apply to alcoholism. 2. See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. 3. Hematopoietic stem cell transplant.

**Figure 3** Recommended immunization schedule for adults aged 19 years or older by medical condition and other indications, United States, 2022. All notes may be accessed at: <https://www.cdc.gov/vaccines/schedules/hcp/imz/adult-conditions.htm>. From the Centers for Disease Control and Prevention.

reactions are reportable to the Vaccine Adverse Event Reporting System (VAERS). VAERS is a national reporting system created in 1990 to unify the collection of all reports of adverse events after vaccination. Its primary purpose is detecting new or rare vaccine adverse events, increases in rates of known side effects, and risk factors for particular types of adverse events.

In 1986, the National Childhood Vaccine Injury Act established the Vaccine Injury Compensation Program (VICP). It is a no-fault program that covers all routinely recommended childhood vaccines. Those claims may be based on a vaccine injury table, which lists the adverse events associated with vaccines and provides a rebuttable presumption of causation, or by proving by preponderant evidence that the vaccine caused an injury not on the table. The table was created to provide swift compensation to those possibly injured by vaccines.

The provider’s role to help ensure safety of vaccination includes proper vaccine storage and administration, timing and spacing of vaccine doses, observation of contraindications and precautions, and reporting adverse events to the VAERS.

**Contraindications and Adverse Events**

A contraindication is a condition in a recipient that increases the chance of a *serious* adverse reaction. A precaution is a condition in a recipient that *might* increase the chance or severity of an adverse reaction or compromise the ability of the vaccine to produce immunity. Situations do arise when the benefits outweigh the risks of a side effect. The only contraindication applicable to all vaccines is a history of a severe allergic reaction (anaphylaxis) after a previous dose of vaccine or to a vaccine component unless the recipient has been

desensitized. Children who experienced encephalopathy within 7 days after administration of a previous dose of DTP,<sup>2</sup> DTaP (Daptacel, Infanrix), or Tdap (Adacel, Boostrix) not attributable to another identifiable cause should not receive additional doses of a vaccine that contains pertussis. The following are *not* contraindications to vaccination:

- Minor illness
- Diarrhea
- Mild or moderate local reaction or fever following a prior dose
- Antimicrobial therapy
- Disease exposure or convalescence
- Pregnant or immunosuppressed person in the household
- Premature birth
- Breast-feeding

Vaccination should be deferred for persons with a moderate or severe acute illness. This precaution avoids causing diagnostic confusion between manifestations of the underlying illness and possible adverse effects of vaccination or superimposing adverse effects of the vaccine on the underlying illness.

Vaccine adverse reactions are classified as local, systemic, or allergic. Allergic reactions might be caused by the vaccine antigen, residual animal protein, antimicrobial agents, preservatives, stabilizers, or other vaccine components. Anaphylaxis is rare and usually begins within minutes of vaccine administration. Children who have had an apparent severe allergic reaction to a vaccine should be evaluated by an allergist to determine the

<sup>2</sup>Not available in the United States.

**COVID immunization schedule for children 6 months through 17 years of age**

Type	Product*	Recipient age	For most people		Those who ARE moderately or severely immunocompromised	
			Doses	Interval between doses <sup>†‡</sup>	Doses	Interval between doses <sup>†‡</sup>
mRNA vaccine	Moderna (Blue vial cap with magenta-bordered label)	6 months through 5 years	Total doses: 2 doses		Total doses: 3 doses	
			Dose 1 to 2	At least 4–8 weeks <sup>†</sup>	Dose 1 to 2	At least 4 weeks
					Dose 2 to 3	At least 4 weeks
	Moderna (Blue vial cap with purple-bordered label)	6 through 11 years	Total doses: 2 doses		Total doses: 3 doses	
			Dose 1 to 2	At least 4–8 weeks <sup>†</sup>	Dose 1 to 2	At least 4 weeks
					Dose 2 to 3	At least 4 weeks
	Moderna (Red vial cap with blue-bordered label)	12 through 17 years	Total doses: 2 doses		Total doses: 3 doses	
			Dose 1 to 2	At least 4–8 weeks <sup>†</sup>	Dose 1 to 2	At least 4 weeks
					Dose 2 to 3	At least 4 weeks
	Pfizer-BioNTech (Maroon vial cap with maroon-bordered label)	6 months through 4 years	Total number: 3 doses		Total number: 3 doses	
			Dose 1 to 2	At least 3–8 weeks <sup>†</sup>	Dose 1 to 2	At least 3 weeks
			Doses 2 and 3	At least 8 weeks	Dose 2 to 3	At least 8 weeks
	Pfizer-BioNTech (Orange vial cap with orange-bordered label)	5 through 11 years	Total number: 3 doses		Total number: 4 doses	
			Dose 1 to 2	At least 3–8 weeks <sup>†</sup>	Dose 1 to 2	At least 3 weeks
			Dose 2 to 3	At least 5 months	Dose 2 to 3	At least 4 weeks
Dose 3 to 4	At least 3 months					
Pfizer-BioNTech (Purple vial cap with a purple-bordered label or gray vial cap with gray-bordered label)	12 years through 17 years	Total number: 3 doses		Total number: 5 doses		
		Dose 1 to 2	At least 3–8 weeks <sup>†</sup>	Dose 1 to 2	At least 3 weeks	
		Dose 2 to 3	At least 5 months	Dose 2 to 3	At least 4 weeks	
				Dose 3 to 4	At least 3 months	
Dose 4 to 5	At least 4 months					

\* Complete the primary series with same product. If the vaccine product previously administered cannot be determined or is no longer available, any age-appropriate mRNA COVID-19 vaccine product may be administered at least 28 days after the first dose. Any COVID-19 vaccine product (age appropriate) may be administered for a booster dose. It does not need to be the same product used for the primary series.

† Persons with a recent SARS-CoV-2 infection may consider delaying a primary series or booster dose by 3 months from symptom onset or positive test (if infection was asymptomatic).

‡ Some studies in adolescents and adults have shown the small risk of myocarditis associated with mRNA COVID-19 vaccines might be reduced and peak antibody responses and vaccine effectiveness may be increased with an interval longer than 4 weeks. An 8-week interval may be optimal for people who are not moderately or severely immunocompromised and ages 6 months–64 years, especially for males ages 12–39 years.

All notes may be accessed at: <https://www.cdc.gov/vaccines/covid-19/downloads/COVID-19-immunization-schedule-ages-6months-older.pdf>. From the Centers for Disease Control and Prevention.

**Figure 4** COVID immunization schedule for children 6 months through 17 years of age .

responsible allergen and to make recommendations regarding future vaccination.

**Barriers**

Barriers to appropriate and timely vaccination include patients’ misconceptions, false contraindications, complexity of the immunization schedules, religious or philosophic beliefs, and cost. The Vaccines for Children Program (VCP) is a federally funded program that provides free ACIP-recommended vaccines to adolescents and children younger than 19 years old. This program has reduced the barrier of cost.

**Recording Vaccinations**

Healthcare providers who administer vaccines covered by the National Childhood Vaccine Injury Act are required to ensure that the permanent medical record of the recipient indicates the date the vaccine was administered, the vaccine manufacturer, the vaccine lot number, and the name, address, and title of the person administering the vaccine. In addition, the provider is required to record the edition date of the VIS distributed and the date those materials were provided. Patients should also keep a record of the immunizations they receive, when they

were received, and at what facility they received them. A permanent vaccination record card should be established for each newborn infant and maintained by the parent or guardian.

Immunization information systems (IIS), formerly referred to as immunization registries, are confidential population-based computerized information systems that collect and consolidate vaccination data from multiple healthcare providers within a geographic area. The CDC oversees a network of 64 IIS programs distributed throughout all 50 states, the District of Columbia, and eight US territories. A fully operational IIS can prevent duplicate vaccinations, provide a complete record of immunizations if the patient has received vaccines from multiple sites, and offer catch-up and needed vaccine information. Although participation of a provider is voluntary, it is highly encouraged.

**Special Populations  
Children**

Although infants are born with some level of immunoglobulin (Ig)G that is contributed from the mother via passive immunity, these levels generally decrease by 9 months of age, leaving them vulnerable to many infectious diseases. Infants begin

**COVID immunization schedule for persons 18 years of age**

Type	Product*	Recipient age	For most people		Those Who ARE moderately or severely immunocompromised	
			Doses	Interval between doses <sup>††</sup>	Doses	Interval between doses <sup>††</sup>
mRNA vaccine	Moderna (Red vial cap with a blue-bordered label)	18 years and older	Total number: 3 or 4 doses		Total number: 5 doses	
			Dose 1 to 2	At least 4–8 weeks <sup>‡</sup>	Dose 1 to 2	At least 4 weeks
			Dose 2 to 3	At least 5 months	Dose 2 to 3	At least 4 weeks
			Dose 3 to 4	At least 4 months for persons ages 50 years and older	Dose 3 to 4	At least 3 months
	Pfizer-BioNTech (Purple vial cap with a purple-bordered label or gray vial cap with gray-bordered label)	18 years and older	Total number: 3 or 4 doses		Total number: 5 doses	
			Dose 1 to 2	At least 3–8 weeks <sup>‡</sup>	Dose 1 to 2	At least 3 weeks
			Dose 2 to 3	At least 5 months	Dose 2 to 3	At least 4 weeks
			Dose 3 to 4	At least 4 months for persons ages 50 years and older	Dose 3 to 4	At least 3 months
Viral vector vaccine	Janssen <sup>§</sup>	18 years and older	Total number: 2 or 3 doses		Total number: 4 doses	
			Dose 1 to 2	At least 8 weeks	Dose 1 to 2	At least 4 weeks (mRNA vaccine) <sup>¶</sup>
			Dose 2 to 3	At least 4 months for persons ages 50 years and older (mRNA vaccine) <sup>**</sup>	Dose 2 to 3	At least 8 weeks <sup>§</sup>
					Dose 3 to 4	At least 4 months (mRNA vaccine) <sup>¶</sup>

\* Complete the primary series with same product. If the vaccine product previously administered cannot be determined or is no longer available, any age-appropriate mRNA COVID-19 vaccine product may be administered at least 28 days after the first dose. Any COVID-19 vaccine product (age appropriate) may be administered for a booster dose. It does not need to be the same product used for the primary series. An mRNA COVID-19 vaccine is preferred.

† Persons with a recent SARS-CoV-2 infection may consider delaying a primary series or booster dose by 3 months from symptom onset or positive test (if infection was asymptomatic).

‡ Some studies in adolescents and adults have shown the small risk of myocarditis associated with mRNA COVID-19 vaccines might be reduced and peak antibody responses and vaccine effectiveness may be increased with an interval longer than 4 weeks. An 8-week interval may be optimal for people who are not moderately or severely immunocompromised and ages 6 months–64 years, especially for males ages 12–39 years.

§ Age-appropriate mRNA COVID-19 vaccines are preferred over the Janssen COVID-19 vaccine for vaccine doses for all vaccine-eligible people 18 years of age and older. Janssen COVID-19 vaccine should only be used in limited situations. See: [www.cdc.gov/vaccines/covid-19/clinical-considerations/covid-19-vaccines-us.html](http://www.cdc.gov/vaccines/covid-19/clinical-considerations/covid-19-vaccines-us.html)

¶ mRNA vaccine must be used.

\*\* People ages 18–49 years: Those who received Janssen COVID-19 vaccine as both their primary series dose and booster dose may receive a second booster dose using an mRNA COVID-19 vaccine at least 4 months after the Janssen booster dose.

All notes may be accessed at: <https://www.cdc.gov/vaccines/covid-19/downloads/COVID-19-immunization-schedule-ages-6months-older.pdf>. From the Centers for Disease Control and Prevention.

**Figure 5** COVID immunization schedule for persons 18 years of age.

developing IgG shortly after birth and continue to increase these levels throughout the first year of life, but they remain generally susceptible to infection until they achieve adult levels of IgG at 10 years of age. Therefore this age group is especially important to vaccinate.

**Breast-Feeding**

Neither inactivated nor live virus vaccines administered to a lactating woman affect the safety of breast-feeding for women or their infants. Breast-feeding is a contraindication for smallpox vaccination of the mother because of the theoretical risk for contact transmission from mother to infant. Yellow fever vaccine (YF-VAX) should be avoided. Breast-fed infants should be vaccinated according to the recommended schedule.

**Pregnancy**

No evidence exists of risk to the fetus from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. Live vaccines, such as smallpox, MMR, and varicella (Varivax), pose a theoretical risk to the fetus and therefore are generally contraindicated during pregnancy. New recommendations from ACIP advise to give all pregnant women a Tdap in every pregnancy. New data indicate that maternal antipertussis antibodies are short-lived; therefore Tdap vaccination in one pregnancy will not provide high levels of antibodies to protect newborns during subsequent pregnancies. Alternatively, if Tdap is not administered during pregnancy, the woman should receive a dose of Tdap as soon as possible after delivery to ensure pertussis immunity and reduce the risk for transmission

to the newborn regardless of when she last received a tetanus booster. Routine influenza vaccination is recommended for all women who are or will be pregnant (in any trimester) during influenza season, which usually occurs early October through late March. Do not use the live attenuated influenza vaccine (LAIV4), which is contraindicated in pregnancy.

### Altered Immunocompetence

Persons with altered immunocompetence include those with primary and secondary causes of immunodeficiency as well as those with asplenia, chronic kidney disease, treatments with therapeutic monoclonal antibodies, and prolonged administration of high-dose corticosteroids. In general, they should receive inactivated influenza virus (Afluria, Fluad, Fluarix, Fluzone) and age-appropriate polysaccharide-based vaccines (pneumococcal conjugate vaccine [PCV, Prevnar], pneumococcal polyvalent [PPSV, Pneumovax 23], meningococcal conjugate [MCV4, Menactra], meningococcal polysaccharide [MPSV4, Menomune], and haemophilus B conjugate [Hib, ActHib, PedvaxHib]). Persons with most forms of altered immunocompetence should not receive live vaccines (MMR, varicella, MMRV [ProQuad], LAIV, zoster [Zostavax], yellow fever, oral typhoid, BCG, and rotavirus).

### Healthcare Personnel

Healthcare personnel are at substantial risk for acquiring or transmitting hepatitis B, influenza, measles, mumps, rubella, pertussis, and varicella and should be counseled on appropriate vaccinations.

## TRAVEL MEDICINE

Method of

Kristine B. Matson, MD, MPH; and Dawd S. Siraj, MD, PhD

The affordability and ease of cross-border travel combined with the growing world population is increasing the number of individuals traveling internationally. According to the United Nations World Tourism Organization (UNWTO), the number of arriving international tourists in 2018 in all countries exceeded 1.4 billion individuals, and the number of arrivals to countries with emerging markets has surpassed the number of arrivals to developed countries (UNWTO; <https://www.e-unwto.org/doi/pdf/10.18111/9789284419876>). This increase in international travel has created a need for the specialty of travel medicine, which focuses on the unique and location-dependent health-related needs of travelers.

An estimated 22% to 64% of travelers report some type of illness while abroad. Most of these illnesses are mild and self-limiting, requiring minimal intervention. Approximately 4% of travelers who seek medical help have an acute, potentially life-threatening disease, and about 1 in 100,000 of these travelers die from complications related to their travel.

The goal of a travel medicine visit is to maximize health and prevent illness while traveling by offering travelers specific structured advice, malaria prophylaxis, and immunization recommendations. Disease risks, current outbreaks, and local health conditions are destination-dependent and constantly change, thus the use of current, up-to-date resources is essential for providing travel medicine care (Table 1). Unfortunately, 20% to 80% of international travelers do not undergo a health consultation or receive location-specific pretravel advice before traveling. Travelers visiting friends and relatives in their country of origin, pregnant mothers, children, and travelers who are staying abroad for a long period are at particularly high risk for morbidity and mortality during their trip, requiring special attention to pretravel medical planning. Ideally pretravel health

consultations should take place 4 to 6 weeks before departure to give travelers adequate time to complete the required vaccination series. Pretravel health consultations should be structured and comprehensive. Table 2 lists items that require consideration and discussion during the consultation according to the type of travel and destination. Patients should arrive to their consultation with documentation of their vaccination history. A useful travel history form is available on the Shoreland Travax website ([www.travax.com](http://www.travax.com)).

### Vaccinations

Travel clinics often provide travelers the opportunity to update routine vaccinations that they missed. Additionally, travel medicine provides vaccinations that are recommended or required because of country-specific or ongoing outbreak-specific risks. When deciding which vaccination to recommend, several factors must be considered, including any specific potential risks associated with the travel itinerary, length of stay, and activities. For each vaccine-preventable disease (VPD), one should consider the prevalence and impact of the disease in question.

### Routine Vaccines

Routine vaccines are those that are administered at a regular interval for all individuals regardless of travel plans. As the risk of acquisition of these diseases increases during international travel, travel medicine providers should confirm that travelers are up to date on their routine vaccinations before departure. The recent importation of diseases such as measles and mumps, which have resulted in outbreaks of these diseases in the travelers' country of origin, are reminders of the importance of updating routine vaccinations before travel. Travelers are advised to bring documentation of all prior vaccinations to confirm vaccination status and determine the need for booster doses.

### Measles-Mumps-Rubella Vaccine

Measles remains a serious cause of morbidity and mortality in the non-Western world. Importation of measles by unvaccinated travelers from regions that report endemic disease, such as Europe, Africa, and parts of Asia, remains a concern for countries where disease transmission has been interrupted (like the Americas). Indeed, several cases have been associated with exposure during air travel itself. All travelers born after 1957 (United States) and 1970 (Canada and the United Kingdom) must have two documented vaccinations or evidence of immunity as confirmed by antibody titer. Infants who are 6 to 11 months of age and are traveling to a measles-endemic area should be given one dose of measles-mumps-rubella (MMR) vaccine before departure. Individuals who have no documented vaccination and a negative antibody titer should receive two doses of MMR vaccine at least 4 weeks apart. Those who have two documented doses are considered immune for at least 20 years.

### Poliovirus Vaccine

As a result of successful efforts to eradicate poliomyelitis, most of the world is now polio free. As of 2019, a few developing countries, particularly Afghanistan and Pakistan, have reported endemic wild-type poliovirus (WPV) outbreaks. In addition, as of February 2022, a small number of developing countries continue to report cases of circulating vaccine-derived poliovirus (cVDPV; [www.polioeradication.org](http://www.polioeradication.org)).

The injectable, inactivated poliovirus vaccine (IPV, IPOL) is the only polio vaccine available in the United States. All children must have four doses of IPV. Travelers who are traveling to countries with WPV or cVDPV and who have completed the age-appropriate series are recommended to receive a single lifetime adult booster dose before travel. The recommendation also applies to travelers to bordering countries and those who have a high risk of exposure, such as individuals working in health-care, refugee camps, or humanitarian aid settings (U.S. Centers for Disease Control and Prevention [CDC] health information for international travel, 2019). As the list of countries with WPV or

**TABLE 1** Information Resources for Risk Assessment of Travel

Travax (Shoreland)	Commercial software-generated reports combining itinerary-specific recommendations on recommended travel vaccines and risks. Requires a fee.	<a href="http://www.shoreland.com">www.shoreland.com</a>
U.S. Department of State	Travel warnings	<a href="https://travel.state.gov/content/passports/en/alertswarnings.html">https://travel.state.gov/content/passports/en/alertswarnings.html</a>
World Health Organization	General travel health information and access to its international travel guide and alerts	<a href="http://www.who.int/ith/en/">www.who.int/ith/en/</a>

**TABLE 2** Checklist of Items to Address in the Pretravel Consultation

CATEGORY	ISSUES THAT SHOULD BE ADDRESSED
Patient risk assessment	Obtain history: itinerary, type of travel, personal medical history, age, underlying diseases, allergies, current medications, pregnancy status, previous vaccination status
Immunizations	Update routine immunizations Provide routine travel immunizations Provide destination-specific immunizations
Malaria prophylaxis	If indicated: Provide malaria education and advice; discuss bite-avoidance measures Prescribe antimalaria prophylaxis
Traveler's diarrhea	Prescribe oral rehydration therapy and loperamide (Imodium) 4 mg initially and 2 mg after each loose stool, not to exceed 16 mg/day Prescribe appropriate antibiotic (see Table 4)
Prevention against mosquito bites	Give advice regarding mosquito-borne disease Discuss personal protection measures
Rabies prevention	Give advice regarding behavior near animals Discuss measures to take if bitten or scratched by an animal—seek urgent medical advice Administer vaccine when indicated
Altitude sickness	Provide education Prescribe acetazolamide (Diamox) 125 mg orally twice a day for 1 day before ascent and continuing for 2 to 3 days on arrival at maximum altitude
Prevention of sexually transmitted diseases	Provide education regarding safe sex
Zika virus	Discuss potential risk of congenital Zika syndrome for pregnant women or women/men planning to conceive following return from an endemic area
Others	Deep venous thrombosis prevention Accident prevention Motion sickness prevention

Some of the recommendations are indicated only for specific destinations or specific at-risk groups.

VDPV circulation and recommendations for vaccine is dynamic, providers are encouraged to refer to the CDC's Travelers' Health web page (<https://wwwnc.cdc.gov/travel>) for up-to-date advice.

A small number of countries require proof of polio vaccination upon entry or before departure, thus administration should be documented on a vaccination certificate.

**Tetanus-Diphtheria-Pertussis Vaccine**

Unvaccinated or inadequately vaccinated travelers are at risk of contracting diphtheria in developing countries as well as tetanus and pertussis anywhere in the world. The potential risk of exposure to pertussis is worldwide, with the highest rates of disease in developing countries where vaccine coverage is low. In recent decades, countries with high vaccination rates, including the United States, have seen a resurgence of pertussis despite adequate vaccination programs. Immunity from natural disease or childhood vaccination wanes over time, thus adolescent and

adult travelers who have completed their childhood series should receive a booster dose of tetanus-diphtheria-pertussis (Tdap) vaccine (Adacel, Boostrix). Once one documented Tdap booster is given, a subsequent booster can be a tetanus-diphtheria (Td) or Tdap vaccine. If more than 5 years have elapsed since the last booster dose, a tetanus-containing booster should be considered for persons going to remote areas where tetanus boosters may not be readily available after a contaminated trauma.

**Varicella Vaccine**

Varicella infection remains prevalent worldwide. Infection can occur via inhalation of aerosols or contact of vesicular fluid from a skin lesion. Exposure to active herpes zoster lesions poses a risk of varicella infection to a susceptible traveler. In children, disease is generally mild and self-limiting. However serious complications can occur in infants, adults, and immunocompromised individuals. Travelers who have not completed age-appropriate

vaccination or do not have laboratory evidence of immunity should receive the varicella vaccination (Varivax) before travel. Those older than 13 years of age should receive two doses at least 4 weeks apart.

### Influenza Vaccine

Influenza is the most common VPD among travelers. Travelers 6 months of age and older should receive the most up-to-date influenza vaccine available in their countries annually if they are traveling to an area where influenza is circulating at the time of their travel (year round in tropical and subtropical areas and winter months in temperate areas). Travelers who are 65 years of age and older should receive the high-dose influenza vaccine (Fluzone High-Dose) to elicit higher levels of antibody response.

### Pneumococcal Vaccine

The prevalence of pneumococcal disease is highest in developing countries. In 2022, the Advisory Committee on Immunization Practices (ACIP) of the CDC recommended administration of pneumococcal conjugate vaccine (PCV15; Vaxneuvance) to all individuals 65 years of age and older who did not receive a pneumococcal vaccine in the past, followed by a dose of pneumococcal polysaccharide vaccine (PPSV23; Pneumovax) given 1 or more years later for immunocompetent patients and 8 or more weeks later for immunocompromised patients. Or more easily, the patient can receive the PCV20 once without the need for a follow-up PPSV23.

## Recommended Travel Vaccines

### Hepatitis A Vaccine

The hepatitis A virus is transmitted through ingestion of contaminated food or water. The virus remains viable in ice and frozen foods. Travelers who visit rural areas, trek in the back country, and often eat in a poor sanitary environment are at high risk of hepatitis A infection. Outbreaks have been reported among men who have sex with men (MSM) traveling to endemic areas. Hepatitis A vaccination is recommended for travel to any developing country and some industrialized countries where sanitary conditions are variable.

Two hepatitis A vaccine preparations are available (Havrix, Vaqta), which are approved for administration in those 12 months of age and older. For infants traveling to a high-risk endemic countries, vaccination is recommended for all children older than 6 months of age. A combination of hepatitis A and B vaccines (Twinrix) is also available and is approved for travelers 18 years of age and older. For those who are traveling on short notice, an accelerated schedule is approved. A single dose of hepatitis A vaccine given any time before travel will provide adequate protection in an immunocompetent traveler. A booster dose given 6 to 12 months after the first dose will ensure lifetime protection. Infants who received one dose before travel should receive two more doses of the vaccine for long-term protection. Immunoglobulin for hepatitis A virus prophylaxis (GamaSTAN S/D), which can be administered to travelers who are not immune and will be traveling in less than 2 weeks, is rarely recommended considering the immunogenicity of the vaccine and long incubation period of hepatitis A. A study comparing hepatitis A vaccine with immunoglobulin to prevent postexposure hepatitis A infection did not show a difference between the two, suggesting the efficacy of the vaccine as an alternate considering its ease and safety compared with immunoglobulin.

### Typhoid Vaccine

Although hepatitis A and typhoid fever are both transmitted through ingestion of contaminated food and water, hepatitis A is 100 times more common than typhoid fever in travelers. The Indian subcontinent seems to be a key focus of typhoid fever in travelers, accounting for more than 80% of travel-related typhoid cases in the United States. The efficacy of typhoid vaccines ranges from 50% to 80% in various published studies.

The typhoid vaccine is protective against *Salmonella enterica* serotype typhi, but not against paratyphoid fever, which is caused by strains of *S. enterica* paratyphi A, B, and C. The typhoid vaccine is recommended for long-term travelers to developing countries, short-term travelers to South Asia, and high-risk travelers to other destinations such as individuals visiting friends and relatives in their country of origin and food adventurers.

Two unconjugated vaccines are available in the United States: the oral live, attenuated typhoid vaccine (Ty21A, Vivotif Berna) that is approved for all travelers older than 6 years of age, and the injectable typhoid Vi polysaccharide vaccine (Typhim Vi) for those older than 2 years of age. The oral vaccine, which consists of four capsules (one taken every other day) is protective for 5 years, while the injectable vaccine is only effective for 2 years. Ideally, either vaccine should be given at least 2 weeks before departure.

### Hepatitis B Vaccine

The hepatitis B virus (HBV) is endemic worldwide, with a high prevalence in Asia and sub-Saharan Africa. Infection is transmitted through contact with blood, blood products, and body fluids and therefore poses a limited risk to most travelers; however, health-care professionals traveling to endemic areas are at high risk.

Travelers should be counseled on HBV transmission and minimizing exposure. All patients who are traveling to intermediate- to high-prevalence countries (>2% prevalence of HBV surface antigen) should receive the vaccination. The vaccines (Engerix-B, Recombivax HB, Twinrix [hepatitis A and hepatitis B vaccine]) are approved as a series of three doses given at day 0, 1 month, and 6 months. For those traveling on short notice, Twinrix is approved for an accelerated schedule of day 0, 7, and 21 to 30 days. For long-term immunity, a booster dose of Twinrix is recommended at 12 months. Two doses of this regimen completed in a 1-week interval provides adequate immediate protection for travel. A new conjugate (adjuvanted) vaccine (Heplisav-B) with two doses 1 month apart has been approved for all travelers 18 years of age and older. Protective immunity of Heplisav-B is robust, with over 95% of those who complete the series achieving immunity, and it will likely replace the vaccines that are currently available.

### Cholera Vaccine

Most cases of cholera are reported from sub-Saharan Africa, Asia, and the island of Hispaniola (Haiti and the Dominican Republic). The risk of cholera to an average traveler is extremely low. The vaccine is indicated for emergency relief workers, healthcare workers traveling to an endemic area, and travelers going to an area with a declared outbreak. The vaccine is not required for entry to any country. In 2016, a single dose, oral, live-attenuated vaccine (Vaxchora) was approved for adults older than 18 years of age.

### Japanese Encephalitis Vaccine

Japanese encephalitis is a mosquito-borne neurologic disease endemic to China, Korea, the Indian subcontinent, Southeast Asia, and the Western Pacific. The risk varies according to destination, length of stay, season, and activities being undertaken. The risk is highest for travelers to rural areas, especially with nighttime outdoor activities. The overall incidence of Japanese encephalitis cases among persons from non-endemic countries traveling to Asia is estimated to be less than 1 per 1 million, though this could be much higher depending on the type, time, and duration of travel. Vaccination should be considered for all frequent travelers and those who are planning to stay longer than 1 month in an endemic country.

An inactivated, cell culture-derived vaccine (IXIARO) is licensed in the United States for use in individuals 2 months of age and older. Children 2 months to 2 years of age are given one-half the dose used for adults. The vaccine is given as a two-dose series at 0 and 28 days. An accelerated vaccination schedule of two doses 1 week apart has been approved for travelers who do not have enough time to complete the series before departure.

## Rabies Vaccine

Rabies is a fatal viral infection that is transmitted through exposure to saliva of a rabid animal. The virus is neurotropic and results in progressive encephalomyelitis that is often fatal. It has a worldwide distribution with the highest prevalence in Asia, Africa, and South and Central America. Dog bites remain the primary source of infection, though bat exposure is increasingly identified as a common risk factor for disease acquisition. There were 66 cases of rabies documented in travelers from 1990 to 2013 (40% from Asia, and 85% following canine exposure). Animal bites are common during travel. Approximately 2700 travelers received care for animal-related exposures and required rabies postexposure prophylaxis at GeoSentinel clinics during a 15-year period (1997 to 2012). Clinical illness follows a variable incubation period ranging from days to months from exposure. Early symptoms include pain and paresthesia at the site of the bite, which is invariably followed by paresis, paralysis, and fatal encephalitis. Hydrophobia, delirium, and convulsions are classic presentations that often are followed by coma and death. Symptomatic and supportive care, including aggressive wound care and postexposure prophylaxis, may improve survival in patients with this uniformly fatal disease.

Veterinarians, animal handlers, field biologists, laboratory workers who handle animals, and children are at high risk and recommended to receive the pre-exposure vaccination.

In the event of an exposure, vaccinated individuals require two additional doses of vaccine 3 days apart, while unvaccinated travelers require four doses of vaccine and additional human rabies immune globulin (HRIG [HyperRab, Imogam Rabies]), which may be expensive, unavailable, or unreliable in the traveler's locale. In light of the devastating consequences of rabies, the fact that animal bites, scratches, or licks over mucous membranes are common among travelers, even during short trips; the difficulties in receiving rabies immune globulin in the developing world; and the fact that a one-time pre-exposure vaccination course is likely protective "for life" suggest that the threshold for recommending rabies vaccination to travelers to the developing world should be low.

A two-dose pre-exposure rabies vaccine (Imovax Rabies, RabAvert) has replaced the old three-dose vaccine and is protective for up to 3 years. High-risk individuals should have their rabies titer checked every 6 months to maintain adequate protection.

## Tick-Borne Encephalitis Vaccine

Tick-borne encephalitis is an arboviral zoonosis transmitted primarily through the bite of *Ixodes* species ticks. It is endemic in many popular tourist destinations in Europe, Eastern Europe, and parts of Asia including China, Japan, Russia, and Siberia. Symptoms include fever, body aches, headache, and arthralgia. Up to 20% to 30% of individuals who are infected will develop encephalitis. Human infections usually are seen in the spring and summer months in temperate zones and in the fall and winter months in the Mediterranean region. A tick-borne encephalitis vaccine (TicoVac) is available in Europe, Canada, and now the United States and is considered immunogenic and safe. Vaccination is recommended for travelers with extensive outdoor exposures such as camping in endemic regions during the transmission season. In addition, travelers should be advised to use insect repellents and avoid tick bites to protect themselves from tick-borne encephalitis.

## Required Vaccines

### Yellow Fever Vaccine

Yellow fever (YF) is a mosquito-borne disease endemic to parts of sub-Saharan Africa and tropical South America. Though most patients with YF are asymptomatic, about 15% develop severe disease, with a reported case fatality rate of 20% to 60%. The YF vaccine (YF-VAX) is a live-attenuated vaccine that travelers should receive at least 10 days before arriving in an endemic country. A large YF outbreak was documented in eastern Brazil in 2016 to 2018, which expanded the previously known endemic

area within Brazil. The World Health Organization (WHO) and the CDC are now recommending YF vaccination for all travelers to eastern and southeastern states of Brazil. The risk of a traveler acquiring YF varies with season, location, activities, and duration of travel. Since January 2018, 10 travel-related cases of YF, including 4 deaths, have been reported in travelers returning from Brazil. None of the 10 travelers received the YF vaccination.

Vaccination is recommended for personal protection of travelers to endemic areas. In addition, under WHO rules, any given country may routinely require YF vaccination for entry into its territory. The aim of the regulation is to protect countries that have the mosquito vector from re-introduction of YF by asymptomatic viremic travelers.

The yellow fever vaccine (YF-VAX) is rarely associated with severe and fatal adverse reactions, which generally follow the first dose. The overall rate of serious adverse reaction is about 1 event per 250,000 doses. The likelihood of serious adverse events increases with age, with patients older than 60 years of age having a much higher risk for a severe adverse reaction.

A change in the International Health Regulations in July 2016 now considers a valid YF vaccination to be effective for life, with no need for booster vaccination at 10-year intervals. This also applies retroactively to YF vaccinations given any time before 2016. The new policy extends the validity of the vaccination for personal protection, with no need for booster doses among healthy, immunocompetent individuals. Per this recommendation, countries cannot require proof of vaccination (booster) against YF as a condition of entry to travelers whose YF vaccination was over 10 years prior. A booster vaccine after 10 years is still recommended for specific high-risk individuals: long-term travelers, travelers to West Africa, and travelers to an area where there is a current outbreak. Travel clinics should confirm requirements of each country when they advise travelers.

### Meningococcal Vaccine

Meningitis is caused by the bacteria *Neisseria meningitidis*. It is acquired by nasopharyngeal droplets during close contact. The disease spectrum ranges from fever and bacteremia to meningitis. There are eight serogroups of meningococci, but most travel-related disease is caused by the A, C, X, and W135 serogroups. Disease is endemic worldwide, but the highest risk area is the sub-Saharan region, which is loosely named the *meningitis belt*. There is seasonality to disease incidence, with seasonal epidemics occurring during the dry season (December to June).

Meningococcal disease is rare in travelers (1:100,000 to <1:1,000,000 per month of travel). A quadrivalent conjugated vaccine that protects against serogroups A, C, X, and W135 (Menactra, Menveo, MenQuadfi, and Nimenrix<sup>2</sup>) is recommended for travelers to endemic areas. Travelers to countries in the meningitis belt who anticipate close contact with crowds or the local population as well as aid workers in refugee camps are considered at high risk and are recommended to receive the vaccine before travel. Vaccination is required for entry to Saudi Arabia during Hajj or Umrah seasons. Travelers returning to Saudi Arabia or high-risk zones should receive a booster vaccination every 5 years.

### Malaria

Reports of malaria cases in the United States have been steadily increasing over the past few decades, mainly as a result of infection in travelers to areas of the world with ongoing malaria transmission. In 2016, there were 2078 cases of malaria reported in the United States. Only 26.3% of U.S. residents who developed malaria that year reported receiving malaria prophylaxis, and 94% did not complete an appropriate chemoprophylactic regimen. Of those who reported a reason for travel, the majority of

<sup>2</sup>Not available in the United States.

**TABLE 3** Medication Options for Chemoprophylaxis of Malaria

DRUG	USE IN PROPHYLAXIS	ADULT DOSE	LENGTH OF TREATMENT
Chloroquine	Areas with chloroquine-sensitive <i>Plasmodium falciparum</i>	500 mg (300 mg base) weekly	Start 1 to 2 weeks before exposure. Continue weekly while in the malaria zone and for 4 weeks after leaving
Mefloquine (Lariam)	Areas with mefloquine-sensitive <i>P. falciparum</i>	250 mg weekly	Start $\geq 2$ weeks before exposure. Continue weekly while in the malaria zone and for 4 weeks after leaving
Atovaquone-proguanil (Malarone)	All malaria zones	250 mg/100 mg once daily	Start 1 to 2 days before exposure. Continue daily while in the malaria zone and for 7 days after leaving
Doxycycline	All malaria zones	100 mg daily	Start 1 to 2 days before exposure. Continue daily while in the malaria zone and for 4 weeks after leaving
Tafenoquine (Arakoda)	All malaria zones	200 mg	A loading dose is 200 mg taken daily for 3 days before exposure. Then continue 200 mg weekly while in the malaria zone and for 1 week after leaving
Primaquine <sup>1</sup>	Areas with $>90\%$ <i>Plasmodium vivax</i>	30 mg base daily	Start 1 to 2 days before exposure. Continue daily while in the malaria zone and for 7 days after leaving

<sup>1</sup>Not FDA approved for this indication.

cases were in travelers visiting friends and relatives in their country of origin (69.4%).

Before travel, a risk assessment should be performed to determine if malaria chemoprophylaxis is indicated. Malaria transmission can vary greatly, even within a country, based on the region and season of travel. The traveler's specific itinerary should be reviewed for the cities visited, type of accommodations (bed nets, window screens, air-conditioning), reason for travel, and special activities while traveling. Mosquito avoidance measures should be recommended in addition to chemoprophylaxis.

The life cycle of malaria in humans involves an initial asymptomatic liver stage followed by a later symptomatic erythrocytic stage. Malaria chemoprophylaxis is used to prevent the development of clinical malaria if a person is infected. Certain chemoprophylactic agents (chloroquine [Aralen], mefloquine [Lariam], and doxycycline [Vibramycin]) only work on the later erythrocytic stage of malaria parasites and are therefore recommended to be taken for a longer time (4 weeks) after leaving a malaria-endemic area. Atovaquone-proguanil (Malarone) can act on the earlier nondormant liver parasite stage, therefore a shorter post-travel duration is recommended (1 week). Unlike other *Plasmodium* species, *Plasmodium vivax* and *Plasmodium ovale* have dormant liver stages known as *hypnozoites*, which are responsible for disease relapse with these species months or years after an acute infection. Tafenoquine (Arakoda) and primaquine<sup>1</sup> are the only available chemoprophylactic medications effective against all liver stages of the malaria parasite, including the liver hypnozoites of *P. vivax* and *P. ovale*.

### Malaria Chemoprophylaxis

All malaria chemoprophylactic options should be started before travel, taken throughout travel, and continued for a period post-travel (Table 3). When choosing a chemoprophylactic agent, factors to consider include the traveler's age and medical history,

pregnancy status, length of the trip, cost of the drug, drug allergies, drug interactions, and drug resistance at the destination.

Chloroquine (Aralen) may only be used for malaria prophylaxis in areas of the world with chloroquine-sensitive *Plasmodium falciparum*. Resistance is found worldwide except in Central America west of the Panama Canal, Haiti, and the Dominican Republic. Chloroquine is used once a week for prophylaxis. It should be started 1 to 2 weeks before travel, taken weekly during travel, and continued for 4 weeks after leaving the malaria zone. The most common side effects are gastrointestinal discomfort, nausea, vomiting, or headache. Serious adverse effects are rare and are more likely to occur with prolonged and high doses of therapy. Retinopathy is associated with high doses and when used for more than 5 years. An overdose of chloroquine could be fatal, and the medication should be stored in childproof containers. If a traveler is already taking hydroxychloroquine (Plaquenil) chronically for a rheumatologic condition, they may not have to take additional malaria prophylaxis.

Four potential options are approved by the U.S. Food and Drug Administration (FDA) for malaria chemoprophylaxis in areas with chloroquine-resistant malaria: atovaquone/proguanil (Malarone), doxycycline, mefloquine (Lariam), and tafenoquine (Arakoda). Primaquine may be used off-label (not FDA approved) for malaria chemoprophylaxis in areas of the world with predominantly *P. vivax* malaria.

Mefloquine should only be used for malaria prophylaxis in areas of the world with mefloquine-sensitive *P. falciparum*. Mefloquine-resistant *P. falciparum* malaria is found in parts of Southeast Asia (along the borders of Thailand with Cambodia and Burma, western Cambodia, eastern Burma, and southern Vietnam), and mefloquine should not be used for malaria prophylaxis in these areas. Mefloquine is used once a week for prophylaxis. It should be started  $\geq 2$  weeks before travel, taken weekly during travel, and continued for 4 weeks after leaving the malaria zone. Adverse effects tend to be noted within the first weeks of mefloquine initiation, therefore the medication can be started 2 to 4 weeks before travel to ensure that it will be tolerated during

<sup>1</sup>Not FDA approved for this indication.

travel. Mefloquine may be associated with sleep disturbances, strange dreams, and insomnia. The FDA also has issued a black-box warning that mefloquine may cause neuropsychiatric adverse effects that can persist after the medication has been discontinued. Mefloquine is contraindicated in those with neurologic and psychiatric disorders and should be avoided in travelers with a significant family history of seizures or major psychiatric disorders. It is also recommended to avoid mefloquine in travelers with cardiac conduction abnormalities. A traveler who is prescribed mefloquine must receive a copy of the FDA medication guide for Mefloquine, which can be found online ([www.accessdata.fda.gov/drugsatfda\\_docs/label/2008/019591s023lbl.pdf](http://www.accessdata.fda.gov/drugsatfda_docs/label/2008/019591s023lbl.pdf)).

Atovaquone-proguanil can be used for malaria prophylaxis in any malaria zone worldwide. Atovaquone-proguanil is a daily prophylactic drug. It should be started 1 to 2 days before travel, taken daily during travel, and continued for 7 days after leaving a malaria zone. The drug is usually well-tolerated, with the most common adverse effect being gastrointestinal upset.

Doxycycline can be used for malaria prophylaxis in any malaria zone worldwide. Doxycycline is a daily prophylactic drug. It should be started 1 to 2 days before travel, taken daily during travel, and continued for 4 weeks after leaving a malaria zone. An added benefit of doxycycline is that it may also provide some protection against rickettsial infections and leptospirosis. However, photosensitivity is a common adverse effect of doxycycline.

Tafenoquine (Arakoda) can be used for malaria prophylaxis in any malaria zone worldwide. Tafenoquine is used once a week for prophylaxis. It should be started 1 to 2 weeks before travel, taken weekly during travel, and continued for 1 week after leaving the malaria zone. G6PD deficiency must be ruled out by laboratory testing before prescribing this medication because fatal hemolysis could occur in individuals with G6PD deficiency. Tafenoquine should be avoided in those with a history of a psychotic disorder because rare psychiatric events have been observed. The most common adverse events include nonsignificant decreases in hemoglobin, gastrointestinal discomfort, and headache. Tafenoquine is the only FDA-approved medication for malaria prophylaxis that has activity on the hypnozoite stage of the malaria parasite. Note that another tafenoquine-based antimalarial (Krintafel) is approved for radical cure of *P. vivax* infections in those older than 16 years of age.

Primaquine is very effective against *P. vivax* and is an option for travel to areas with >90% *P. vivax* malaria.<sup>1</sup> It is taken daily starting 1 to 2 days before exposure. It is continued daily while in the malaria zone and until 7 days after leaving. It cannot be used in those with G6PD deficiency and may cause gastrointestinal upset.

### Post-travel

No prophylaxis is 100% effective. Travelers should be advised to seek medical attention during travel if malaria symptoms occur. They should also be told to notify their physician of their travel history if they develop a febrile illness for up to 1 year post-travel.

### COVID-19

Since COVID-19 was identified in late 2019, there have been more than 500 million confirmed cases worldwide with over 6 million deaths. Travel requirements during this time have been frequently revised. As of June 12, 2022, the CDC no longer requires air passengers traveling from a foreign country to the United States to show a negative COVID-19 viral test or documentation of recovery from COVID-19 before boarding their flight. All non-immigrant, non-U.S. citizen air travelers to the United States are required to be fully vaccinated and to provide proof of vaccination status before boarding, with limited exceptions. The CDC continues to recommend masks during public transportation and at transportation hubs, but masks are no longer required.

Travelers to other countries should also be aware of travel health notices and arrival restrictions at their destination. Passengers should not travel if they are sick, have recently been exposed to COVID-19 and recommended to quarantine, or have recently tested positive for COVID-19. More information on international travel during COVID-19 can be found on the CDC Travel Recommendations by Destination website (<https://www.cdc.gov/coronavirus/2019-ncov/travelers/map-and-travel-notice.html>).

### Personal Protection Measures

Risk for vector-borne disease depends on many factors, including the traveler's destination, season of travel, and length of stay. Viral diseases that may be of concern include Japanese encephalitis, Zika virus, dengue, and chikungunya virus. Rickettsial diseases are found worldwide on all continents with the exception of Antarctica. Malaria is the parasite of greatest concern, but leishmaniasis, trypanosomiasis, and filariasis are other potential parasitic diseases spread by arthropod vectors.

The type of accommodation can affect the traveler's risk of vector-borne diseases. An air-conditioned room for sleeping, effective window screens, and/or bed nets are protective. Wearing long-sleeve shirts, long pants, and socks can also decrease risk. For added protection, a clothing insect repellent, such as permethrin, is recommended. Permethrin activity is maintained on treated clothes despite several wash cycles.

Insect repellents for use on skin have variable efficacy depending on the repellent type and form, concentration, frequency of application, and vector. Typically, a higher concentration of insecticide will provide a longer duration of protection. However, there is a peak at which no further protection is seen, and more toxicity could result. DEET, at a concentration of 20% to 25%, has efficacy against all mosquito species and some tick species, biting flies, chiggers, and fleas. Concentrations above DEET 50% do not appear to provide added benefit. Products containing picaridin (icaridin outside the United States) are also good options. Potential benefits of picaridin over DEET are that it is odorless and does not damage plastic. Products containing IR3535 are another option and appear to have particularly good activity against *Ixodes scapularis* ticks (commonly known as *deer ticks* or *black-legged ticks*).

### Traveler's Diarrhea

During a 2-week trip, traveler's diarrhea has an incidence between 10% and 40%. Higher-risk areas include parts of Asia and Central/West Africa. Certain behaviors may affect the risk of developing diarrhea. Practicing hand hygiene measures before eating has been shown to reduce the incidence of diarrhea. Other potentially beneficial measures include avoiding food that has not been properly cooked, avoiding ice, and drinking only bottled or treated water in resource-poor settings.

Traveler's diarrhea is predominantly caused by bacterial pathogens. However, antibiotic prophylaxis to prevent traveler's diarrhea is rarely indicated, given both the cost and potential for adverse events. Bismuth subsalicylate (BSS [Pepto-Bismol])<sup>1</sup> has shown efficacy in decreasing the risk of traveler's diarrhea and may be considered for prevention. However, BSS requires frequent dosing, causes blackening of the tongue, and has the potential for drug-drug interactions.

### Treatment

Treatment recommendations for traveler's diarrhea depend on the severity of illness. Ensuring adequate hydration is always a mainstay of treatment. In the case of severe diarrhea, the WHO recommends oral rehydration therapy (ORT), which is available at most pharmacies. An antimotility agent such as loperamide (Imodium) can also provide symptomatic benefit for mild to severe traveler's diarrhea. Loperamide is not recommended to be used alone in travelers with dysentery.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Treatment Options for Empiric Treatment of Traveler's Diarrhea

ANTIBIOTIC	ADULT DOSE	DURATION	COMMENTS
Rifaximin (Xifaxan)	200 mg TID	3 days	Not recommend in patients with fever or bloody diarrhea
Rifamycin SV (Aemcolo)	388 mg BID	3 days	Not recommend in patients with fever or bloody diarrhea
Azithromycin (Zithromax) <sup>1</sup>	1000 mg	Single dose (or two divided doses on the same day to reduce nausea)	Preferred empiric option in Southeast Asia, and preferred treatment for dysentery
	500 mg daily	3 days	
Ciprofloxacin (Cipro) <sup>1</sup>	750 mg	Single dose	
	500 mg BID	3 days	
Levofloxacin (Levaquin) <sup>1</sup>	500 mg daily	1 to 3 days	

<sup>1</sup>Not FDA approved for this indication.

When antibiotics are used for self-treatment of traveler's diarrhea, they may reduce the duration of diarrhea by 1 to 3 days. Several effective antibiotic options are available (Table 4). A combination of an antibiotic with loperamide further shortens the duration of diarrhea. However, the benefits of antimicrobial treatment of traveler's diarrhea must be weighed against the potential risks. Each antibiotic option has the potential for specific side effects, such as tendinopathies in the case of fluoroquinolones. Antibiotic use also increases the risk of developing *Clostridioides difficile* diarrhea. Further, multiple studies have shown that antibiotic use for the self-treatment of traveler's diarrhea increases the risk of developing colonization with antibiotic-resistant bacteria, including extended-spectrum B-lactamase-producing *Enterobacteriaceae* and carbapenemase-producing *Enterobacteriaceae*.

Given the potential risks, antimicrobial therapy is not recommended for acute diarrhea that is tolerable and does not interfere with planned activities. Loperamide or BSS can be used alone for these mild cases. Loperamide, with or without an antibiotic, may be used in the case of moderate diarrhea that is distressing or interferes with planned activities. An antibiotic is recommended to treat severe traveler's diarrhea, which includes all dysentery cases, as well as diarrhea that is incapacitating or prevents planned activities. Single-dose antibiotic treatment regimens are as effective as 3-day regimens for most cases of traveler's diarrhea.

Fluoroquinolones, such as ciprofloxacin (Cipro)<sup>1</sup> and levofloxacin (Levaquin),<sup>1</sup> have long been used to treat traveler's diarrhea. However, there has been increasing resistance to fluoroquinolones among diarrheal pathogens, especially *Campylobacter* isolates in South and Southeast Asia. In this area of the world, azithromycin (Zithromax)<sup>1</sup> is preferred for empiric treatment of traveler's diarrhea. Azithromycin is also the preferred treatment for dysentery.<sup>1</sup> Rifaximin (Xifaxan) is approved to treat traveler's diarrhea caused by non-invasive strains of *Escherichia coli*. Rifamycin SV (Aemcolo) is a nonabsorbable antibiotic with an enteric coating, and it has the same mechanism of action as rifaximin. Because rifamycin SV and rifaximin are not recommended for treatment of invasive diarrhea, their role in the self-treatment of diarrhea is limited.

### High-Altitude Illness

High-altitude illnesses (HAIs) caused by hypoxia can occur during travel to high-elevation areas, typically areas with an elevation greater than 8000 feet above sea level. There are three syndromes that may comprise altitude illness: acute mountain sickness (AMS), high-altitude cerebral edema (HACE), and high-altitude pulmonary edema (HAPE).

AMS is the most common form of HAI, and symptoms may include headache, nausea, and fatigue. If left untreated, AMS can progress to HACE, which is a more serious condition. Manifestations of HACE can include ataxia, drowsiness, confusion, and even death. Acute hypoxia may also lead to HAPE. The pathophysiology of HAPE is different from that of AMS/HACE and is presumably caused by pulmonary vasoconstriction that leads to pulmonary edema. Cough, dyspnea on exertion, and pulmonary congestion can progress to death if ascent is continued.

### Prevention of High-Altitude Illnesses

Certain individuals are more susceptible to HAI, but it is not possible to reliably predict who may develop symptoms. Rate of ascent, ultimate elevation, underlying medical conditions, and degree of physical exertion are all potential factors in determining risk of developing HAI. The body's ability to acclimate to a high elevation typically takes 3 to 5 days. A slow ascent that allows time for acclimatization is helpful in preventing the development of all forms of HAI; however, this is not always possible. There are several popular high-altitude tourist destinations that may be reached via direct flights from areas of low elevation. Examples include Cuzco, Peru, located at 11,000 feet; La Paz, Bolivia, at 12,000 feet; and Lhasa, Tibet, at 12,000 feet.

Acetazolamide (Diamox) is a nonantibiotic sulfonamide that was developed as a diuretic to treat hypertension. Its efficacy for this purpose was limited. However, multiple studies have since shown that the preemptive use of acetazolamide can decrease the risk of developing AMS. Acetazolamide is able to block carbonic anhydrase, primarily in the kidney. This decreases reabsorption of bicarbonate and leads to the development of metabolic acidosis, compensating for the respiratory alkalosis associated with high elevations. Acetazolamide is associated with an increased risk of paresthesia and diuresis. The recommended dose of acetazolamide, to prevent AMS while minimizing adverse effects, is 125 mg orally twice a day. It is generally recommended to start 1 day before ascent and continue through the first 2 days at peak elevation.

A number of other medications have been studied to prevent AMS, but the benefits of alternative therapies are less clear. Dexamethasone (Decadron)<sup>1</sup> is one of the more commonly used alternatives. The typical dose for prophylaxis is 2 mg every 6 hours or 4 mg every 12 hours. Inhaled budesonide (Pulmicort)<sup>1</sup> was found to be ineffective in preventing AMS in a recent randomized controlled study and is not recommended.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

## Treatment

Symptomatic travelers should not continue to ascend further until all symptoms resolve, and they should descend to a lower elevation immediately if symptoms progress. Acetazolamide can be considered for treatment of AMS, but it is better at preventing than treating this disorder. Dexamethasone is more reliable for treatment of moderate to severe AMS. However, descent is often needed as well and should occur immediately in cases of HACE or HAPE.

## Summary

A pretravel consultation should include a health assessment, interventions, and counseling to decrease travel-related risks and improve the likelihood of a safe and enjoyable travel experience.

## GENOMIC TESTING

Method of

Gregory A. Plotnikoff, MD, MTS

In 2021, the National Institutes of Health's National Human Genomic Research Institute (HGRI) proclaimed that by the year 2030, "The regular use of genomic information will have transitioned from boutique to mainstream in all clinical settings, making genomic testing as routine as complete blood counts (CBCs)." In many ways, we are on our way to fulfilling this bold prediction. Affordable testing now exists that strengthens our diagnostic capacities and optimizes our therapeutic strategies. Testing that cost \$100 million in 2001 could be performed for less than \$1000 in 2021. As costs continue to plummet, clinically meaningful genomic testing will be increasingly available, both in clinical settings as well as in direct-to-consumer product offerings. Our challenge as clinicians is to keep up to date with the implications for prescribed therapies.

### Genotyping

The new world of clinical genomics refers to the study of the entire genome of an organism. Genotyping is the clinical application of genomics in which molecular assays are used to detect the presence or absence of a specific variant (or variants) in DNA. *Variants* in coding DNA is the key operative term here. Three types of genomic variations exist: (1) single-nucleotide variants (SNVs; 1 base pair, e.g., A to G); (2) indels (small; <50 base pair insertions, e.g., GC to GAAC) and deletions (e.g., ATGC to AC); and (3) structural variants (SVs). Of the latter, two types occur: copy-number variability (CNV) and others (non-CNV). Two subcategories of genotyping apply to current clinical practice: pharmacogenomic testing and widely advertised direct-to-consumer genetic testing.

### Pharmacogenomics

Pharmacogenomics is the study and clinical application of genetic determinants of both drug efficacy (dose response) and drug toxicity including reactions caused by impaired or rapid clearance as well as drug-drug, drug-herb, or drug-nutrient interactions. Pharmacogenomic testing identifies clinically important genetic variations that may affect the safety and efficacy of any prescribed medication. Knowledge of a patient's baseline variation in the metabolism of pharmaceuticals can guide both optimal drug choice and optimal dosing and thus minimize both toxicity and time to effect.

Pharmacogenomic testing results demonstrate that standard doses may not be appropriate for all patients. Clinically meaningful genetic variations can occur in any of the genes involved in absorption, distribution, metabolism, translocation, binding, or clearance (excretion). This leads to a new clinical competency. Prescribers now must understand how genetic variations influence both the pharmacokinetics and pharmacodynamics of drug effects and responses.

Commonly seen examples of pharmacogenomic variability include genetically determined variations in INR response to

warfarin dosing, variations in risk for chemotherapy-associated side effects, and variations in antidepressant drug response by ethnicity. Additional pharmacogenomic concerns include the additive epigenetic induction or inhibition of drug clearance by such commonly prescribed medications such as clarithromycin (Biaxin), diltiazem (Cardizem), erythromycin, fluconazole (Diflucan), or verapamil or by uncommonly prescribed medications such as rifampin (Rifadin) or ritonavir (Norvir).

In 2023, physicians can readily order pharmacogenomic testing for their patients. Testing companies include focused pharmacogenomic laboratories such as OneOme, GenoMind, GeneSight, and TruGenX; large genetic testing companies such as Invitae; and large national testing laboratories such as ARUP, LabCorp, and Quest Diagnostics.

Moreover, physicians and healthcare team members including nurses and pharmacists can readily access evidence-based guidelines that synthesize information relevant to genomic/pharmacogenomic tests and selection of drug therapy (see the resources provided at the end of this chapter).

To navigate effectively requires a fluency in both genetic concepts and nomenclature. To begin, *genotype* refers to the combination of the two alleles (one maternal, one paternal) of a gene at a particular location on a chromosome. The non-variant or usual type of allele is referred to as the *wild-type*. Most variations are in a single nucleotide. If this variant is found in >1% of the population, it is termed a *single-nucleotide polymorphism* (SNP, pronounced "snip"). Variants found in less than 1% of the population are termed *mutations*. One variant allele is termed a *heterozygous variant*. When both alleles are variants, the patient is deemed to have a homozygous variant.

Variations and mutations are described by either the "rs" identifying number (for the reference SNP) or by the "star" nomenclature for one or both alleles. To illustrate the importance of nomenclature, for the cytochrome P450 (CYP450) enzyme termed *CYP2C19*, approximately 25 genetic variants in the exonic region of the *CYP2C19* gene have been identified. Of these 25 variations, a change in guanine (G) to adenine (A) at position 681 in exon 5 will result in an aberrant splice site that alters the metabolism of several medications including the antiplatelet medication clopidogrel (Plavix). For precise communication, this variation can be described by its rs identifying number (rs4244285) or by its star nomenclature (*CYP2C19\*2*). In pharmacogenomic reporting for *CYP450* genes, the star nomenclature is most often used. However, the genomic nomenclature is not always easy because nucleotide position and nucleotide change are often used to report other pharmaceutical metabolizing genes. Examples of the nomenclature complexity include the ATP-binding cassette, subfamily B, member 1 variation termed *ABCB1 3435C>T*. This is also known as *multidrug resistance gene 1 (MDR1)* and encodes for P-glycoprotein (P-gp). Likewise, catechol O-methyltransferase (COMT) rs4680 is also reported as COMT Val158Met. To further the nomenclature challenge, haplotypes refer to a simultaneously linked set of SNPs in an individual. For example, for the thiopurine S-methyltransferase gene, *TPMT\*3A* refers to a haplotype composed of two non-synonymous SNPs (rs1800460 and rs1142345).

Within the human genome, several million SNPs have been identified. Of these, most are termed *synonymous* and do not alter the protein products of the gene expression and have no measurable

**TABLE 1** Polymorphisms That Adversely Affect Drug Metabolism

POLYMORPHISM	STAR NAME	ACTIVITY CHANGE	EXAMPLE MEDICATIONS AFFECTED
Premature stop codon	<i>CYP2C19</i> *2, <i>CYP2C19</i> *3	Blocked enzyme activity	Clopidogrel (Plavix), omeprazole (Prilosec)
Variable number tandem repeats	<i>TMPT</i> *2, <i>TMPT</i> *3	Enhanced active metabolite production	Mercaptopurine (Purinethol)
Gene deletion	<i>CYP2D6</i> *5	Gene absence	Antidepressants, beta blockers, antihistamines, numerous prodrugs, others
Copy number variants	<i>CYP2D6</i> *2 <i>XN</i>	Gene amplification and ultra-rapid function	Antidepressants, beta blockers, antihistamines, numerous prodrugs, others

effects. The consequences of other sequence variants can result in altered structure and function of the encoded proteins or altered level of gene expression. Inheritance of these alleles means that standard doses of a drug therapy can lead to an adverse drug reaction or chemotherapy failure. Several types of polymorphisms can adversely affect drug metabolism. These are illustrated in Table 1. Patients with reduced function of *CYP2C19* metabolism who are prescribed clopidogrel have significantly lower levels of its active metabolite and therefore diminished platelet inhibition. Clinically, this translates to a higher rate of major adverse cardiovascular events including stent thrombosis after stent placement for coronary artery disease. Patients with *TMPT* impairment who are prescribed mercaptopurine will have reduced nonactive metabolite production, which in turn results in enhanced active metabolite production and a significantly increased risk of toxicity, including leukopenia. Surprisingly, *CYP2D6* variations can result in a 200-fold effect on drug metabolism (from poor to ultra-rapid metabolism). The amplified activity with copy number variants such as in *CYP2D6*\*2*XN* results in faster clearance. The *N* refers to the number of copies of the gene on a single chromosome. For *CYP2D6*\*2, this can range from 2 to 13.

Reported pharmacogenomic *CYP450* data are often presented as one of four phenotypic categories: (1) *ultra-rapid*, (2) *extensive* (normal), (3) *intermediate*, and (4) *poor*. A tragic example of ultra-rapid *CYP2D6* metabolism of the prodrug codeine into its active metabolite morphine has been seen in children who received codeine following a routine tonsillectomy. The rapid transformation of codeine to morphine results in rapid systemic delivery of a morphine bolus. As a result, children have died from the sudden onset of opioid-induced central respiratory depression, increased sedation, and decreased supraglottic airway tone. Tragic examples of poor *CYP2D6* metabolism of the prodrug hydrocodone into its active metabolite hydromorphone has been seen in patients with insufficient analgesia being labeled as drug-seekers. This risk of insufficient analgesia despite “normal” dosing would be worsened with concomitant administration of *CYP2D6*-inhibiting medications such as bupropion (Wellbutrin), fluoxetine (Prozac), paroxetine (Paxil), quinidine, or terbinafine (Lamisil).

The latter point emphasizes why prescribers must also understand the numerous medications and natural products that can modify existing pharmacogenomic function via either induction or inhibition of *CYP450* drug-metabolizing enzymes or drug transporters such as P-glycoprotein, BCRP (breast cancer resistance protein), OAT family proteins (solute carrier organic anion transporters), MATE1 and MATE2 (multidrug and toxin extrusion proteins 1 and 2), and OCT1 and OCT2 (organic cation transporters 1 and 2). Helpful information can be found on the U.S. Food and Drug Administration (FDA) website (<https://www.fda.gov/drugs/drug-interactions-labeling/drug-development-and-drug-interactions-table-substrates-inhibitors-and-inducers#table5-2>).

Despite existing knowledge, the presence of clinically significant adverse drug-drug interactions may be high in cardiology, oncology, and psychiatry. Likewise, natural product–drug interactions also exist. For example, medicinal cannabis (THC) and cannabidiol (CBD)<sup>7</sup> appear to inhibit multiple *CYP450* enzymes including *CYP2D6*. Saint John’s wort (*Hypericum perforatum*)<sup>7</sup> induces *CYP3A4* activity, the liver enzyme responsible for metabolizing the vast majority of currently available prescription medications. Berberine, an active ingredient in several herbal medicines such as goldenseal (*Hydrastis canadensis*)<sup>7</sup> and also sold as an isolated, purified, and concentrated ingredient, can inhibit *CYP2D6* and *CYP3A4* as well as increase P-glycoprotein function.

Future clinical practice will undoubtedly bring pharmacogenomic data to the point of care either via the electronic medical record and/or further incorporation of specially trained pharmacists. The future will likely see calls for each person, perhaps starting at birth, to be tested for clinical variations that are relevant to optimal prescribing and dosing. To support enhanced clinician competency in pharmacogenomics, several excellent resources are noted later in this chapter.

### Direct-To-Consumer Genotyping

At this time, the primary genotyping service used in clinics is for pharmacogenomic data to guide therapy. However, since at least 2006, the lay public has seen advertising for home genetic testing for genealogical purposes. Indirectly, direct-to-consumer genomic testing such as [23andme.com](http://23andme.com) and [ancestry.com](http://ancestry.com) introduced to the public microarray genotyping and single-nucleotide variants. Soon afterward, clinicians and others recognized the potential value of the information found in the common (>1% of the population) SNPs that is found in the unreported raw data in the genomic testing. Consumer-empowering websites that could upload 23andme.com raw data and then sort, organize, and prioritize SNPs for interpretative health reasons quickly appeared (e.g., MTHFRsupport.com, livewello.com, geneticgenie.com). Consumers suddenly had access to their genetic information outside of a physician’s office, and patients had the capacity to ask very sophisticated health questions that could overwhelm unprepared physicians.

The greatest value in 23andme.com and related consumer-directed SNP analysis services may be in generating hypotheses relevant to guiding therapeutic recommendations. Clinically relevant categories that can be addressed include the following:

- Vitamin activation (e.g., Beta-Carotene Oxygenase 1 [BCO1] for vitamin A, Vitamin K Epoxide Reductase Complex Subunit 1 [VKORC1] for vitamin K)
- Neurotransmitter production impairment (e.g., L-DOPA decarboxylase [DDC] for dopamine and serotonin; glutamate decarboxylase 1 [GAD1] for gamma aminobutyric acid [GABA])

<sup>7</sup> Available as dietary supplement.

- Metabolic pathway analyses (e.g., genes for methylation, trans-sulfonation, and nicotinamide adenine dinucleotide [NAD<sup>+</sup>] production)
- Detoxification capacity (e.g., paraoxonase 1 [PON1], glucuronidation capacity, glutathione-production genes)
- Apolipoprotein E (APOE) status (genetic risk of Alzheimer disease)

The predictive value and clinical utility of such genotyping services has yet to be validated. However, the future will see tremendous growth in nutrigenomics (the study of the bidirectional interaction of nutrition and genes), intestinal microbiomics, and the combination of the two perspectives. In 2022, the National Institutes of Health announced \$170 million in funding for 11 significant new initiatives to provide insight into personalized nutrition. The NIH has acknowledged how poorly understood the intestinal microbiome, metabolism, nutritional status, genetics, and the environment interact to affect health. For healthcare professionals, this initiative promises to catalyze significant scientific advances to generate an evidence base beyond “one-size-fits-all” diets toward precision in dietary guidance for optimal health.

### Cell-Free DNA

*Cell-free DNA* (cfDNA) refers to non-encapsulated DNA fragments released into the blood or other body fluids as a result of secretion, apoptosis, and/or necrosis. Technology now allows separation of circulating fetal DNA, mitochondrial DNA, tumor DNA, and microbial DNA. This breakthrough has resulted in profound changes in diagnostic capacities in both obstetrics with non-invasive prenatal testing (NIPT) and primary care with multi-cancer early detection (MCEd). This breakthrough has also led to identification of cell-free mitochondrial DNA (cf-mtDNA) as a marker of trauma, inflammation, acute psychological distress, as well as physiologic distress. Elevated levels are clearly linked to an increase in hospital mortality. Elevated levels also appear to be linked to cognitive and neurodegenerative disorders. Unlike NIPT and MCEd, however, meaningful translation to clinical therapies has yet to be defined.

For oncologic therapy guidance, the capacity to separate tumor DNA from germline DNA from a simple blood draw (referred to as a *liquid biopsy*) means that surgery is no longer required to obtain tumor tissue for tumor mutation profiling with any solid advanced-stage malignant neoplasm. Such testing can reliably and rapidly determine clinically pertinent DNA point mutations, indels, amplifications, and fusions. Identification of tumor genomic status (e.g., *EGFR*, *ALK*, *BRAF*) can guide optimal selection of targeted chemotherapy for non-small cell lung cancer or colon cancer. At this time, Medicare covers this testing for all solid advanced-stage tumors. In the future, the simultaneous mapping of multiple biomarkers of genomic alterations will drive a deeper understanding of multitargeted therapies and resistance mechanisms. Additionally, I believe these data will lead us to a better understanding of the optimal use of off-label pharmaceuticals and specific dietary interventions as adjunctive therapies for patients with cancer.

In infectious disease, another form of liquid biopsy is available for microbial cell-free DNA sequencing on plasma. This has revolutionized the non-invasive and rapid identification of more than 1000 pathogens including bacteria, fungi, DNA viruses, and protozoans. In this process, cell-free DNA fragments are extracted from the specimen, converted to shotgun DNA sequencing libraries, and then sequenced. The concentration of cell-free DNA molecules from any potential pathogen is then calculated.

An April 2022 report in the Case Records of the Massachusetts General Hospital demonstrated the great value of this testing for targeted and precise treatment of an unknown pathogen. The authors described the clinical challenges of diagnosing a 56-year-old male patient with myalgias, fever, bradycardia, and inflammatory changes in the epicardial fat abutting the non-coronary sinus of the aortic valve. In this case, testing detected *Listeria monocytogenes* at a concentration of 42

cell-free DNA molecules per microliter (reference value <10). This finding confirmed the diagnosis of listeriosis. The authors noted that these results were associated with a 95% sensitivity (at 41 molecules per microliter) and a 98% to 99.99% specificity for the diagnosis of listeriosis.

Such testing means that culture-based methods for microbial identification are likely to be replaced by cfDNA-based methods. The advantages are clear in terms of identifying difficult-to-culture pathogens, the time to results, and the non-invasive sampling. The advantage over rapid multiplex polymerase chain reaction (PCR) tests is that a presumptive diagnosis of a single pathogen is not needed. The bottom-line implication of microbial cfDNA testing is that presumptive or empiric antipathogen therapies will be less necessary for acute illness. Likewise, such testing, similar to interferon-gamma release assays, may clarify the length of treatment required for clearance. And to speculate boldly, microbial cfDNA testing may help define the presence of an unexpected chronic infectious disease driving perplexing chronic illness.

### Whole-Exome Sequencing/Genome Sequencing

As a result of the profound reduction in cost and the marked increase in the capacity to manage huge databases, advanced sequencing is now readily available for diagnostic purposes in clinical settings. Whether termed *whole-exome sequencing* (WES) or *whole-genome sequencing* (WGS), next-generation sequencing (NGS) represents numerous advancements over the previously available Sanger sequencing. NGS not only detects the aforementioned DNA changes of interest (e.g., single-nucleotide changes, indels, copy number variants) but also detects RNA alterations such as transcriptional abundance and fusion transcripts. The greatest challenge to widespread implementation after cost include management of the massive amount of data generated and the intensive process of annotation, which involves marking specific features in a DNA, RNA, or protein sequence with descriptive information about structure or function. Specific challenges include lengthy turnaround time as well as the interpretation of both incidental findings unrelated to the initial reason for which the sequencing tests were ordered and variants in a gene of phenotypic significance but of unknown clinical significance (variants of unknown significance [VUS]).

In the clinic, such advanced testing is primarily used for diagnostic purposes. This includes nonfocused or whole-genome sequencing for rare illnesses as well as focused testing for phenotypic patterns such as hypermobility or genetic risk for cancer. Of great interest is the potential presence or absence of incidentally found “actionable” gene mutations relevant to the avoidance of significant morbidity or mortality. In 2013, the American College of Medical Genetics and Genomics (ACMG) released a recommendation suggesting that known pathogenic or expected pathogenic constitutional variants detected in 56 genes, representing 24 conditions with well-known guidelines for prevention or treatment, should be reported to patients sequenced in a clinical setting. In 2017, four genes were added, and in 2021 an additional nine such genes were added. Examples include mutations in the *RYR1* gene, which are causally linked to malignant hyperthermia with administration of halothane gas anesthesia or succinylcholine, and the *BRCA1*, *BRCA2*, and *PALB2* genes, which are demonstrably connected with breast and ovarian cancers.

Most important for future therapies will likely be the creation of genome-wide polygenic risk scores for an individual’s susceptibility to disease. The focus on single-gene causality appears to have blinded us to the networked or polygenic nature of most noncommunicable diseases including cancer and heart disease. Single variants are too often insufficient for assessing disease risk. Even traits thought to be the result of single genes, such as eye color, are actually highly polygenic. And for a trait such as height, approximately 80% of an individual’s height requires contribution of more than 700

genomic variants. To move beyond single-variable science with a polygenic risk score requires the merger of classic genomic sequencing for monogenic variants with artificial intelligence programming. The goal is to enable early recognition and treatment of high-risk individuals before the onset of disease. An additional benefit may be to uncover new causal disease pathways. The future will bring us a deeper understanding of the clinical utility of such scores.

## Conclusion

In the future, genomic testing will be as common as ordering a CBC. Advances in genotyping, cfDNA testing, and whole-genome sequencing will clearly transform multiple dimensions of patient care in every subspecialty. With such changes will also come new insights into the multiple forms of noncoding RNA as well as the role of imprinting and transgenerational epigenetic changes. Whereas current genomic testing may only describe what cards one has been dealt, the secondary “-omics” revolution (e.g., in transcriptomics, metabolomics, and proteomics) will allow us to know not only what cards one has been dealt but also how they are being played. This will undoubtedly completely transform the practice of medicine.

## Genomic Resources

### General

#### ClinGen

<http://clinicalgenome.org>

An NIH-funded resource that defines the clinical relevance of genes and variants for use in medicine and research.

#### ClinVar

<http://www.ncbi.nlm.nih.gov/clinvar/>

A public archive of reports about the relationship between specific genetic variants and associated phenotypes (symptoms).

#### dbSNP

<https://www.ncbi.nlm.nih.gov/snp/>

A database for human single-nucleotide variations, microsatellites, and small-scale insertions and deletions along with publication, population frequency, molecular consequences, and genomic and RefSeq mapping information for both common variations and clinical mutations.

### GeneReviews

<http://www.ncbi.nlm.nih.gov/books/NBK1116/>

A collection of chapters written by experts in the field for healthcare providers, with each chapter focused on an individual genetic condition or disease.

### OMIM

<https://www.omim.org/> or <https://www.ncbi.nlm.nih.gov/omim>

Information on genes and diseases. The entries on genes are particularly useful.

### PharmGKB (PharmacogenomicsKnowledgeBase)

<http://www.pharmgkb.org/>

A database of pharmacogenomic research findings. This includes free access to the peer-reviewed Clinical Pharmacogenetics Implementation Consortium (CPIC) Guidelines (<https://cpicpgx.org/guidelines/>) for prescribing decisions from genetic laboratory results with supplemental information and updates.

### Pharmacogenomic Testing

Laboratories that offer pharmacogenomic testing include OneOme, GenoMind, GeneSight, TruGenX, and Invitae. Large laboratories that also offer genetic testing include ARUP, LabCorp, and Quest Diagnostics.

## Education

### Genetics/Genomics Competency Center

<https://www.genome.gov/G2C2/resources>

Categorized educational resources in genetics/genomics and pharmacogenomics for healthcare educators and clinicians

### National Human Genome Research Institute

<https://www.genome.gov/For-Health-Professionals/Provider-Genomics-Education-Resources>

Information for healthcare professionals and patients on genetics, pharmacogenomics, direct-to-consumer testing, and more including terminology, videos, and illustrations.

### PharmGenEd

<http://pharmacogenomics.ucsd.edu/>

Free educational materials (including recorded lectures and handouts) focused on clinical applications of pharmacogenomics for healthcare students and practitioners.

## Medical-Legal

### GeneReviews: Resources for Genetics Professionals—Direct-to-Consumer Genetic Testing

## MONOCLONAL ANTIBODIES

Method of

Michael Dougan, MD, PhD; and Crystal M. North, MD, MPH

### CURRENT DIAGNOSIS

- Monoclonal antibodies are unique, specific, and homogeneous antibodies manufactured by immortalizing and copying an antibody-secreting B cell of interest.
- Monoclonal antibodies have a wide variety of applications in diagnostic medicine including identification of pathogens, tissue typing, cancer diagnosis, enzyme-linked immunosorbent assay, radioimmunoassay, and other laboratory testing methods.

### CURRENT THERAPY

- Monoclonal antibodies have tremendous applications in the field of therapeutic medicine for treatment of numerous diseases affecting every organ system in the body.
- Monoclonal antibodies can be used alone or to carry drugs, cytotoxic agents, or radioactive substances to targeted cells.
- Monoclonal antibodies are useful as drug-reversal agents (e.g., digoxin and dabigatran).
- Monoclonal antibodies are far superior to polyclonal antibodies because of their highly specific and reproducible affinity for target antigens as well as their controlled manufacturing processes.
- The “humanization” of monoclonal antibodies significantly reduces drug side effects.
- Monoclonal antibodies are delivered via injection or infusion.
- Because of the proliferation of monoclonal therapeutic agents, full prescribing information should be reviewed before administration.

### Introduction

Antibodies are key components of the adaptive immune system and are produced by B cells. Antibodies provide protection from infections in two broad ways. They bind tightly to their targets, sometimes inhibiting or neutralizing target activity, and they activate other components of the immune system that can recognize antibody-bound structures.

In the setting of a typical infection, the natural immune response develops dozens of antibodies that recognize the invading microbe. These antibodies typically bind at multiple sites and with varying levels of affinity. As an immune response evolves over the course of weeks or on subsequent exposure to the same infection, these antibodies are further refined, typically targeting a distinct region of the infectious organism with increasingly higher-affinity antibodies. This response, termed a *polyclonal response*, is also what happens in the setting of a vaccine.

Each antibody is genetically encoded at the DNA level and produced by a distinct B cell (termed a *clonotype*). These B cells can proliferate and produce multiple progeny cells that manufacture the antibody that we detect in the blood. B cells can also differentiate into plasma cells, which reside in the bone marrow and are responsible for the production of the most high-affinity antibodies.

By isolating specific B cells and determining the affinity and binding specificity of the antibodies they make, genomic technologies can be used to produce unique antibodies that have medically useful binding properties. These are termed *monoclonal antibodies*. After the DNA encoding them is sequenced and cloned into an expression vector that introduces the specific gene

into a target cell that directs the cell's ability to synthesize proteins, large quantities of antibodies can be produced at pharmaceutical grade. These antibodies can be used for the diagnosis and treatment of disease.

### Properties of Antibodies as Drugs

Antibodies have several features that make them excellent drugs. The first is that they naturally evolve to bind to their targets with exquisite specificity and high affinity, generally exceeding that of typical receptor-ligand interactions. In theory, antibodies can bind to any structure, including carbohydrates, proteins, DNA, and small-molecule drugs that are covalently bound to proteins. This means that they can be used to selectively bind to any target of interest including human proteins, drugs and other small molecules, or infectious organisms. Their high affinity means that they are unlikely to dissociate from their target after binding. Antibodies have two binding arms, increasing their avidity for targets with recurrent structural motifs or with multiple copies of the binding target.

### Monoclonal Antibody Structure

Classic antibodies are composed of four polypeptides, two heavy chains, and two light chains that are bound to the N-terminal region of the heavy chains (Figure 1A). The complex of two heavy chains and two light chains produces two broad structural domains: the target (antigen)-binding regions that are fixed at the ends of the antibody arms and the antibody stalk, which attaches to each binding arm through a flexible linker (see Figure 1A). The antibody arms are referred to as *Fab domains* and are made up of a variable region that binds the target and a constant region that connects to the stalk. The heavy chain and the light chain both contribute to the Fab domains. The amino acid sequence in each arm of a naturally occurring antibody is identical to the sequence in the other arm, but the sequence within the variable region differs from all other antibody clones. The unique sequences in these antibody arms confer the binding properties of the antibody. Antibodies can be bioengineered to have nonidentical arms, generating synthetic bispecific antibodies, an area of increasing therapeutic interest.

The antibody stalk is referred to as the *Fc domain* and is responsible for most antibody effector functions through interactions with Fc receptors. The effector functions conferred by the Fc domain include activation of complement, facilitated phagocytosis (opsonization), activation of NK cells, secretion across mucosal barriers (IgA in particular), and activation of mast cells and eosinophils (IgE in particular). The Fc domain is part of the constant region of the antibody, but it comes in multiple classes that define the distinct “isotypes” of antibodies: IgM, IgG1 to IgG4, IgA, and IgE. For IgG, the Fc domain also dramatically extends the half-life of antibodies through interactions with the serum protein FcRn. This half-life extension can be modified through point mutations, allowing for infrequent dosing of antibody drugs.

The size of monoclonal antibodies prevents efficient absorption across mucosal barriers or the skin. Consequently, all monoclonal antibodies are administered either as injections or as infusions.

Antibodies are produced as part of a normal immune response in all vertebrates, and much of their sequence is highly conserved. Although some important differences exist between human antibody genes and the coding sequence of other animals, modification of antibody sequences to generate “humanized” antibodies is now routinely used to generate drugs from antibodies that were initially identified in other animals. These humanized antibodies have been generated in model organisms such as mice and in culture systems using viruses and bacteria such as *Escherichia coli*. More recent pharmaceutical-grade antibodies have been identified directly in patients. These newer techniques have replaced older techniques for generating antibodies such as the construction of animal-human chimeric antibodies (see Figure 1B), where significant sections of animal sequence remained in the therapeutic antibody, increasing the risk of hypersensitivity reactions during infusion or loss of function caused by antidrug antibodies.

**Figure 1** Structure of classic antibodies.

Antibodies are recycled from the serum through protein turnover in a process that is independent of hepatic and renal clearance mechanisms. Consequently, antibodies rarely interact with other drugs.

Interestingly, a subset of antibodies produced by camelids (e.g., alpacas, llamas, and camels) are formed without a light chain. These heavy-chain-only antibodies still retain the same variable antigen-binding domains and constant regions found in conventional antibodies, and they demonstrate approximately the same binding affinities for their targets.

### Therapeutic Uses of Monoclonal Antibodies

Monoclonal antibodies have been used for a wide variety of therapeutic purposes. Most antibodies in clinical use neutralize the activity of their target, which is often a protein. This has been especially successful when targeting circulating self-proteins that have been dysregulated as part of a disease process. Most of these neutralizing monoclonal antibodies belong to the IgG4 isotype. This isotype retains the ability to bind to FcRn, but lacks engagement with other Fc receptors, reducing the risk of unintended side effects as discussed in more detail later in this chapter.

Cytokines and their receptors are the targets of many monoclonal antibodies that are used for the treatment of autoimmune and allergic diseases. These targets are particularly amenable to monoclonal antibody targeting because they are secreted and are often present in the interstitial fluid and in circulation, making them accessible to infused antibodies. Multiple other immune receptors have been successfully targeted by monoclonal antibodies, resulting in inhibition of receptor-ligand interactions and blockade of essential functions such as cell trafficking (e.g., to treat autoimmunity) or immune regulation (e.g., to treat cancer).

Monoclonal antibodies are also used to inhibit several serum proteins including components of the complement cascade, receptors involved in platelet activation, and more recently a key regulator of the low-density lipoprotein (LDL) receptor. Similar to cytokines, these factors are ideally suited to monoclonal antibody neutralization because of the accessibility of the target in circulation.

Multiple monoclonal antibodies have been developed that enhance phagocytosis of target-expressing cells and activation of

cell-mediated immunity and/or complement. These monoclonal antibodies are often IgG1 antibodies and are often used in cancer treatments, binding directly to the malignant cells. Antitumor antibodies are now incorporated into standard treatment regimens for a wide variety of hematologic and solid tumors, resulting in substantial improvements in outcomes. Similar depletion strategies can be used to treat a variety of autoimmune diseases by depleting the immune cells responsible for the disease.

Although the majority of monoclonal antibody therapies target self proteins, an important class of therapeutics has been developed against infectious targets. These antibodies can be highly specific for their targets with minimal or no effects in uninfected people. Antibodies have been developed against viral and bacterial infections, target cell surface proteins, and secreted toxins. Monoclonal antibodies have had some important successes in viral therapy, as discussed later, but they are generally used less frequently than small-molecule antimicrobial drugs.

### Monoclonal Antibody Side Effects

Most side effects associated with monoclonal antibodies relate directly to their mechanism of action. Inhibition of self proteins can lead to deficiencies in function that may overcorrect the disease process; this is most evident with antibodies that inhibit the immune system to treat autoimmunity. The infection-related side effects are common, though often less severe than with broader forms of immune suppression such as systemic glucocorticoids. Antibodies can also improve a disease in one organ system while damaging another. Antibodies that deplete target cells can lead to side effects related to the loss of those cells or to damage to the tissues that express the target. This can occur with some of the antitumor antibodies in which the targets are often expressed on healthy cells in addition to malignant ones.

Because of their specificity and target affinity, off-target side effects of monoclonal antibodies are rare. This is a considerable advantage when comparing monoclonal antibodies to other classes of drugs, such as small-molecule inhibitors. Side effects related to hepatic metabolism or renal clearance are also unlikely with monoclonal antibodies because they are not

eliminated through these organs, leading to a relatively good safety profile in patients with multiple comorbid conditions.

Infusion reactions and the formation of antidrug antibodies are significant limitations to all monoclonal antibody treatments. The risk of these reactions is related to the fraction of nonhuman sequence present in the antibody structure. The highest-risk monoclonal antibodies currently in use are the few drugs that are chimeric mouse-human antibodies with human constant regions and mouse variable regions. As a result, few chimeric antibodies are still being developed. Most next-generation antibodies are either humanized, with the animal sequence mutated to resemble the human sequence, or human, the result of antibody identification techniques that start from the human antibody genes either inserted into the mouse genome or produced through *in vitro* techniques. Monoclonal antibodies have been identified directly in patients, and these antibodies have substantial clinical safety value.

### Monoclonal Antibody Nomenclature

The naming of monoclonal antibodies is determined by the World Health Organization International Nonproprietary Names (INN) program, which was established in 1991. Each name consists of a prefix, a target substem (also called an *infix*), a source substem (if named before 2018), and a stem (Figure 2). The prefix does not carry any specific meaning. It is a combination of letters that, when combined with the stem and substems, results in an easily pronounced name. The target substem, also called the infix, indicates the target of the monoclonal antibody. It is composed of a consonant, a vowel, and a final consonant that is sometimes dropped if the name of the monoclonal antibody would otherwise not be easily pronounced. Examples include *-ci-* for agents that target the cardiovascular system and *-vi-* for agents that target viral products. The source substem indicates the animal from which the antibody was derived but was removed from the nomenclature starting in 2017. Examples include *-u-* for human-derived antibodies, *-o-* for mouse-derived antibodies, and *-xi-* for chimeric antibodies composed of both human and nonhuman components. The stem for all monoclonal antibodies named before 2021 is *-mab*. Starting in late 2021, monoclonal antibodies are given one of four stems: *-tug* (unmodified immunoglobulins) *-bart* (antibody artificial), *-mig* (multi-immunoglobulin), or *-ment* (fragment).

### Examples of Monoclonal Antibodies Used in Clinical Practice

Monoclonal antibodies have been developed for an ever-expanding number of clinical conditions. Included in the following sections are representative examples of monoclonal antibodies used in a variety of disease processes. This list is not meant to be exhaustive; the pace of monoclonal antibody production would make a comprehensive list outdated by the time of publication. We have grouped these examples by body system or shared mechanism, but many monoclonal antibodies are used for several clinical indications. Not all of the clinical uses described are approved by the U.S. Food and Drug Administration (FDA), but they represent common clinical practice. Side effects that are common to most monoclonal antibodies

are highlighted in the previous section, and additional side effects that are of special interest for a given monoclonal antibody are highlighted here. The list of side effects is also meant to be illustrative rather than comprehensive, and full prescribing information should be reviewed before administration of these drugs clinically.

### Oncology

#### Rituximab (Rituxan)

Target: The CD20 antigen on the surface of B cells, leading to depletion of these cells

Similar monoclonal antibodies: Ocrelizumab (Ocrevus), ofatumumab (Arzerra, Kesimpta), obinutuzumab (Gazyva)

Adverse effects of interest: Infusion reactions are quite common, particularly during the first infusion; new and reactivated infections caused by immunosuppression

Initial clinical indication: Relapsed or refractory low-grade or follicular, B-cell non-Hodgkin lymphoma. Rituximab was one of the first monoclonal antibodies developed clinically and the first monoclonal antibody used in oncology.

Other clinical indications: Various lymphomas (non-Hodgkin lymphoma, diffuse large B-cell lymphoma, follicular lymphoma), chronic lymphocytic leukemia, various autoimmune conditions (e.g., rheumatoid arthritis, systemic lupus erythematosus,<sup>1</sup> granulomatosis with polyangiitis)

#### Bevacizumab (Avastin)

Target: Vascular endothelial growth factor (VEGF), impairing microvascular growth

Similar monoclonal antibodies: Ranibizumab

Adverse effects of interest: Hemorrhage, gastrointestinal perforation (rarely)

Initial clinical indication: First-line treatment, in combination with 5-fluorouracil, of metastatic colon and rectal carcinoma

Other clinical indications: Macular degeneration,<sup>1</sup> diabetic retinopathy<sup>1</sup>

#### Cetuximab (Erbix)

Target: Epidermal growth factor receptor (EGFR), impairing cell growth and proliferation, depletion of target-expressing cells

Similar monoclonal antibodies: Panitumumab (Vectibix)

Adverse effects of interest: IgE-mediated allergic reactions, dermatologic reactions

Initial clinical indication: EGFR-expressing metastatic colorectal carcinoma

Other clinical indications: *BRAF* V600E+ metastatic colorectal carcinoma, squamous cell carcinoma of the head and neck

#### Ipilimumab (Yervoy)

Target: Cytotoxic T lymphocyte antigen (CTLA)-4, an immune checkpoint receptor

Similar monoclonal antibodies: Ipilimumab is considered a “checkpoint inhibitor” along with drugs targeting PD-1 and PD-L1

Adverse effects of interest: Multiple inflammatory toxicities referred to as *immune-related adverse events* (irAEs); these resemble autoimmune diseases and most commonly affect the skin, gastrointestinal tract, and endocrine organs

Initial clinical indication: Metastatic or unresectable melanoma

Other clinical indications: Malignant mesothelioma, hepatocellular carcinoma, metastatic colorectal carcinoma, metastatic non-small cell lung cancer, renal cell carcinoma

#### Nivolumab (Opdivo)

Target: Programmed cell death-1 (PD-1) receptor, blocking the ligands PD-L1 and PD-L2 from binding with the receptor, enhancing T-cell-mediated antitumor responses

Similar monoclonal antibodies: Pembrolizumab (Keytruda), cemiplimab (Libtayo), atezolizumab (PD-L1, Tecentriq), durvalumab (PD-L1, Imfinzi), avelumab (PD-L1, Bavencio)

**Figure 2** An example of the nomenclature used to name a monoclonal antibody.

<sup>1</sup>Not FDA approved for this indication.

Adverse effects of interest: Multiple inflammatory toxicities (irAEs); these resemble autoimmune diseases as most commonly affect the skin, gastrointestinal tract, and endocrine organs

Initial clinical indication: Metastatic or unresectable melanoma

Other clinical indications: Metastatic mismatch repair deficient/microsatellite instability high (MMRd/MSI-H) colorectal carcinoma, Merkel cell carcinoma, metastatic gastric or gastroesophageal junction carcinoma, squamous cell head and neck cancer, hepatocellular carcinoma, Hodgkin lymphoma, malignant mesothelioma, non-small cell lung cancer, renal cell carcinoma, urothelial cell carcinoma

#### ***Trastuzumab (Herceptin)***

Target: Human epidermal growth factor receptor 2 (HER2; a member of the EGFR receptor family), depleting target-expressing cells, inhibiting cell growth and proliferation

Similar monoclonal antibodies: Margetuximab (Margaenza), pertuzumab (Perjeta)

Adverse effects of interest: Cardiac toxicity, teratogenic

Initial clinical indication: Metastatic HER2-expressing breast cancer

Other clinical indications: Metastatic HER2-expressing gastric or gastroesophageal junction adenocarcinoma

### **Rheumatologic/Autoimmune Diseases**

#### ***Infliximab (Remicade)***

Target: Tumor necrosis factor alpha (TNF $\alpha$ )

Similar monoclonal antibodies: Adalimumab (Humira), certolizumab (Cimzia), golimumab (Simponi)

Adverse effects of interest: Immunodeficiency, reactivation of mycobacterium tuberculosis, reactivation of hepatitis B virus

Initial clinical indication: Treatment of moderate to severe Crohn's disease

Other clinical indications: Ulcerative colitis, rheumatoid arthritis, psoriasis (plaque, arthritis, pustular<sup>1</sup>), ankylosing spondylitis, pyoderma gangrenosum<sup>1</sup>

#### ***Tocilizumab (Actemra)***

Target: Membrane-bound and soluble interleukin 6 receptor (IL-6R), preventing IL-6 cytokine activity

Similar monoclonal antibodies: Sarilumab (Kevzara), satralizumab (Enspryng)

Adverse effects of interest: Immunodeficiency, reactivation of mycobacterium tuberculosis

Initial clinical indication: Moderate to severe rheumatoid arthritis

Other clinical indications: Cytokine release syndrome, rheumatoid arthritis, hospitalized patients with COVID-19,<sup>1</sup> giant cell arteritis, systemic sclerosis-associated interstitial lung disease, juvenile idiopathic arthritis

#### ***Belimumab (Benlysta)***

Target: Soluble human B-lymphocyte stimulator (BLyS) protein, also known as *BAFF*

Similar monoclonal antibodies: None

Adverse effects of interest: Impaired humoral immunity

Initial clinical indication: Systemic lupus erythematosus

Other clinical indications: None

#### ***Basiliximab (Simulect)***

Target: Alpha chain of interleukin 2 receptor on activated T lymphocytes

Similar monoclonal antibodies: None

Adverse effects of interest: Severe immunodeficiency

Initial clinical indication: Prophylaxis of acute renal transplant rejection

Other clinical indications: Graft-versus-host disease,<sup>1</sup> prophylaxis of acute transplant rejection in heart, liver, and lung transplantation<sup>1</sup>

### **Gastrointestinal Diseases**

#### ***Ustekinumab (Stelara)***

Target: The shared p40 component of interleukin 12 and interleukin 23, preventing binding to their target receptors and reducing differentiation of TH1 and TH17 cells, potential reduced activation of NK cells

Similar monoclonal antibodies: None

Adverse effects of interest: Immunodeficiency

Initial clinical indication: Plaque psoriasis

Other clinical indications: Psoriatic arthritis, Crohn's disease, ulcerative colitis

#### ***Vedolizumab (Entyvio)***

Target:  $\alpha 4\beta 7$  integrin, blocking binding with MAdCAM-1, inhibiting lymphocyte migration into the gut

Similar monoclonal antibodies: None

Adverse effects of interest: Minimal

Initial clinical indication: Ulcerative colitis

Other clinical indications: Crohn's disease

### **Hematology**

#### ***Emicizumab (Hemlibra)***

Target: Binds and bridges activated factor IXa and factor X, acting in place of factor VIII to initiate hemostasis

Similar monoclonal antibodies: None

Adverse effects of interest: Minimal

Initial clinical indication: Hemophilia A

Other clinical indications: None

#### ***Caplacizumab (Cabliivi)***

Target: A1 domain of von Willebrand factor, preventing binding to platelet glycoprotein Ib-X-V and reducing platelet adhesion and consumption; single-domain antibody

Similar monoclonal antibodies: None

Adverse effects of interest: Bleeding

Initial clinical indication: Acquired thrombotic thrombocytopenic purpura

Other clinical indications: None

### **Cardiovascular Disease**

#### ***Alirocumab (Praluent)***

Target: Binds to proprotein convertase subtilisin/kexin type 9 (PCSK9), which then prevents degradation of hepatocyte LDL receptors, increasing LDL uptake and decreasing plasma LDL levels

Similar monoclonal antibodies: Evolocumab (Repatha)

Adverse effects of interest: Minimal

Initial clinical indication: Familial hypercholesterolemia or atherosclerotic cardiovascular disease with elevated LDL-C

Other clinical indications: Hyperlipidemia

### **Pulmonary Disease**

#### ***Omalizumab***

Target: Inhibits IgE binding to IgE receptors on mast cells and basophils, thereby reducing the allergic response

Similar monoclonal antibodies: None

Adverse effects of interest: Rare hypersensitivity/anaphylactoid reactions

Initial clinical indication: Moderate to severe persistent asthma

Other clinical indications: Chronic spontaneous urticaria, nasal polyps

### **Allergic Conditions**

#### ***Mepolizumab (Nucala)***

Target: Inhibits binding of interleukin-5 (IL-5) to the IL-5 receptor, reducing eosinophil production, activation, and survival.

Similar monoclonal antibodies: Benralizumab (anti-IL-5R, Fasenera), reslizumab (anti-IL-5R, Cinqair)

Adverse effects of interest: Potential increased susceptibility to parasitic infections

<sup>1</sup>Not FDA approved for this indication.

Initial clinical indication: Severe eosinophilic asthma  
 Other clinical indications: Eosinophilic granulomatosis with polyangiitis, hypereosinophilic syndrome, rhinosinusitis with nasal polyps

#### **Dupilumab (Dupixent)**

Target: Binds to the interleukin 4 receptor alpha (IL-4R $\alpha$ ) subunit, inhibiting IL-4 and IL-13 signaling  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: conjunctivitis, potential increased susceptibility to parasitic infections  
 Initial clinical indication: Atopic dermatitis  
 Other clinical indications: Moderate to severe asthma, eosinophilic esophagitis, rhinosinusitis with nasal polyps

#### **Neurologic Conditions**

##### **Natalizumab (Tysabri)**

Target: Alpha-4 integrin subunit, blocking binding to vascular receptors and thereby reducing leukocyte adhesion and transmigration from circulation into the gut and brain  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: Increased risk of progressive multifocal leukoencephalopathy  
 Initial clinical indication: Multiple sclerosis  
 Other clinical indications: Inflammatory bowel disease (essentially supplanted by the development of the more specific antibody, vedolizumab [Entyvio])

#### **Infectious Diseases**

##### **SARS-CoV-2 (COVID-19)**

**Note:** all listed monoclonal antibodies were selected against the parent SARS-CoV-2 virus and have variable activity against subsequent novel variants of concern. We will use the BA.2 variant (Omicron) as an example for how monoclonal antibody activity varies compared to the parent virus, but each agent is likely to have variable activity against future variants of concern.

##### **Bamlanivimab/Etesevimab**

Target: Nonoverlapping epitopes of the spike protein of SARS-CoV-2, blocking attachment to the ACE2 receptor  
 Activity against BA.2 (Omicron) variant: None  
 Adverse effects of interest: None  
 Initial clinical indication: Mild to moderate COVID-19 and postexposure prophylaxis<sup>1</sup>  
 Other clinical indications: None

##### **Bebtelovimab**

Target: Spike protein of SARS-CoV-2, blocking attachment to the ACE2 receptor  
 Activity against BA.2 (Omicron) variant: Yes  
 Adverse effects of interest: None  
 Initial clinical indication: Mild to moderate COVID-19<sup>1</sup>  
 Other clinical indications: None

##### **Sotrovimab**

Target: Spike protein receptor binding domain of SARS-CoV-2, inhibits step between virus attachment and viral/cell membrane fusion  
 Activity against BA.2 (Omicron) variant: substantially reduced  
 Adverse effects of interest: None  
 Initial clinical indication: Mild to moderate COVID-19<sup>1</sup>  
 Other clinical indications: Probable inhibition of SARS-CoV-1<sup>1</sup>

##### **Casirivimab/Imdevimab (Regen-COV)**

Target: Nonoverlapping epitopes of the SARS-CoV-2 spike protein receptor binding domain, blocking attachment to the ACE2 receptor

Activity against BA.2 (Omicron) variant: None  
 Adverse effects of interest: None  
 Initial clinical indication: Mild to moderate COVID-19 and postexposure prophylaxis<sup>1</sup>  
 Other clinical indications: None

##### **Tixagevimab/Cilgavimab (Evusheld)**

Target: Nonoverlapping epitopes of the SARS-CoV-2 spike protein receptor binding domain, blocking attachment to the ACE2 receptor  
 Activity against BA.2 (Omicron) variant: Reduced (tixagevimab does not bind, cilgavimab binding is preserved)  
 Adverse effects of interest: None  
 Initial clinical indication: Preexposure prophylaxis against SARS-CoV-2 infection in patients who are at high risk for severe outcomes<sup>1</sup>  
 Other clinical indications: None

#### **Respiratory Syncytial Virus (RSV)**

##### **Palivizumab (Synagis)**

Target: RSV F glycoprotein  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: None  
 Initial clinical indication: Preexposure prophylaxis against respiratory syncytial virus in pediatric patients at high risk of RSV disease  
 Other clinical indications: None

#### **Bacillus Anthracis (Anthrax)**

##### **Raxibacumab**

Target: The free protective antigen component of *Bacillus anthracis* toxin, inhibiting toxin delivery to host cells via the anthrax toxin receptor  
 Similar monoclonal antibodies: Obiltoxaximab  
 Adverse effects of interest: None  
 Initial clinical indication: Treatment of inhalational anthrax, prophylaxis against inhalational anthrax following exposure to *Bacillus anthracis*  
 Other clinical indications: None

#### ***Clostridium difficile***

##### **Bezlotoxumab (Zinplava)**

Target: *Clostridium difficile* toxin B, causing neutralization and preventing toxic effects  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: None  
 Initial clinical indication: Prevent recurrence of *C. difficile* infection in patients on antimicrobial therapy and at high risk for recurrence  
 Other clinical indications: None

#### **Drug-Reversal Agents**

##### **Digoxin Immune Fab (Digifab)**

Target: Free digoxin; digoxin-specific antibody fragments (Fab) form digoxin-immune fragment complexes, decreasing circulating free digoxin concentrations and facilitating the dissociation of digoxin bound to the Na-K-ATPase.  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: None  
 Initial clinical indication: Life-threatening or potentially life-threatening digoxin toxicity  
 Other clinical indications: None

##### **Idarucizumab (Praxbind)**

Target: Free dabigatran and acyl glucuronide metabolites with a binding affinity much greater than that of thrombin, neutralizing the anticoagulant properties  
 Similar monoclonal antibodies: None  
 Adverse effects of interest: None  
 Initial clinical indication: Dabigatran reversal in the setting of uncontrolled bleeding or urgent/emergent surgical procedures  
 Other clinical indications: None

<sup>1</sup>Not FDA approved for this indication.

## STEM CELL THERAPY

Method of

Sunil Abhyankar, MD; and Rupal Soder, PhD

The two words “stem cell” evoke a vision of a multipotent cell that can develop into different kinds of tissue cells. Only *embryonic stem cells* fit this definition and they are guided in their development by external growth factors and environmental events in their final path to form a particular tissue and ultimately a body organ.

The progeny of the embryonic stem cells function as *differentiated stem cells* that are capable of forming new cells for the tissue in which they reside. These are *tissue-specific stem cells*. Such is the case, for example, with hematopoietic stem cells, which reside in the bone marrow (BM) space and are responsible for producing all the cells that make up the blood components. Most of the tissue stem cells have the capacity to regenerate tissue and, under certain growth conditions, can be coaxed to produce related tissues. An example of the latter is the *mesenchymal stem cell* (MSC), also located in the bone marrow, which under certain growth conditions can form cartilage, bone, and other connective tissue cells.

Another category of stem cell is the one artificially produced in the laboratory termed the *induced pluripotent stem cell* (iPSC). These are generally derived from tissue cells (e.g., fibroblasts) and made to grow in selective conditions into the cell of interest, hence the term induced pluripotent cells. iPSCs are finding increasing uses in cellular therapy in the cancer arena.

This review will focus on the committed stem cells that harbor in our tissues and are responsible for healing and replenishing cells of that tissue that are naturally dying (Figure 1).

In the United States, the US Food and Drug Administration (FDA) has the authority to approve cellular therapies. The FDA lists approved cellular and gene therapy products on their website, [https://www.fda.gov/vaccines-blood-biologics/cellular-gene-](https://www.fda.gov/vaccines-blood-biologics/cellular-gene-therapy-products/approved-cellular-and-gene-therapy-products)

[therapy-products/approved-cellular-and-gene-therapy-products](https://www.fda.gov/vaccines-blood-biologics/cellular-gene-therapy-products/approved-cellular-and-gene-therapy-products).

The list includes cellular therapies with chimeric antigen receptor technology utilized in cancer therapy, autologous cultured chondrocytes on a porcine collagen membrane, and mesenchymal cells used in treatment of severe nasolabial folds defects. The stem cell-based products that are FDA-approved for use in the United States consist of blood-forming stem cells (hematopoietic progenitor cells) derived from cord blood. The blood stem cells are approved for use in patients with disorders that affect the body system that is involved in the production of blood (i.e., the hematopoietic and the immune system). Bone marrow also is used for these treatments but is generally not regulated by the FDA for this use and is considered “grandfathered” for FDA approval. The use of bone marrow-derived MSC has been approved for use in Canada and Japan for the treatment of graft versus host disease in pediatric patients who have undergone a bone marrow transplant.

## Transplantation of Hematopoietic Stem Cells

The first report of the use of a hematopoietic stem cells from the bone marrow for transplant was in 1957 by E. Donell Thomas, when he and colleagues performed a bone marrow transplant (BMT) in monozygotic twins, one of whom had acute leukemia. This is considered a *syngeneic* (i.e., genetically identical) transplant. Although the procedure was successful, the patient subsequently relapsed. Dr. Thomas continued his pioneering work in BMT and was the recipient of the Nobel Prize in Medicine in 1990.

Utilization of *allogeneic* (genetically dissimilar) bone marrow stem cells in transplant was first described in the 1960s in pediatric patients with congenital immune deficiency (SCID). Subsequently allogeneic BMT has been used to treat a host of hematologic and immunologic conditions including aplastic anemia, hemoglobinopathies (sickle cell anemia and thalassemia), acute and chronic leukemias, and myelodysplastic syndromes. Success of allogeneic BMT has improved over the past decades as shown by data from the Center for International Blood and Marrow Transplant Research registry (CIBMTR). This has been due to several factors including improvements in human leukocyte antigen (HLA) typing resulting in better matched donors, improved supportive care, and an improved understanding of the immune process at play in allogeneic BMT. Thus young patients with idiopathic aplastic anemia can expect a 90% or higher long-term survival with an HLA matched related bone marrow stem cell donor. Despite these advances, the long-term success after an allogeneic BMT in adults is typically in the 50% range; survival is higher in younger compared with older adult patients. A major cause of the lower success in older patients is due to the risk of relapse of the underlying malignancy as well as acute and chronic graft versus host disease (GvHD) occurring after transplantation and the risk of opportunistic infections, usually viral and fungal. Newer approaches to mitigate and treat GvHD (e.g., the use of MSC in acute GvHD), measures to prevent relapse after transplant (e.g., use of targeted chemotherapeutic agents for maintenance therapy after transplant), and the use of viral specific T cells to treat viral infections post-BMT are being investigated. The outcomes of allogeneic BMT continue to improve.

Hematopoietic stem cells can be obtained from the bone marrow, the peripheral blood, and from umbilical cord blood. BM stem cells to be used in transplantation can be harvested surgically from the donor's bone marrow under general anesthesia or from the peripheral blood when stem cells can be mobilized from the BM with high doses of granulocyte colony-stimulating factor (G-CSF). These peripheral blood stem cells are BM stem cells isolated from the blood, making it easier on the donor. Umbilical cord blood (UCB) is also rich in hematopoietic stem cells and can be easily obtained after the birth of the baby after the cord has been cut. The leftover blood from the umbilical cord and placenta can be banked for use in transplantation.

Which source of stem cells is to be used in hematopoietic transplantation? This is dependent on the patient diagnosis and age. In patients who have malignant hematologic diseases, stem cells

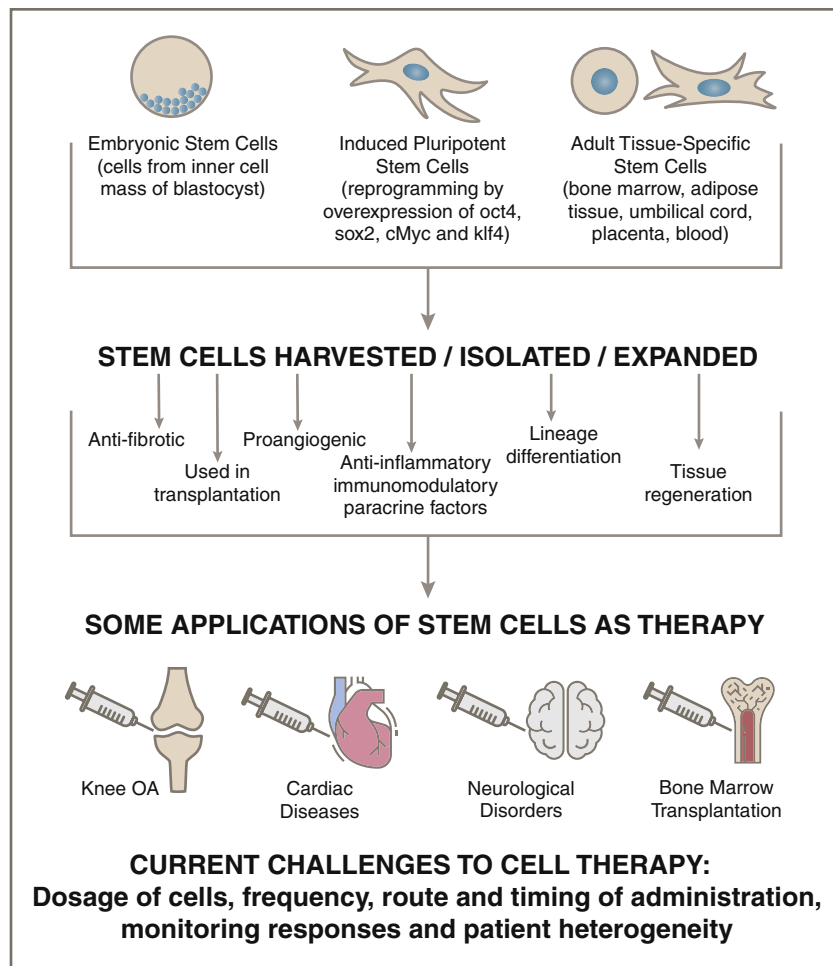

Figure 1 Current stem cell therapies.

obtained from the peripheral blood of the donor are often preferred as these stem cell collections are accompanied by a higher number of T lymphocytes, which can improve a patient's ability to fight off their cancerous cells. In contrast, in patients with aplastic anemia or sickle cell anemia, bone marrow harvested stem cells are preferred due to the lower amount of T cells in this product causing less GvHD.

With advances in hematopoietic transplantation, almost every person who will benefit from an allogeneic transplant will be able to find a donor. The choice for finding a donor includes searching for sibling matches and donors in the National Marrow Donor Program (NMDP) database, which contains the HLA typing results of more than 25 million volunteers. For those patients with rare HLA genotypes or for whom a matched donor is not readily available, a half (haplo) matched donor from a family member (e.g., sibling, parent, child, nephew, niece) can often be identified. The use of haploidentical donors in transplantation has been pioneered in the last decade from the BMT team at Johns Hopkins University.

UCB can also serve as the donor source for hematopoietic cells with the advantage that they are readily available and do not need a complete HLA matching for the transplant. BMT teams in Minnesota and Memorial Sloan Kettering have pioneered the use of UCB for transplant. UCB as a source of hematopoietic stem cells for transplant is more often used in the pediatric age group than in adults due to the paucity of the stem cells in UCB samples, which is adequate for engraftment in a child but insufficient for an adult who will either need two cord blood units or the use of UCB stem cells that are expanded by growing them in the laboratory.

In contrast to allogeneic BMT, *autologous* hematopoietic stem cell transplantation uses the patient's own BM stem cells collected from their blood to treat myeloma, lymphoma, and certain autoimmune conditions like severe systemic sclerosis, lupus, certain types of multiple sclerosis, and diabetes. In autologous transplant the stem cells are harvested from the patient's own blood and cryopreserved. The cells are then infused after high-dose chemotherapy to "rescue" the patient. In this situation the benefit from the procedure is mainly due to the effect of the high-dose chemotherapy on the underlying malignancy or autoimmune lymphocytes. In the future it is likely that chimeric antigen receptor (CAR) cell therapy may supplant the need for the high-dose chemotherapy and autologous stem cell rescue.

### Mesenchymal Stem Cell Therapy for Acute Graft Versus Host Diseases

Acute graft versus host disease (aGvHD) is a complication that occurs in about 50% of patients undergoing a donor hematopoietic stem cell transplant. The donor T cells attack and try to reject the recipient patient's body. aGvHD results in skin rash, diarrhea, and liver damage. MSCs, because of their immunoregulatory properties, have been used to treat severe forms of aGvHD. The use of bone marrow-derived MSCs has been approved for use in Canada and Japan for the treatment of aGvHD in pediatric patients who have undergone a bone marrow transplant. Umbilical cord tissue derived MSCs (Wharton's jelly MSC) have been studied in a Phase I clinical trial.

### Stem Cell Therapy in Knee Osteoarthritis (OA)

Knee osteoarthritis (OA), the most common form of arthritis, is characterized by loss of articular cartilage, osteophyte formation, and inflammation of the synovial membrane. The main therapeutic approach for knee OA is to improve joint function by cartilage repair, reduction of inflammation, and control of pain. Using cartilage tissue or chondrocytes to replace damaged articular cartilage is one of the potential therapeutic approaches in treating knee OA. In 1997 the FDA approved implantation of autologous chondrocytes, which are allowed to divide and proliferate in vitro, in a process known as expansion, and then injected into the defective cartilage tissue.

Currently, the third generation of this technology, matrix-induced autologous cultured chondrocytes implantation on porcine collagen membrane (MACI), is used where chondrocytes are amplified on a three-dimensional scaffold system before introduction into the joint for the repair of symptomatic cartilage defects of the knee in adult patients. This technology has demonstrated positive results in a 20-year follow-up compared with bone cartilage transplantation. However for autologous chondrocyte transplantation, the number of healthy chondrocytes that can be harvested from older adults are limited in number, and cartilage repair takes a long time after the implantation of chondrocytes. Hence for cartilage repair, several cell sources are under investigation.

Based on the *in vivo* and *in vitro* potential of the MSC to differentiate into chondrocytes and osteocytes and their immunomodulatory and immunosuppressive potential, the employment of MSCs for the treatment of OA is a rapidly growing area of clinical research. The use of MSC therapies in the treatment of OA has been determined to be feasible and safe in several different studies; however, there are differences in types of cells used, harvesting techniques, cell yield, and chondrogenic potential. The most used MSCs for the clinical use of the treatment of OA are bone marrow-derived mesenchymal stem cells (BMMSC) and adipose-derived stem cells (ASCs), with bone marrow being the gold standard source for musculoskeletal tissue engineering approaches. Various preclinical animal experiments revealed that MSCs, when injected intraarticularly into joints, inhibited synovial lining thickening, inhibited induction of ligament damage, and protected the joint from destruction by both anabolic and metabolic mediators.

Clinical feasibility, safety, and efficacy of allogenic human BMMSC was studied in a randomized controlled trial of 30 patients with chronic knee OA. Patients who received intraarticular injection of 40 million cells displayed improved cartilage quality posttreatment based on MRI imaging and reported improved knee function and a significant decrease in knee pain. There were no adverse events reported. A multinational meta-analysis report of use of MSC therapy in knee OA involving 582 patients suggested that MSC therapy is safe with low rates of adverse events and improved pain and functional scores after 24-month follow-up compared with controls. ASCs have also been studied in the treatment of OA. Intraarticular injection of ASC exhibited a dose-response effect with significant improvement in knee pain and function in the patients who received a higher dose (i.e.,  $1 \times 10^8$  cells).

Due to invasiveness of harvesting procedures for BMMSC and ASCs, various allogeneic MSC products are now available commercially. Park et al. reported the results of a first-in human clinical trial utilizing a stem cell-based product called Cartistem, a composite of allogenic human UCB-derived MSCs and HA hydrogel. A single dose of Cartistem was demonstrated to be safe with no detectable immunologic issues, improved joint function, and improved quality of life over 7 years of follow-up. The South Korean government approved the sale of Cartistem produced by Medipost Inc. in 2012, as the world's first allogenic, off-the-shelf stem cell drug for the treatment of degenerative arthritis and knee cartilage defects. Though current clinical trials have demonstrated the safety of allogeneic MSCs, there is still a debate about whether there is benefit. Larger randomized controlled trials with large sample sizes utilizing standardized and established outcome scores are required. The combination of MSCs with scaffolds,

platelet rich plasma (PRP), and growth factors is also being investigated to determine the optimal therapeutic effect.

Overall, for OA of the knee, there is limited availability of strong clinical effectiveness data, a lack of study comparability, and a lack of standardization associated with patient selection and assessment parameters, making it difficult to justify recommendation for the use of this therapy.

### Stem Cell Therapy for Cardiac Diseases

Cardiovascular diseases are the most common cause of death, accounting for approximately one-third of deaths worldwide. It has been nearly two decades since the first encouraging preclinical studies reported the repair of infarcted cardiac tissue utilizing bone marrow stem cell transplantation in a model of myocardial infarction. Various studies over the years hypothesize multiple mechanisms by which transplanted cells contribute to repair. The proposed modes of actions include differentiation of cells into cardiomyocytes and paracrine signaling via secretion of cytokines, growth hormones, exosomes, and mitochondrial transfer.

Fueled by the preclinical findings, randomized clinical studies were conducted utilizing BMMSCs and demonstrated safety and improved left ventricular function in patients with acute myocardial infarction. The POSEIDON-DCM study was designed to test the safety and efficacy of allogenic versus autologous BMMSCs in patients with nonischemic dilated cardiomyopathy. The data indicated that allogenic BMMSCs were superior at providing a greater magnitude of clinical efficacy, improved endothelial function, and reduction in the proinflammatory cytokine tumor necrosis factor (TNF)- $\alpha$  in the study population. A recent meta-analysis report that included data between 2017 and 2019 in patients with advanced heart failure suggested that stem cell therapy was safe and was associated with moderate improvement in cardiac function. BOOST, REPAIR-AMI, and REGENERATE-AMI are some of the other trials that aimed to investigate BMMSC therapy for myocardial infarction (MI) and reported significant improvements in left ventricle (LV) function and emphasized the importance of the timing of cell delivery post-MI.

In contrast to these findings, the SWISS-AMI, Late TIME, and TIME trial showed no improvement in LV function, LV volumes, or infarct size in the treatment group leading to discordant conclusions. These inconsistencies can be attributed to patient variability, heterogenous population of bone marrow-derived cells, different processing procedures, timing of cell delivery, study endpoints, and the unpredictable dynamic course of MI. BioCardia is currently conducting the Phase III CardiAMP Heart Failure (HF) trial using autologous bone marrow cells in patients who developed heart failure post-MI. The study is designed to apply a personalized medicine approach by selecting patients and tailoring treatment to those who are most likely to benefit.

ASCs have been evaluated for their usability, safety, and beneficial effects in a few clinical trials in patients with chronic ischemic heart disease and refractory angina. The initial results from the Precise Trial showed improved left ventricular mass and improved exercise capacity at 18-month follow-up. Intracardiac infusion of two doses of autologous ASCs (40 million and 80 million) were assessed in the Athena trial. While the findings supported the feasibility, safety, and scalability for the treatment of ischemic cardiomyopathy, the efficacy was limited with benefits observed on symptoms, quality of life, and  $VO_2$ max. There were no differences observed in left ventricular ejection fraction (LVEF) or LV volumes. These findings clearly require confirmation in additional trials.

Safety and efficacy of Wharton's jelly (WJ) MSC was evaluated for the first time in 2015 in patients with ST-elevation MI (STEMI). In this randomized multicenter trial with 116 patients, Gao et al. reported reductions in scar size, improved LVEF, and increased cardiac function after intracoronary infusion of WJ MSCs in patients with ST-elevation acute MI.

Cardiac stem cells (CSCs), a heterogenous cell population in the heart representing multipotent, self-replicating, c-kit+ cells expressing cardiac markers, have an effective capacity to differentiate into cardiomyocytes. CSCs were first tested in humans in the

**TABLE 1** Advantages and Disadvantages of Stem Cells Evaluated for the Treatment of Cardiovascular Disorders

CELL TYPES	ADVANTAGES	DISADVANTAGES
Bone marrow mononuclear cells (BMMNCs)	Extensively studied in clinical trials; safe; some trials showed improved LV functions and contractility.	Heterogenous cell population; inconsistent results regarding therapeutic action; lack of standard methodologies between trials; recent trials showing no improvement.
Mesenchymal stem cells (MSCs)	Autologous and allogeneic sources used; safe; no evidence of tumorigenicity; low risk of rejection; ease of isolation and expansion; immunomodulatory and immunoprivileged ability.	Lack standard study methodologies; limited differentiation potential; inconsistent reports of efficacy; need long-term follow-up.
Cardiac stem cells (CSCs)	Autologous transplantation; safe; immunomodulatory and immunosuppressive ability.	Invasive isolation procedure; limited cell quantity; poor cell quality from older donors; costly expansion.
Embryonic stem cells (ESCs)	Pluripotent; off-the-shelf products; differentiate into cardiomyocytes that can integrate with cardiac muscle.	Ethical concerns; tumorigenic potential; genetic instability; risk of immune rejection; availability issues.
Induced pluripotent stem cells (iPSCs)	Pluripotent; derived from adult somatic cells; no ethical concerns; unlimited quantity; superior functional integration into host cardiac tissue.	Tumorigenic potential; genetic instability; possible risk of immune rejection; lack of efficient procedures to induce pluripotency; no clinical translation yet.

SCIPIO phase I clinical trial in which c-kit<sup>+</sup> CSCs were isolated from biopsies obtained from patients with ischemic cardiomyopathy undergoing coronary artery bypass grafting and administered via intracoronary infusion 4 months later. The results showed improved LVEF and decreased infarct size at 12-month follow-up. Similarly, the CADUCEUS trial reported that intracoronary infusion of autologous CDCs after MI led to scar reduction, an increase in viable heart mass, and improved cardiac contractility. Advantages and disadvantages of stem cells evaluated for the treatment of cardiovascular disorders is outlined in Table 1.

Whereas lessons learned from more than 200 trials of cardiovascular diseases demonstrated the safety and feasibility of the addition of various stem cell types to the routine of care, efficacy studies only showed marginal improvements in cardiac function. The disappointing clinical success of stem cell therapy in heart disease has been attributed to the low retention and poor survival of transplanted cells. In addition, the cell type that would result in maximal benefit is yet to be determined.

### Stem Cell Therapy for Neurologic Disorders

Several clinical trials have been conducted to evaluate the safety and efficacy of stem cell therapy for central nervous system disorders. MSCs were shown to be able to cross the blood–brain barrier through paracellular pathways despite the presence of tight junctions. Stem cells can be transplanted into the brain directly intracerebrally or intrathecally or can be delivered by blood infusion. Several mechanisms by which stem cell therapy may offer therapeutic potential in patients with neurologic disorders include:

- Transplantation of stem cells and differentiated neuronal or glial cells to replace damaged neural cells with new, viable cells
- Transplanted cells may promote angiogenesis and neuroprotection by secreting several neurotropic and growth factors
- Induction of neurogenesis by activating endogenous stem cells accelerating new nerve growth in proliferative niches
- Immunomodulation by reducing the local inflammatory response and promoting remyelination in damage nervous system

Over the past few decades, safety and feasibility of stem cell therapy have been demonstrated in experimental animal models and in phase I/II clinical trials of neurologic diseases such as Alzheimer’s disease, stroke, spinal cord injury, amyotrophic lateral sclerosis, multiple sclerosis, traumatic brain injury, cerebral infarction, and Parkinson’s disease. Cell sources for these studies include autologous or allogeneic umbilical cord blood, autologous

bone marrow, fetal neural stem cells, embryonic stem cells, and mesenchymal stromal cells derived from adipose tissue or umbilical cord tissue. Most of these trials are registered for stroke, multiple sclerosis, and spinal cord injury. Use of MSCs in early stage clinical trials (phase I/II) for ischemic stroke and multiple sclerosis has demonstrated improvements in motor impairment scales and signs of clinical stabilization. Intrathecal and/or intravenous infusion of MSCs following expansion in patients with spinal cord injury demonstrated that MSC administration is safe and well tolerated, with apparent and subtle improvements in sensory (e.g., light touch and pin prick) and bladder functions. However, relative to rehabilitation therapy, no significant improvements in motor function were reported. Japanese authorities have recently granted approval of stem cell therapy (Stemirac) for spinal cord injury based on positive outcomes of a 13-patient study, which was not placebo controlled. Independent researchers warn of the premature nature of this approval and that the trial design cannot claim definitive efficacy.

Bone marrow stem cells have been used in an autologous stem cell transplant setting after high-dose chemotherapy for select patients with multiple sclerosis as reported by Burt and colleagues from Chicago. This needs to be validated by other centers before being accepted as the standard.

Whereas the future of stem cell therapy for neurologic disease appears to be promising, the variables to be determined include the optimal type of stem cell, dosage, route and timing of administration, and the stage of the patient’s disease. Evidence is also accumulating on advantages of combined administration of different stem cells/progenitor cells along with various scaffolds. Since complex disease requires complex therapies, it is unlikely that stem cell therapy could be administered as a monotherapy but rather will form part of a more holistic approach that aims to significantly improve the quality of life of affected patients.

### Other Promising Indications for Stem Cell Therapy

The future of stem cell therapies looks promising with ongoing clinical research trials for macular degeneration, Crohn disease, rheumatoid arthritis, muscular dystrophy, wound healing, and baldness. Currently there are no approved stem cell therapies for any of the conditions.

Recently, MSCs (BM or umbilical cord derived) have undergone clinical investigation for the treatment of COVID-19-related complications, especially ARDS pneumonia and inflammation in critically ill ICU patients. Lanzoni et al reported beneficial effects of umbilical cord MSCs in a randomized study of patients

with COVID-19 complicated by ARDS. This use does not have FDA-approval.

## BIOLOGIC AGENTS REFERENCE CHART

Method of

Laurie A.M. Hommema, MD; and Kevin Hommema, BSME

Biological weapons are devices used intentionally to cause disease or death through dissemination of microorganisms or toxins in food and water, by insect vectors, or by aerosols. Potential targets include human beings, food crops, livestock, and other resources essential for national security, economy, and defense. Unlike nuclear, chemical, and conventional weapons, the onset of a biological attack will probably be insidious. For some infectious agents, secondary and tertiary transmission could continue for weeks or months after the initial attack. In the United States, anthrax has been used in 2001 and ricin in 2003, 2004, and 2013 to target individuals. The Department of Homeland Security leads a national strategy to prevent, detect, respond to, and recover from acts of bioterrorism.

Initial detection of an unannounced biological attack will likely occur when an astute health professional notices an unusual case or disease cluster and reports his or her concerns to local public health authorities. Due to the incubation period of most biologic agents, subjects may have traveled from site of exposure to other geographic locations. Physicians and other health professionals should be alert to the following:

- Unusual temporal or geographic clustering of illnesses in humans, as well as animals
- Increase in specific lab testing or prescription drugs
- Sudden increase of illness in previously healthy persons
- Sudden increase in nonspecific illnesses such as pneumonia; flulike illness; bleeding disorders; unexplained rashes, particularly in adults; neuromuscular illnesses; and gastrointestinal syndromes

To enhance detection and treatment capabilities, physicians and other health professionals in acute care settings should be familiar with the clinical manifestations, diagnostic techniques, isolation precautions, treatment, and prophylaxis for likely causative

agents (e.g., smallpox, pneumonic plague, anthrax, viral hemorrhagic fevers). [Table 1](#) provides a quick summary of diagnostic and treatment considerations for various infectious and toxic biological agents. For some of these agents, delay in medical response could result in a potentially devastating number of casualties. To mitigate such consequences, early identification and intervention are imperative. Frontline physicians must have an increased level of suspicion regarding the possible intentional use of biological agents as well as an increased sensitivity to reporting those suspicious to public health authorities, who, in turn, must be willing to evaluate a predictable increase in false-positive reports.

Medical response efforts require coordination and planning with emergency management agencies, law enforcement, health care facilities, and social services agencies. Due to the criminal nature of the act, samples need to be collected and handled as evidence. Healthcare agencies should ensure that physicians know whom to call with reports of suspicious cases and clusters of infectious diseases, and they should work to build a good relationship with the local medical community. Resource integration is absolutely necessary to:

- Establish adequate capacity to initiate rapid investigation of an outbreak
- Establish and ensure decontamination protocols are in place
- Educate and protect healthcare workers and the public
- Coordinate mass distribution of antibiotics and vaccines
- Address psychological consequences

In an epidemic, overwhelming numbers of critically ill patients will require acute and follow-up medical care. Both infected persons and the worried well will seek medical attention, with a corresponding need for medical supplies, diagnostic tests, and hospital beds. The impact—or even the threat—of an attack can elicit widespread panic and civil disorder, overwhelm hospital resources, and disrupt social services.

Any suspicious or confirmed exposure to a biological weapons agent should be reported immediately to the local health department, local Federal Bureau of Investigation office, National Response Center (800-424-8802), and the Centers for Disease Control and Prevention Operation's Center (770-488-7100).

**TABLE 1** Quick Reference Chart on Biological Weapon Agents

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
<b>Bacteria</b>							
Anthrax <i>Bacillus anthracis</i> (all forms)		1–6 days (perhaps ≤60 days) <sup>†</sup>	Gram stain and culture of blood, pleural fluid, cerebrospinal fluid, ascitic fluid, vesicular fluid, or lesion exudate Confirmatory serologic and PCR tests are available through public health laboratory network.		Steroids may be considered for severe edema and for meningitis. Penicillin G should be considered if strain is susceptible and does not possess inducible β-lactamases.	Ciprofloxacin or doxycycline with or without vaccination If strain is susceptible, penicillin VK <sup>1</sup> or amoxicillin <sup>1</sup> (Amoxil) should be considered. Anthrax Vaccine Adsorbed (BioThrax) Preexposure (PrEP): 5 IM injections given at day 0, 1 month, and 6 months, then 12 and 18 months; and annually thereafter for persons who remain at risk. Postexposure (PEP): SC injection given at 0, 2, and 4 weeks combined with po ciprofloxacin or doxycycline for up to 60 days. Raxibacumab (ABthrax) is approved for PEP if no other options are available.	If meningitis is suspected, doxycycline may be less optimal because of poor CNS penetration. Sporicidal decontamination is necessary, such as sodium hypochlorite (chlorine bleach).
Cutaneous	Evolving <i>painless</i> skin lesion (face, neck, arms), progresses to vesicle, depressed ulcer, eschar with edema and regional lymphadenopathy		Gram stain and culture of unroofed vesicle, or under eschar	20% if untreated, otherwise rarely fatal	Ciprofloxacin <sup>1</sup> or doxycycline		
Gastrointestinal	Oropharyngeal: fever, severe pharyngitis, oral ulcers with patches and pseudo-membranes Intestinal: Nausea, vomiting, abdominal pain, bloody diarrhea, sepsis Widened mediastinum on chest radiograph is occasionally seen <sup>‡</sup> .		Gram stain and culture of throat lesions or stool culture	Approaches 100% if untreated, but data are limited. Rapid, aggressive treatment can reduce mortality.			

**TABLE 1** Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
Inhalational	Abrupt onset of flulike symptoms, fever with or without chills, sweats, fatigue or malaise, non- or minimally productive cough, nausea, vomiting, dyspnea, headache, chest pain, followed in 2–5 days by severe respiratory distress, mediastinitis, hemorrhagic meningitis, sepsis, shock <sup>5</sup> Widened mediastinum on chest radiograph or CT is characteristic <sup>‡</sup> .		Routine blood culture, CSF, and pleural effusions. Sputum is rarely positive.	Once respiratory distress develops, mortality rates approach 90%. Begin treatment when inhalational anthrax is suspected; do not wait for confirmatory testing <sup>‡</sup> .	Combination therapy of ciprofloxacin <sup>1</sup> or doxycycline plus one or two other antimicrobials should be considered <sup>¶</sup> . Raxibacumab (a human monoclonal antibody) and Anthrasil (an anthrax immune globulin IV [AIGIV]) are also available as FDA-approved drugs to treat inhalational anthrax.		
Brucellosis <i>Brucella abortus</i> , <i>B. canis</i> , <i>B. melitensis</i> , <i>B. suis</i>	Nonspecific flulike symptoms, fever, headache, profound weakness, profuse sweats, chills, weight loss, malaise. Abdominal pain, nausea, vomiting, and diarrhea are common. Hepatomegaly and splenomegaly may be found on exam, as well as osteoarticular findings.	5–60 days, usually 1–2 months	Blood and bone marrow culture (can require 6 weeks to grow <i>Brucella</i> ) Confirmatory culture and serologic testing	Fatality is rare; morbidity is often significant.	Doxycycline plus rifampin <sup>1</sup> <i>Alternative therapies:</i> Ofloxacin <sup>1</sup> plus rifampin <sup>1</sup> Doxycycline plus gentamicin (Garamycin) <sup>1</sup> TMP-SMX <sup>1</sup> plus gentamicin	Doxycycline plus rifampin <sup>1</sup> for high-risk exposure. No approved human vaccine; livestock vaccines are available.	Osteoarticular complications are common, including sacroiliitis, bursitis, tenosynovitis, paravertebral abscess, or discitis.
Glanders <i>Burkholderia mallei</i> Melioidosis <i>Burkholderia pseudomallei</i>	Fever, sweats, myalgias, headaches, cough, lymphadenopathy. Can progress to hepatosplenomegaly with pustular eruptions. CXR with infiltrates, cavitation, abscess, or military lesions. Imaging with splenic or hepatic abscesses.	Glanders: days to weeks Melioidosis: days to decades	Gram stain, culture, and PCR	Fatal if untreated	IV ceftazidime (Fortaz) <sup>1</sup> , meropenem (Merrem) <sup>1</sup> or imipenem (+ cilastatin [Primaxin]) <sup>1</sup> and prolonged oral TMP-SMX <sup>1</sup>	No approved PEP or vaccines available. TMP-SMX <sup>1</sup> can be considered.	One of the first bacterial agents to be weaponized. Prostatic abscess may be seen. Life-long follow-up for melioidosis as risk of relapse is 10%.

Continued

**TABLE 1** Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
Typhoidal tularemia <i>Francisella tularensis</i>	Sudden onset of acute febrile illness, weakness, chills, headache, generalized body aches, elevated WBCs Pulmonary symptoms such as dry cough, chest pain, or tightness with or without objective signs of pneumonia Progressive weakness, malaise, anorexia, and weight loss, potentially leading to sepsis and organ failure. Temperature/pulse mismatch may be seen.	3–5 days' range, 1–21 days	Largely clinical Culture of blood, sputum, biopsies, pleural fluid, bronchial washings; notify laboratory if suspected as culturing poses risk in standard lab.	~30%–60% Fatal if untreated	Streptomycin or gentamicin <sup>1</sup> <i>Alternative therapies:</i> Ciprofloxacin <sup>1</sup> Doxycycline Chloramphenicol (Chloromycetin) <sup>1</sup>	Tetracycline Doxycycline Ciprofloxacin <sup>1</sup> Live, attenuated vaccine (USAMRIID, IND) given by scarification; currently under FDA review, limited availability	Ulceroglandular forms with regional lymphadenopathy may also be seen.
Pneumonic plague <i>Yersinia pestis</i>	Acute onset of flulike prodrome: fever, myalgia, weakness, headache; within 24 h of prodrome, chest discomfort, cough with bloody sputum, and dyspnea By day 2–4 of illness, symptoms progressing to cyanosis, respiratory distress, shock, and bleeding diathesis.	1–6 days	Gram stain and culture of blood, CSF, sputum, lymph node aspirates, bronchial washings Confirmatory serologic and bacteriologic tests available through public health laboratory network	Almost 100% if untreated 20%–60% if appropriately treated within 18–24 h of symptoms	Streptomycin, gentamicin <sup>1</sup> <i>Alternative therapies:</i> Doxycycline Tetracycline Ciprofloxacin <sup>1</sup> Chloramphenicol <sup>1</sup> (Chloromycetin) is first choice for meningitis except for pregnant women.	Tetracycline Doxycycline Ciprofloxacin <sup>1</sup> Previous licensed vaccine not effective against aerosol exposure	Pneumonic plague is expected outcome of biological agent attack, as opposed to the presentation of Bubonic plague with swollen lymph nodes. Begin treatment when diagnosis of plague is suspected; do not wait for confirmatory testing.
Rickettsia Q-fever <i>Coxiella burnetii</i>	Nonspecific febrile disease, chills, cough, weakness and fatigue, pleuritic chest pain Pneumonia is possible.	10–17 days, up to 5 weeks	Isolation of organism may be difficult; IgG antibody testing by IFA is gold standard. Confirmatory testing via serology or PCR available through public health laboratory network.	1%–3% Fatalities are uncommon, except in cases of endocarditis. Pregnancy loss if infected in first trimester.	Tetracycline Doxycycline	Tetracycline doxycycline, not endorsed by CDC. Inactivated whole-cell vaccine (Q-Vax) is available in Australia and Europe, but only available in USA for investigational basis (IND).	Chronic disease may occur, including endocarditis. Skin test to determine prior exposure to <i>C. burnetii</i> is recommended before vaccination.

**TABLE 1** Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
<b>Viruses</b>							
Smallpox Variola major virus	Prodrome of high fever, malaise, prostration, headache, vomiting, delirium followed in 2–3 days by maculopapular rash uniformly progressing to pustules and scabs, mostly on extremities and face	7–17 days	Clinical pharyngeal swab, vesicular fluid, biopsies, scab material for electron microscopy and PCR testing through public health laboratory network	30% in unvaccinated persons	Supportive care Tecovirimat (Tpoxx) was approved for the treatment of smallpox under the FDA's Animal Rule; however, its efficacy in humans has not been determined. Other IND products are available including cidofovir (Vistide).	Live, attenuated vaccinia vaccine (ACAM2000) derived from calf lymph; given by scarification (licensed, restricted supply) New vaccine being developed from tissue culture Vaccination given within 3–4 days following exposure can prevent or decrease the severity of disease.	Requires astute clinical evaluation; may be confused with chickenpox, erythema multiforme with bullae, or allergic contact dermatitis. Strict airborne and contact precautions. Notify CDC Poxvirus Section at 404-639-2184.
<b>Viral Encephalitis</b>							
All forms	Systemic febrile illness, with encephalitis developing in some populations Generalized malaise, spiking fevers, headache, myalgia		Clinical and epidemiologic diagnosis WBC count can show striking leukopenia and lymphopenia. Confirmatory test and viral isolation available through public health laboratory network.		Supportive care Analgesics, anticonvulsants as needed	No accepted PEP. Several IND vaccines available.	Incidence of seizures and/or focal neurologic deficits may be higher after biological attack.
Eastern equine encephalitis		5–15 days		50%–75%			
Western equine encephalitis		5–10 days		10%			
Venezuelan equine encephalitis		2–6 days		<10%			

*Continued*

**TABLE 1** Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
<b>Viral Hemorrhagic Fevers</b>							
Arenaviruses (Lassa, Junin, and related viruses) Bunyaviruses (Hanta, Congo-Crimean, Rift Valley) Filoviruses (Ebola, Marburg) Flaviviruses (yellow fever, dengue, various tick-borne disease viruses)	Fever with facial flushing, mucous membrane bleeding, petechiae, thrombocytopenia, and hypotension. Malaise, myalgias, headache, vomiting, diarrhea possible	4–21 days	Clinical diagnosis. Confirmatory testing and viral isolation available through BSL-4 laboratories.	Variable depending on viral strain; 15%–25% with Lassa fever to ≤90% with Ebola	Supportive therapy Ribavirin (Virazole) <sup>1</sup> may be effective for Lassa fever, Rift Valley fever, Argentine hemorrhagic fever, and Congo-Crimean hemorrhagic fever.	Ribavirin (Virazole) <sup>1</sup> is suggested for Arenaviruses and Bunyaviruses. Yellow fever vaccine (YF-VAX) is the only licensed vaccine available for yellow fever prevention. Vaccines for some of the other VHF exist but are for investigational use only.	Strict airborne, droplet, and contact precautions. Call CDC Special Pathogens Office at 404-639-1115.
<b>Biological Toxins</b>							
Botulism <i>Clostridium botulinum</i> toxin	Cranial nerve palsies including diplopia, dry mouth, ptosis, dysphagia. As disease progresses, acute bilateral descending flaccid paralysis, respiratory paralysis resulting in death	1–5 days, typically 12–36 h	Clinical Serum and stool should be assayed for toxin by mouse neutralization bioassay, which can take several days. NCV or EMG.	60% without ventilatory support	Intensive and prolonged supportive care; ventilation may be necessary. Heptavalent Botulism Antitoxin (HBAT) is available.	Pentavalent toxoid (A–E), no longer available. Antitoxin may be sufficient to prevent illness following exposure but is not recommended until patient is showing symptoms.	Anaphylaxis and serum sickness are potential complications of antitoxin. Aminoglycosides and clindamycin (Cleocin) must not be used.
Enterotoxin B <i>Staphylococcus aureus</i>	Inhaled: acute onset of fever, chills, headache, nonproductive cough Ingested: nausea, vomiting, cramps, diarrhea	3–12 h inhaled, 1–6 h ingested	Clinical Normal chest radiograph Serology on acute and convalescent serum can confirm diagnosis.	Probably low (few data available for respiratory exposure)	Supportive care	No vaccine available. Use of mask to prevent inhalation.	
Ricin toxin <i>Ricinus communis</i>	Weakness, nausea, chest tightness, fever, cough, pulmonary edema, respiratory failure, circulatory collapse, hypoxemia resulting in death (usually within 36–72 h)	≤6–24 h	Clinical and epidemiologic Confirmatory serological testing available through public health laboratory network.	Mortality data are not available, but likely to be high with extensive exposure.	Supportive care Treatment for pulmonary edema Gastric decontamination if toxin is ingested. NSAIDs.	No vaccine or antitoxin available. Use of mask to prevent inhalation.	Hypochlorite inactivates.

**TABLE 1** Quick Reference Chart on Biological Weapon Agents—cont'd

DISEASE AND AGENT	SIGNS AND SYMPTOMS	DIAGNOSTIC CONSIDERATIONS			TREATMENT CONSIDERATIONS*		
		INCUBATION PERIOD	DIAGNOSIS	LETHALITY	TREATMENT	PROPHYLAXIS	COMMENTS
T-2 Mycotoxins <i>Fusarium</i> <i>Myrothecium</i> <i>Trichoderma</i> <i>Stachybotrys</i>	Skin pain, pruritis, erythema, vesiculation, and sloughing. Throat pain, rhinorrhea, cough, and hemoptysis. Weakness, ataxia, shock can occur in severe exposure.	Minutes to hours	Suspect if “yellow rain” with oily pigmented fluids staining close and environment.	Can be seen in severe exposures.	Clinical support	No vaccine available.	Soap and water washing within 4–6 h reduces dermal toxicity; washing within 1 h can eliminate toxicity entirely.
Other filamentous fungi			Confirmation requires testing blood, tissue, and environmental samples.	Severe exposure can cause death in hours to days.			Consult with local health department regarding specimen collection and diagnostic testing procedures.

<sup>1</sup>Not FDA approved for this indication.

\*Different situations can require different dosage and treatment regimens. Please consult other references and an infectious disease specialist for definitive dosage information, especially dosages for pregnant women and children.

<sup>†</sup>Data from 22 patients infected with anthrax in October and November 2001 indicate a median incubation period of 4 days (range, 4–7 days) for inhalational anthrax and a mean incubation of 5 days (range, 1–10 days) for cutaneous anthrax.

<sup>‡</sup>Chest radiograph abnormalities include paratracheal and hilar fullness and may be subtle. Consider chest computed tomography if diagnosis is uncertain.

<sup>§</sup>Limited data from the October and November 2001 anthrax infections indicate hemorrhagic pleural effusions to be strongly associated with inhalational anthrax; rhinorrhea was present in only 1/10 patients.

<sup>||</sup>Limited data from the 2001 terrorist-related anthrax infections indicate that early treatment significantly decreased the mortality rate.

<sup>¶</sup>Other agents with in vitro activity suggested for use in conjunction with ciprofloxacin or doxycycline for treatment of inhalational anthrax include rifampin<sup>1</sup>, vancomycin (Vancocin)<sup>1</sup>, imipenem (Primaxin)<sup>1</sup>, chloramphenicol (Chloromycetin)<sup>1</sup>, penicillin G and ampicillin<sup>1</sup>, clindamycin (Cleocin)<sup>1</sup>, and clarithromycin (Biaxin)<sup>1</sup>.

CDC, Centers for Disease Control and Prevention; CNS, central nervous system; CSF, cerebrospinal fluid; GI, gastrointestinal; IND, investigational new drug; PEP, post-exposure prophylaxis; PCR, polymerase chain reaction; TMP-SMX, trimethoprim-sulfamethoxazole; USAMRIID, U.S. Army Medical Research Institute of Infectious Diseases; VHF, viral hemorrhagic fever; WBC, white blood cell.

## POPULAR HERBS AND NUTRITIONAL SUPPLEMENTS

Method of

Miriam Chan, PharmD

### Popular Herbs and Nutritional Supplements

#### HERB OR NUTRITIONAL SUPPLEMENT

#### COMMON USES

#### REASONABLE ADULT ORAL DOSAGE\*

#### PRECAUTIONS AND DRUG INTERACTIONS

Aloe vera

Commonly found in skin products as a moisturizer  
Used topically to treat burns, wounds, skin infections, and inflammation  
Approved in Germany to use orally as a laxative  
Used orally for a variety of conditions, including diabetes, asthma, epilepsy, and osteoarthritis

For external use, apply aloe gel on the skin tid to qid  
For constipation, 40–170 mg of dried aloe juice or latex (corresponds to 10–30 mg hydroxyanthracene derivatives) taken in the evening  
For other conditions, no established dosage documented

Aloe gel is generally well tolerated and safe when used topically  
Aloe gel taken orally can cause hypoglycemia in patients who are concomitantly taking antidiabetic drugs  
Aloe juice or latex contains anthraquinone, a cathartic laxative and should not be taken by people with intestinal obstruction, acute intestinal inflammation, and ulcers  
Pregnant women should not take aloe latex because it may cause uterine contractions  
Oral use of aloe latex can cause abdominal cramps and diarrhea. Long-term use or abuse can cause electrolyte imbalances, albuminuria, hematuria, and pseudomelanosis coli. Prolonged use of high doses ( $\geq 1$  g/d) can cause nephritis, acute renal failure, and death  
In 2002, the FDA banned the sale of aloe-containing laxative products in the United States because of the lack of safety data  
Aloe can decrease platelet aggregation and should be avoided at least 2 weeks before surgery

Astragalus

Used in combination with other herbs to support and enhance the immune system  
Used to prevent and treat common colds and upper respiratory infections  
Used for heart disease  
Widely used in China for chronic hepatitis and as an adjunctive therapy in cancer

Extract: 250–500 mg tid to qid standardized to 0.4% 4-hydroxy-3-methoxyisoflavone 7-sug  
Powdered root: 500–1000 mg tid  
Tincture (1:5) in 30% ethanol: 3–5 mL tid  
Decoction: 3–6 g of dried root per 12 oz water tid

Avoid using astragalus in organ transplant patients and those with autoimmune disorders  
Side effects include mild stomach upset and allergic reactions  
Astragalus can decrease the effects of cyclophosphamide and other immunosuppressants

Bilberry fruit

Often used orally to improve visual acuity and to treat degenerative retinal conditions  
Used orally to treat chronic venous insufficiency, varicose veins, and hemorrhoids  
Approved in Germany to use orally for acute diarrhea and topically for mild inflammation of the mucous membranes of mouth and throat

For eye conditions and circulation, 80–160 mg tid of the extract standardized to at least 25% anthocyanosides  
For diarrhea, 20–60 g/d of the dried, ripe berries or as a tea preparation (5–10 g of crushed dried berries in 150 mL water, brought to a boil for 10 min, then strained)  
For external use, 10% decoction

No known side effects reported with bilberry fruit and extract  
However, bilberry leaf taken in large quantities or used long term has been shown to cause wasting, anemia, jaundice, acute excitation, disturbances of tonus, and death in animals  
The anthocyanidin extracts from bilberry can increase the risk of bleeding in those taking warfarin or other blood thinners

Black cohosh root

Commonly used to relieve hot flashes and other menopausal symptoms  
Used to treat premenstrual discomfort and dysmenorrhea

20 mg bid of the rhizome extract standardized to triterpene glycosides  
Remifemin is the proprietary brand used in a number of clinical trials  
The German guidelines do not recommend its use for > 6 months

Black cohosh may have an estrogen-like effect and should be avoided in women with breast cancer  
Large doses may induce miscarriage and it is contraindicated during pregnancy  
It may cause GI disturbances, headache, and hypotension  
International case reports of liver dysfunction suspected to be associated with its use

Black haw

To relieve uterine cramps and painful periods  
To prevent miscarriage and ease pain that follows childbirth

For menstrual pain, 5 mL of tincture in water, taken 3–5 times daily  
For prevention of miscarriage, 1–2 cups of tea per day (1 tsp of dried herb in 1 cup of boiling water, steeped for 10 min)

Black haw should not be used in pregnancy because of its uterine relaxant effects  
The salicylate constituent in black haw could trigger allergic reactions in individuals with aspirin allergies or asthma  
Black haw may aggravate tinnitus  
Large doses of black haw can prolong bleeding time  
The oxalic acid component of black haw can increase kidney stone formation in susceptible individuals  
Black haw can interact with warfarin and increase risk of bleeding

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Cat's claw	<p>Used primarily to reduce pain in osteoarthritis and rheumatoid arthritis</p> <p>Used for a variety of health conditions, including viral infections (e.g., herpes, HIV), Alzheimer disease, and cancer</p> <p>Used to support the immune system and promote kidney health</p> <p>Used to prevent and abort pregnancy</p>	<p>For osteoarthritis, 100 mg/d of the dry encapsulated extract</p> <p>For rheumatoid arthritis, 20 mg tid of the dry extract standardized to 1.3% pentacyclic oxindole alkaloids free of tetracyclic oxindole alkaloids</p> <p>For general uses, 1–3 cups of tea per day (1 g root bark boiled for 15 min in 250 mL of water) or 1 mL of tincture 2–3 times/d</p>	<p>Avoid using cat's claw during pregnancy or breastfeeding</p> <p>People with autoimmune diseases and transplant recipients should avoid cat's claw because of its immune stimulating effects</p> <p>Side effects include headaches, dizziness, and vomiting</p> <p>Cat's claw can lower blood pressure and cause hypotension when used with antihypertensive drugs</p> <p>Cat's claw can inhibit CYP3A4 enzyme and increase levels of drugs metabolized by this enzyme</p>
<p>Cannabidiol (CBD) (A cannabinoid extracted from the hemp plant and often made into an oil for use)</p>	<p>For relieving anxiety, insomnia, chronic pain, and many common ailments</p> <p>Epidiolex, a purified CBD solution, is the only prescription CBD approved by the FDA to treat Lennox-Gastaut syndrome, Dravet syndrome, or tuberous sclerosis complex in patients aged 1 year and older</p> <p>Various CBD products (oils, gummies, capsules, sprays, drinks, vapes, topical lotions, and creams) are sold as dietary supplements and CBD-infused foods</p> <p>While the 2018 Farm Bill legalized CBD oil derived from the hemp plant containing ≤ 0.3% tetrahydrocannabinol (THC) at the federal level, all 50 states have laws legalizing CBD with varying degrees of restriction. CBD products are readily obtainable in most parts of the United States and have become the hot new products in states that have legalized medical marijuana</p> <p>Currently, the FDA does not allow CBD to be added in foods and it does not approve CBD to be sold as dietary supplements</p>	<p>No established dosage documented for CBD supplement</p> <p>In general, start CBD at a low dose and titrate dose slowly. The usual daily dose is 200 mg or less. Doses of 300–600 mg have been used for anxiety</p> <p>There are concerns about the quality and purity of CBD products. Many have shown to be mislabeled and contain THC (&gt;3%) and other contaminants (e.g., toxic chemicals including heavy metals and pesticides). Consumers should look for the US Hemp Authority seal that certifies the quality of CBD products. A product's certificate of analysis (COA) if available can also be used to determine labeling accuracy and presence of contaminants</p>	<p>Marijuana contains THC and CBD. Unlike THC, pure CBD does not cause a “high”</p> <p>CBD may cause nausea, diarrhea, fatigue, and irritability</p> <p>High CBD doses are linked to elevated liver function tests</p> <p>Effects of cumulative CBD exposure are unknown</p> <p>Avoid CBD in infants and children, and in pregnant or breastfeeding women</p> <p>Many potential drug interactions:</p> <ul style="list-style-type: none"> <li>Worsening sedation when combining with CNS depressants</li> <li>CBD inhibits CYP2C8, 2C9, and 2C19 enzymes and can increase levels of drugs such as carbamazepine, warfarin, amitriptyline, citalopram, phenytoin, and valproic acid</li> <li>CBD levels can be increased by CYP3A4 inhibitors, such as clarithromycin, ritonavir, and verapamil</li> </ul> <p>Increased sedation when CBD is taken with herbal supplements, including kava, melatonin, and St. John's wort</p>
Chamomile flower	<p>Used orally to calm nerves and treat GI spasms and inflammatory diseases of the GI tract</p> <p>Used topically to treat wounds, skin infections, and skin or mucous membrane inflammation</p>	<p>1 cup of freshly made tea 3–4 times daily (1 tbsp or 3 g of dried flower in 150 mL boiling water for 5–10 min)</p>	<p>Chamomile can cause an allergic reaction, especially in people with severe allergies to ragweed or other members of the daisy family (e.g., echinacea, feverfew, and milk thistle)</p> <p>It should not be taken concurrently with other sedatives, such as alcohol or benzodiazepines</p>
Chaste tree berry (Chasteberry, Vitex)	<p>For normalizing irregular menstrual periods and relieving premenstrual complaints</p> <p>For relieving menopausal symptoms</p> <p>For restoring fertility in women</p> <p>For treating acne associated with menstrual cycles</p> <p>For increasing breast milk production in lactating women</p>	<p>For menstrual irregularities and premenstrual complaints, 30–40 mg/d of the dried berries or an equivalent amount of aqueous-alcoholic extracts (50%–70% v/v)</p> <p>Dried fruit extract, standardized to 0.6% agnusides, is used in doses of 175–225 mg/d</p> <p>For other conditions, no established dosage documented</p>	<p>Chaste tree berry can have uterine stimulant properties and should be avoided in pregnancy</p> <p>Women with hormone-dependent conditions (e.g., breast, uterine, and ovarian cancers, and endometriosis and uterine fibroids) and men with prostate cancer should avoid chaste tree berry because it contains progestins</p> <p>Side effects include intramenstrual bleeding, dry mouth, headache, nausea, rash, alopecia, and tachycardia</p> <p>High doses (≥480 mg/d extract) can paradoxically decrease lactation</p> <p>Chaste tree berry is thought to have dopaminergic effects and can interact with dopamine antagonists, such as antipsychotics and metoclopramide</p> <p>Chaste tree berry can decrease the effects of oral contraceptives and hormone therapy</p>

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Chondroitin	Orally, used frequently in combination with glucosamine for osteoarthritis Topically, in combination with sodium hyaluronate, as a viscoelastic agent in cataract surgery	Oral: 200–400 mg tid	Occasional mild side effects include nausea, indigestion, and allergic reactions Chondroitin derived from bovine cartilage carries a potential risk of contamination with diseased animals
Chromium	For diabetes For hypercholesterolemia Commonly found in weight-loss products Also promoted for body building	For diabetes, 100 µg bid for ≤4 months or 500 µg bid for 2 months For hypercholesterolemia, 200 µg tid or 500 µg bid for 2–4 months For body building, 200–400 µg/d Chromium picolinate has been used in most studies, even though the chloride form is also available	Adverse effects are rare, but they include headaches, insomnia, sleep disturbances, irritability, and mood changes; some patients may also experience cognitive, perceptual, and motor dysfunction Long-term use of high doses (600–2400 µg/d) can cause anemia, thrombocytopenia, hemolysis, hepatic dysfunction, and renal failure Interstitial nephritis has been reported A few studies suggest that chromium can cause DNA damage Chromium competes with iron for binding to transferrin and can cause iron deficiency Antacids, H <sub>2</sub> blockers, and proton pump inhibitors can decrease the absorption of chromium
Coenzyme Q10	As adjunctive treatment for congestive heart failure, angina, hypertension, and diabetes Used for reducing cardiotoxicity associated with doxorubicin Used to treat statin-induced myopathy	For heart failure, 100 mg/d in 2 or 3 divided doses For angina, 50 mg tid For hypertension, 60 mg bid For diabetes, 100–200 mg/d	Mild adverse events include gastric distress, nausea, vomiting, and hypotension Doses >300 mg/d can cause elevated liver enzyme levels Coenzyme Q10 can reduce the anticoagulation effects of warfarin Oral hypoglycemic agents and HMG-CoA reductase inhibitors can reduce serum coenzyme Q10 levels
Cranberry	To prevent and treat UTIs or <i>Helicobacter pylori</i> infections that can lead to stomach ulcers To prevent dental plaque As an antioxidant to prevent cardiovascular disease and cancer	For UTIs, 150–600 mL of cranberry juice daily or 300–400 mg of standardized extract bid For other conditions, no dosage determined	Drinking excessive amounts of juice could cause GI upset or diarrhea Prolonged use of cranberry juice in large doses increases the risk of kidney stone formation because of its high oxalate content Cranberry can interact with warfarin and cause an increase in INR The effectiveness of proton pump inhibitors can be reduced by cranberry because of its acidity
Creatine	To enhance muscle performance, especially during short-duration, high-intensity exercise	Loading dose of 20 g/d for 5–7 d followed by a maintenance dose of ≥2 g/d An alternative dosing of 3 g/d for 28 d has been suggested	Creatine can cause gastroenteritis, diarrhea, heat intolerance, muscle cramps, and elevated serum creatinine levels Creatine is contraindicated in patients taking diuretics Concurrent use with cimetidine, probenecid, or non-steroidal antiinflammatory drugs increases the risk of adverse renal effects Caffeine can decrease creatine's ergogenic effects
Dehydroepiandrosterone (DHEA)	Replace low serum DHEA levels in adrenal insufficiency Treat SLE Reverse aging Used in many other conditions, including Alzheimer disease, depression, diabetes, menopause, osteoporosis, impotence, and AIDS Used to promote weight loss Used by bodybuilders to increase muscle mass	For replacement therapy, 25–50 mg/d For SLE, 200 mg/d For antiaging and osteoporosis, 50 mg/d For other conditions, no established dosage documented	Most common side effects are androgenic in nature and include acne, hair loss, hirsutism, and deepening of the voice Cases of hepatitis have been reported When used in high doses, DHEA can cause insomnia, manic symptoms, and palpitations DHEA at physiologic doses increases circulating androgens in women, but not in men; it also increases circulating estrogens in both men and women Avoid use of DHEA in individuals with a history of sex hormone-dependent malignancy Safety of DHEA in individuals aged < 30 years is unknown DHEA inhibits CYP3A4 enzyme and could increase serum concentrations of drugs metabolized by this enzyme (e.g., lovastatin, ketoconazole, itraconazole, and triazolam)

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Dong quai root	Commonly used for the relief of premenstrual and menopausal symptoms Used as a “blood tonic” and a strengthening treatment for the heart, spleen, liver, and kidneys	For premenstrual and menopausal symptoms, 3–4 g/d in 3 divided doses For other conditions, no established dosage documented	Dong quai should not be used in pregnant women because of its uterine stimulant and relaxant effects Women with hormone sensitive conditions (e.g., breast, uterine, and ovarian cancers, and endometriosis and uterine fibroids) should avoid dong quai because of its estrogenic effects Drinking the essential oil of dong quai is not recommended because it contains a small amount of carcinogenic constituents Dong quai contains psoralens that can cause photosensitivity and photodermatitis Dong quai contains natural coumarin derivatives that can increase the risk of bleeding in those who are taking anticoagulant or antiplatelet drugs
Echinacea	As an immune stimulant, particularly for the prevention and treatment of the common cold and influenza Supportive therapy for lower urinary tract infections Used topically to treat skin disorders and promote wound healing	300 mg tid of <i>Echinacea pallida</i> root or 2–3 mL tid of expressed juice of <i>Echinacea purpurea</i> herb Do not use for >8 weeks because echinacea may suppress immunity if used long term	Echinacea should not be used in transplant patients and those with autoimmune disease or liver dysfunction Allergic reactions have been reported Adverse events are rare and include mild GI effects It should be discontinued as far in advance of surgery as possible Echinacea can decrease effectiveness of the immunosuppressants
Ephedra (ma huang)	For diseases of the respiratory tract with mild bronchospasm Promoted for weight loss and performance enhancement	1 tsp or 2 g of dried herb (15–30 mg of ephedrine) in 240 mL boiling water for 10 min In Canada, the maximum allowable dosage of ephedrine is 8 mg per dose or 32 mg/d	Ephedra contains ephedrine, which has sympathomimetic activities; consequently, it should not be used in patients who have cardiovascular disease, diabetes, glaucoma, hypertension, hyperthyroidism, prostate enlargement, psychiatric disorders, or seizures Serious adverse effects, including seizures, arrhythmias, heart attack, stroke, and death, have been associated with the use of ephedra; as a result, the FDA banned the sale of ephedra-containing products in the United States. The ban does not apply to traditional Chinese herbal remedies Because of the cardiovascular effects of ephedrine, patients taking ephedra should discontinue use at least 24 h before surgery Concurrent use of ephedra and digitalis, guanethidine, monoamine oxidase inhibitors, or other stimulants, including caffeine, is not recommended
Evening primrose oil	For PMS, especially if mastalgia is present For treatment of atopic eczema Used for other medical conditions, including rheumatoid arthritis, menopausal symptoms, Raynaud phenomenon, Sjögren syndrome, and diabetic neuropathy	For PMS, 2–4 g/d For atopic eczema, 6–8 g/d For rheumatoid arthritis, 2.8 g/d These doses are based on products standardized to 9% $\gamma$ -linolenic acid Daily dose can be given in divided doses	Evening primrose oil can increase the risk of pregnancy complications Side effects include indigestion, nausea, soft stools, and headache Seizures have been reported in patients with schizophrenia who were taking phenothiazines and evening primrose oil concomitantly Evening primrose oil can interact with anesthesia and cause seizures Concomitant use of evening primrose oil with anticoagulant and antiplatelet drugs can increase the risk of bleeding
Fenugreek seed	For diabetes and hypercholesterolemia For constipation, dyspepsia, gastritis, and kidney ailments Approved in Germany for use orally for loss of appetite and topically as a poultice for local inflammation	For loss of appetite, 1–2 g of the seed tid or 1 cup of tea (500 mg seed in 150 mL cold water for 3 h) several times a day Maximum 6 g/d For other conditions, no established dosage documented For topical use, 50 g powdered seed in 0.25 L of hot water to form a paste	Fenugreek can cause uterine contractions and should be avoided in pregnancy Individuals who have allergies to peanuts or soybeans might also be allergic to fenugreek Fenugreek can cause diarrhea and flatulence; it can also make urine smell like maple syrup Hypoglycemia can occur if fenugreek is taken in large amounts Repeated external applications can result in undesirable skin reactions Fenugreek contains small amounts of coumarins and can interact with anticoagulants and antiplatelet drugs High mucilage content of fenugreek can affect the absorption of oral drugs; therefore, fenugreek should not be taken within 2 h of other drugs

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Feverfew	For migraine headache prophylaxis For treatment of fever, menstrual problems, and arthritis	Migraine prevention: 25–75 mg bid of the encapsulated dried leaf extract standardized to 0.2% parthenolide, for up to 4 months 2.08–18.75 mg tid for MIG-99 preparation (a carbon dioxide extract enriched with parthenolide) for 3–4 months For other conditions, no established dosage documented	Feverfew can induce menstrual bleeding and is contraindicated in pregnancy Fresh leaves can cause oral ulcers and GI irritation Sudden discontinuation of feverfew can precipitate rebound headache Feverfew can interact with anticoagulants and potentiate the antiplatelet effect of aspirin
Fish oils (omega-3 fatty acids)	Commonly used in the treatment of hypertriglyceridemia Used to prevent CHD and stroke Used in many noncardiac conditions, including depression, diabetes, dysmenorrhea, rheumatoid arthritis, and IgA nephropathy Used to reduce the risk of developing age-related maculopathy, Alzheimer disease, and cancer Promotes visual and mental development in children	For hypertriglyceridemia, 3–5 g/d For cardioprotection, 1 g/d for patients with CHD; oily fish at least twice a week, or about 0.5 g/d for people with no known heart disease For other conditions, no established dosage documented Fish oils are composed of EPA and DHA; fish oil capsules vary widely in amounts and ratios of EPA and DHA; the most common fish oil capsules in the United States provide 180 mg of EPA and 120 mg DHA per capsule, and three capsules will provide about 1 g/d of omega-3 fatty acids	Common side effects include fishy aftertaste, GI disturbances, belching, halitosis, and heartburn High doses can cause nausea and loose stools Doses > 3 g/d can inhibit platelet aggregation, suppress immune function, worsen glycemic control, and raise LDL cholesterol levels Long-term use may be associated with weight gain Less well-controlled preparations can contain appreciable amount of organochloride contaminants Fish oil can increase the risk of bleeding in patients taking warfarin, an antiplatelet agent, or herbs that have antiplatelet constituents (e.g., garlic, ginkgo, and red clover) Fish oils can lower blood pressure and can have additive effects with antihypertensive agents Oral contraceptives can interfere with the triglyceride lowering effects of fish oils
Flaxseed	Orally, approved in Germany for chronic constipation, irritable bowel, and other colon disorders Often used orally for hypercholesterolemia and atherosclerosis Topically, approved in Germany for painful skin inflammation	For constipation, 1 tbsp (5 g) of whole or “bruised” seeds (not ground) in 150 mL of liquid 2–3 times daily For bowel inflammation, 2–3 tbsp of milled flaxseed soaked in 200–300 mL water and strain after 30 min For hypercholesterolemia, 1–2 tbsp flaxseed oil daily Topical: 30–50 g flaxseed flour as poultice or compress for a moist-heat direct application directly to the skin	Flaxseed should be taken with plenty of water to prevent possible intestinal blockage Patients with ileus should not take flaxseed High mucilage content of flaxseed can delay absorption of other drugs taken at the same time
Garlic	To lower blood pressure and serum cholesterol To prevent atherosclerosis	Fresh clove: one 4 g clove per day Tablet: 300 mg bid to tid standardized to 0.6%–1.3% allicin	Intake of large quantities can lead to stomach complaints Garlic has antiplatelet effects, so patients should discontinue use of garlic at least 7 d before surgery Concomitant use of garlic and anticoagulants can increase the risk of bleeding
Ginger root	As an antiemetic For prevention of motion sickness	Fresh rhizome: 2–4 g/d Powdered ginger: 250 mg 3–4 times daily Tea: 1 cup of tea tid (0.5–1 g dried root in 150 mL boiling water for 5–10 min)	Ginger should not be used by patients with gallstones because of its cholagogic effect It can inhibit platelet aggregation; cases of postoperative bleeding have been reported Large doses of ginger can increase bleeding time in patients taking antiplatelet agents
<i>Ginkgo biloba</i> leaf	To slow cognitive deterioration in dementia To increase peripheral blood flow in claudication To treat sexual dysfunction associated with the use of SSRIs	60–120 mg bid of extract Egb761 standardized to 24% flavonoids and 6% terpenoids	Adverse effects are rare and can include mild stomach or intestinal upset, headache, or allergic skin reaction Ginkgo can inhibit platelet aggregation; reports of spontaneous bleeding have been published Patients should discontinue ginkgo at least 36 h before surgery Concurrent use of ginkgo and anticoagulants, antiplatelet agents, vitamin E, or garlic can increase the risk of bleeding

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Ginseng root	As a tonic during times of stress, fatigue, disability, and convalescence To improve physical performance and stamina	Root: 1–2 g/d Tablet: 100 mg bid of extract standardized to 4%–7% ginsenosides A 2- to 3-week period of using ginseng followed by a 1- to 2-week “rest” period is generally recommended Ginseng is commonly adulterated, especially Siberian ginseng (eleuthero) products	Ginseng has a mild stimulant effect and should be avoided in patients with cardiovascular disease Tachycardia and hypertension can occur Overdosages can lead to ginseng abuse syndrome, characterized by insomnia, hypotonia, and edema Ginseng has estrogenic effects and can cause vaginal bleeding and breast tenderness Ginseng has been shown to inhibit platelets, so patients should discontinue ginseng use at least 7 d before surgery Ginseng should not be used with other stimulants Patients taking antidiabetic agents and ginseng should be monitored to avoid the hypoglycemic effects of ginseng Ginseng can interact with warfarin and cause a decreased INR Siberian ginseng can increase digoxin levels Ginseng can interact with phenelzine (a MAOI) resulting in insomnia, headache, tremulousness, and manic-like symptoms
Glucosamine	For osteoarthritis	500 mg tid with meals Glucosamine is available in the form of sulfate, hydrochloride, or N-acetyl salt; glucosamine sulfate is the form that has been used in most clinical studies	Side effects are generally limited to mild GI symptoms, including stomach upset, heartburn, diarrhea, nausea, and indigestion Glucosamine derived from marine exoskeletons may cause reactions in people allergic to shellfish Glucosamine may raise blood glucose level in patients with diabetes
Goldenseal	Often combined with echinacea to treat colds and other upper respiratory infections Used for diarrhea, dyspepsia, and gastritis Used topically as an eyewash, mouthwash, feminine cleansing product, and skin remedy	Oral: 0.5–1 g of the dried rhizome/root or 2–4 mL tincture (1:10, 60% ethanol) or 0.3–1 mL fluid extract (1:1, 60% ethanol) tid Eyewash: For trachoma infections, 2 drops of a 0.2% aqueous berberine solution tid × 3 week	Avoid using goldenseal during pregnancy and breast feeding; berberine, the principle constituent in goldenseal, can cause uterine contractions and neonatal jaundice Avoid using goldenseal in kidney failure because of inadequate urinary excretion of its alkaloids High dosages or long-term usage can lead to nausea, vomiting, headache, hypotension, bradycardia, leucopenia, and mucosal irritation Berberine can increase the risk of bleeding in patients taking warfarin or an antiplatelet agent Be aware that other herbs containing berberine, including Chinese goldthread and Oregon grape, are sometimes substituted for goldenseal
Grape seed	For conditions related to the heart and blood vessels, such as atherosclerosis, high blood pressure, high cholesterol, and poor circulation For vision problems, diabetic neuropathy or retinopathy, and swelling after an injury or surgery For cancer prevention and wound healing	For general health purposes, 100–300 mg daily of a standardized extract (95% oligomeric proanthocyanidin complexes)	Side effects include headache, dizziness, nausea, and dry, itchy scalp Concomitant use with warfarin or antiplatelet agents can increase risk of bleeding because of the tocopherol content of grape seed oil
Hawthorn leaf with flower	Commonly used in Germany to increase cardiac output in patients with New York Heart Association stage I and II heart failure	160–900 mg water-ethanol extract (30–169 mg procyanidins or 3.5–19.8 mg flavonoids) divided into 2–3 doses	Side effects include GI upset, palpitations, hypotension, headache, dizziness, and insomnia Concomitant use with CNS depressants can have additive CNS effects Hawthorn can potentiate effects of digoxin and vasodilators
Hops	For mood disturbances such as restlessness and anxiety For sleep disturbances Commonly found in combination products with other herbal sedatives	0.5 g of cut or powdered strobile in a single dose; can be taken as tea (0.5 g in 150 mL water), fluid extract 1:1 (0.5 mL), tincture 1:5 (2.5 mL), or dry extract 6–8:1 (60–80 mg) The preparation contains at least 0.35% (v/w) essential oil	Side effects are rare but include drowsiness and allergic reactions Hops is not recommended for use during pregnancy and lactation It can potentiate the sedative effect of CNS depressants (e.g., benzodiazepines, alcohol) and other herbal tranquilizers

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Horse chestnut seed	To relieve symptoms of chronic venous insufficiency	250 mg bid of extract standardized to 50 mg aescin in delayed-release form Unsafe to ingest the raw seed, which contains significant amounts of the most toxic constituent, esculin	Mild GI symptoms, headache, dizziness, and pruritis have been reported Ingestion of high doses can cause renal, hepatic, and hematologic toxicity Concomitant use with anticoagulants can increase the risk of bleeding Horse chestnut can potentiate the effects of hypoglycemic drugs
Kava kava	As an anxiolytic for nervous anxiety, stress, and restlessness As a sedative to induce sleep	Herb and preparations equivalent to 60–120 mg/d of kava pyrones Most clinical trials have used 100 mg tid of extract standardized to 70% kava pyrones for anxiety disorders	Kava should not be used by patients with depression Kava should be avoided in pregnant or nursing women Kava can affect motor reflexes and judgment, so it should not be taken while driving and/or operating heavy machinery Accommodative disturbances have been reported; kava can exacerbate Parkinson disease Extended use can cause a temporary yellow discoloration of skin, hair, and nails Reports have linked kava use to at least 25 cases of severe liver toxicity; sale of products containing kava has been banned in Canada and several European countries Kava has been shown to have additive CNS depressant effects with benzodiazepines, alcohol, and herbal tranquilizers Kava can potentiate the sedative effects of anesthetics, so kava should be discontinued at least 24 h before surgery
Lutein	Commonly used to prevent AMD and cataracts Used to prevent skin cancer, breast cancer, and colon cancer Used to protect against cardiovascular disease	For AMD and cataracts, 6–20 mg/d of lutein from diet For other uses, no established dosage documented Foods containing high concentrations of lutein include kale, spinach, broccoli, and romaine lettuce Not known if supplemental lutein is as effective as natural lutein Supplemental lutein in the form of esters might require a higher fat intake for effective absorption than purified lutein	No major adverse effects and drug interactions have been reported
Lycopene	Commonly used to prevent and treat prostate cancer Used for cancer prevention, atherosclerosis prevention, and reduction of asthma symptoms	For decreasing the growth of prostate cancer, 15 mg supplement bid For prostate cancer prevention, at least 6 mg/d from tomato products (or ≥10 servings/wk) For other uses, no established dosage documented Heat processing converts lycopene in fresh tomatoes from the <i>trans</i> - to the <i>cis</i> -configuration. The <i>cis</i> isomer has better bioavailability Lycopene supplements usually do not specify the type and amount of isomers in their product labeling	Lycopene, when consumed in amounts found in foods, is generally considered to be safe Concomitant ingestion of beta-carotene can increase lycopene absorption Lycopene may reduce cholesterol levels and potentiate the effects of statins
Melatonin	For jet lag, insomnia, shift-work disorder, and circadian rhythm disorders For other medical conditions, including depression, multiple sclerosis, tinnitus, headache, and cancer	For jet lag, 5 mg at bedtime for 2–5 d beginning the day of return For sleep disorders, 0.3–5 mg taken 2 h before bedtime Avoid melatonin from animal pineal gland because of the possibility of contamination.	Avoid use in pregnancy because melatonin decreases serum luteinizing hormone concentrations and increases serum prolactin levels The common adverse reactions include headache, transient depressive symptoms, daytime fatigue and drowsiness, dizziness, abdominal cramps, irritability, and reduced alertness Concomitant use of melatonin with alcohol, benzodiazepines, or other CNS depressants can cause additive sedation Melatonin can affect immune function and may interfere with immunosuppressive therapy Concomitant use with other herbs that have sedative properties (e.g., chamomile, goldenseal, hop, kava, valerian) can produce additive CNS-impairing effects

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Milk thistle fruit	As a hepatoprotectant and antioxidant, particularly for treatment of hepatitis, cirrhosis, and toxic liver damage Used in Europe for the treatment of hepatotoxic mushroom poisoning from <i>Amanita phalloides</i>	Average daily dose is 12–15 g of crude drug or formulations equivalent to 200–400 mg of silymarin	Adverse effects are rare but include diarrhea and allergic reactions Milk thistle can potentiate the hypoglycemic effect of antidiabetic agents
Peppermint	Commonly used for indigestion and irritable bowel syndrome (IBS) Used externally for myalgia and neuralgia	Indigestion: 1 tsp dried leaves in 1 cup of boiling water, steeped for 10 min; drink 4–5 times/d between meals IBS: 1–2 enteric coated cap (0.2 mL of peppermint oil/cap) 2–3 times/d. Take peppermint ≥2 h before or after an acid-reducing drug to ensure adequate absorption	Peppermint, in amounts normally found in food, is likely to be safe Larger supplemental amounts can cause side effects including heartburn, flushing, headache, and mouth sores Hypersensitivity reactions, contact dermatitis, and exacerbations of asthma may occur Peppermint can exacerbate symptoms in patients with gastroesophageal reflux disease (GERD) because it can relax the lower esophageal sphincter Peppermint tea has been shown to reduce free testosterone levels in men Peppermint can decrease the blood levels of cyclosporine and drugs that metabolized by the CYP3A4 isoenzyme
Probiotics	Prevent and treat antibiotic-associated diarrhea and acute infectious diarrhea Relieve symptoms of IBS Treat atopic dermatitis for at-risk infants	Dosage varies based on preparations <i>Lactobacillus</i> sp., <i>Bifidobacterium</i> sp., <i>Saccharomyces boulardii</i> are the most widely used organisms For <i>Lactobacillus</i> sp., 10 billion CFUs/d For <i>Lactobacillus</i> sp./ <i>Bifidobacterium</i> sp., 100 million to 35 billion CFUs/d For <i>Saccharomyces boulardii</i> , 250–500 mg/d Quality of products varies among brands Refrigeration is required to maintain potency	Avoid use in short-gut syndrome and severe immunocompromised condition Common adverse effects include flatulence, mild abdominal discomfort, and, rarely, septicemia
Red clover flower	Commonly used for conditions associated with menopause, such as hot flashes, cardiovascular health, and osteoporosis Used for PMS, benign prostate hyperplasia, and cancer prevention Used topically to treat psoriasis, eczema, and other rashes	For hot flashes, 40 mg/d of the isoflavones extract (Promensil) For other conditions, no established dosage documented	Red clover has estrogenic activity and should be avoided during pregnancy and lactation Women with hormone-dependent conditions (e.g., breast, uterine, and ovarian cancer, and endometriosis and uterine fibroids) and men with prostate cancer should also avoid taking red clover Side effects include headache, myalgia, nausea, and rash Red clover contains coumarin derivatives and can increase the risk of bleeding in those who are taking anticoagulants or antiplatelet drugs Preliminary report suggests that red clover might antagonize the effects of tamoxifen Some evidence suggests that red clover can increase the levels of drugs that metabolized by the cytochrome P450 3A4 isoenzyme (e.g., lovastatin, ketoconazole, itraconazole, fexofenadine, and triazolam)
SAME (S-adenosyl-L-methionine)	For treatment of osteoarthritis, depression, fibromyalgia, and liver disease	For osteoarthritis, 200 mg tid For depression and fibromyalgia, 800 mg bid For liver disease, 600–800 mg bid	Common side effects include flatulence, nausea, vomiting, and diarrhea SAME can cause anxiety in people with depression and hypomania in people with bipolar disorder Concurrent use of SAME and other antidepressants can cause serotonin syndrome
Saw palmetto berry	To treat symptomatic benign prostatic hyperplasia and irritable bladder	160 mg bid of extract standardized to 85%–95% fatty acids and sterols	Adverse effects are rare but include headache, nausea, and upset stomach High doses can cause diarrhea

HERB OR NUTRITIONAL SUPPLEMENT	COMMON USES	REASONABLE ADULT ORAL DOSAGE*	PRECAUTIONS AND DRUG INTERACTIONS
Soy	Commonly used for cholesterol reduction in combination with a low-fat diet Used for menopausal symptoms and for prevention of osteoporosis and cardiovascular disease in postmenopausal women	For lowering cholesterol, 25–50 g/d of soy protein For hot flashes, 20–60 g/d of soy protein For osteoporosis, 40 g/d of soy protein containing 90 mg isoflavones	Soy, when consumed as whole foods (e.g., tofu or soy milk), has minimal adverse effects Consumption of large amounts of soy can cause gastric complaints such as constipation, bloating, and nausea Long-term use of soy tablets containing isoflavones (150 mg/d for 5 years) has been shown to cause endometrial hyperplasia
St. John's wort	Used for treatment of mild to moderate depression May have antiinflammatory and antiinfective activities	300 mg tid of hypericum extract standardized to 0.3% hypericin	St. John's wort should not be used in pregnancy Side effects include dry mouth, GI upset, dizziness, fatigue, and constipation St. John's wort can induce photosensitivity, especially in fair-skinned individuals It can cause serotonin syndrome if used with other antidepressants, including SSRIs, or other serotonergic drugs It has been shown to induce CYP3A4 and decrease blood levels of many drugs such as indinavir, nevirapine, cyclosporine, digoxin, theophylline, simvastatin, oral contraceptive pills, and warfarin St. John's wort should be discontinued at least 5 d before surgery to avoid any potential drug interactions
Stinging nettle root	Approved in Germany for difficulty in urination in BPH stage 1 and 2	4–6 g/d of cut root; can be taken as tea (1.5 g in 150 mL boiling water for 10–20 min, tid), fluid extract 1:1 (1.5 mL tid), tincture 1:5 (5–7.5 mL tid), or dry extract 5.4–6.6:1 (0.22–0.33 g tid)	Occasionally, mild GI upsets may occur No known interactions with drugs
Turmeric root	Approved by the German Commission E for dyspeptic conditions Used extensively in Ayurveda medicine for its antiinflammatory and antiarthritic effects Other uses include allergic rhinitis, depression, nonalcoholic fatty liver disease, osteoarthritis and cancer	For dyspeptic conditions: 1.5–3 g/d of cut root as tea infusion or equivalent preparations (e.g., powder, extract, tincture) The Commission E monograph requires turmeric to contain not less than 3% curcuminoids, calculated as curcumin and not less than 3% volatile oil	Side effects are uncommon and are generally limited to mild stomach distress Topical curcumin can cause allergic contact dermatitis Individuals with bile duct obstruction or gallstones should avoid curcumin due to its stimulating effects on the gallbladder
Valerian root	Used as a mild sedative for insomnia and anxiety	2–3 g of dried root or 1–3 mL of tincture, qd to several times per day Two clinical trials found 400–450 mg of the root extract effective for insomnia	Valerian has a bad odor and can cause morning drowsiness Long-term administration can lead to paradoxical stimulation, including restlessness and palpitations Because of the risk of benzodiazepine-like withdrawal, valerian should be tapered over a period of several weeks before surgery It can potentiate the sedative effect of CNS depressants (e.g., benzodiazepines, alcohol) and other herbal tranquilizers

\*Doses presented in the table are adapted from the German Commission E Monographs and/or data from clinical trials. Products from different manufacturers vary considerably. A reliable product should have a label clearly stating the botanical name of the herb and milligram amount contained in the product. Standardized extracts should be used whenever possible and are often disclosed on the label of quality products.

AMD, Age-related macular degeneration; BPH, benign prostatic hyperplasia; CFU, colony-forming unit; CHD, coronary heart disease; CNS, central nervous system; CYP3A4, cytochrome P450 3A4; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FDA, Food and Drug Administration; GI, gastrointestinal; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; INR, international normalized ratio; LDL, low-density lipoprotein; MAOI, monoamine oxidase inhibitor; PMS, premenstrual syndrome; SLE, systemic lupus erythematosus; SSRIs, selective serotonin reuptake inhibitors; UTIs, urinary tract infections.

## TOXIC CHEMICAL AGENTS REFERENCE CHART

Method of

Laurie A.M. Hommema, MD; and Kevin Hommema, BSME

Toxic chemical agents are poisonous vapors, aerosols, gases, liquids, or solids that have toxic effects on people, animals, or plants. Most of these agents are liquid at room temperature and are disseminated as vapors and aerosols. They may be released as bombs, sprayed from aerosolizing devices, through ventilation systems or introduced to food or water supply. Some of these agents are highly toxic and persistent, features that can render a site uninhabitable and require costly and potentially hazardous decontamination and remediation. Health effects range from irritation and burning of skin and mucous membranes to rapid cardiopulmonary collapse and death.

Efficient deployment of hazardous materials (HazMat) teams is critical to control a chemical agent attack. Although all major cities and emergency medical systems have plans and equipment in place to address this situation, physicians and other health professionals must be aware of principles involved in managing a patient or multiple patients exposed to these agents. Chemical weapon agents have a high potential for secondary contamination from victims to responders. This requires that medical treatment facilities have clearly defined procedures for handling contaminated casualties, many of whom will transport themselves to the facility. Precautions must be used until thorough decontamination has been performed or the specific chemical agent is identified. Healthcare professionals must first protect themselves (e.g.,

by using protective suits, respiratory protection, and chemical-resistant gloves) because secondary contamination with even small amounts of these substances (particularly nerve agents such as VX) may be lethal.

Primary detection of exposure to chemical agents is based on the signs and symptoms of the potential victim (Table 1). Confirmation of a chemical agent, using detection equipment or laboratory analyses, takes considerable time and will not likely contribute to the early management of mass casualty victims. Several patients presenting with the same symptoms should alert physicians and hospital staff to the possibility of a chemical attack. If a chemical attack occurs, most victims will likely arrive within a short time. This situation differentiates a chemical attack from a biological attack involving infectious microorganisms, which can take days for symptom onset. Additional diagnostic clues include the following:

- Unusual temporal or geographic clustering of illness
- Any sudden increase in illness in previously healthy persons
- Sudden increase in nonspecific syndromes (e.g., sudden unexplained weakness in previously healthy persons; dimmed or blurred vision; hypersecretion, inhalation, or burn-like syndrome)

A coordinated communication network is critical for transmitting reliable information from the incident scene to treatment facilities. Any suspicious or confirmed exposure to a chemical weapons agent should be reported to the local health department, local Federal Bureau of Investigation office, National Response Center (800-424-8802), and the Centers for Disease Control and Prevention (770-488-7100).

**TABLE 1** Quick Reference Chart on Chemical Weapon Agents

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
<b>Cyanides—Asphyxiant/Blood</b>								
Cyanogen chloride (CK) Hydrogen cyanide (AC)	“Cherry red” skin Resp: SOB, chest tightness, hyperventilation, resp arrest GI: nausea, vomiting CV: ventricular arrhythmias, hypotension, cardiac arrest, shock CNS: anxiety, headache, drowsiness, weakness, apnea, convulsions, seizure, coma Metabolic acidosis and increased concentration of venous oxygen (possibly also cyanosis)	Rapid, seconds to minutes	Bitter almond, musty, or chlorine-like	Binds cellular cytochrome oxidase, causing chemical asphyxia	Cyanide, thiocyanate, serum lactate levels Venous and arterial partial oxygen pressure	Immediate treatment of symptomatic patients is critical. Hydroxocobalamin (vitamin B <sub>12a</sub> [Cyanokit]) administered IV with sodium thio sulfate <sup>5,†</sup> Activated charcoal <sup>1</sup> for oral exposure Mechanical ventilation as needed Circulatory support with crystalloids and vasopressors Metabolic acidosis corrected with IV sodium bicarbonate Seizures controlled with benzodiazepines	Sodium nitrite and sodium thiosulfate (Nithiodote); repeat one-half initial doses of both agents in 30 min if inadequate clinical response; amyl nitrite <sup>1</sup> capsules are available for first aid until intravenous access is achieved. Hydroxocobalamin (vitamin B <sub>12a</sub> , Cyanokit)	Cyanide antidote kits are commercially available. CNS effects may be confused with carbon monoxide and hydrogen sulfide poisoning. Non-persistent, not contact hazard.
<b>Incapacitating Agents</b>								
Agent 15 3-quinuclidinyl benzilate (BZ)	May appear as drug intoxication with erratic behaviors, hallucinations. Mydriasis, blurred vision, dry mouth, dry skin, possible atropine-like flush, initial rise in heart rate, hyperthermia, decreased level of consciousness, confusion, disorientation, impaired memory.	Hours—up to 36 h if only on skin 0–4 h: parasympathetic blockade and mild CNS effects 4–20 h: stupor with ataxia and hyperthermia 20–96 h: full-blown delirium Resolution phase: paranoia, deep sleep, reawakening, crawling, climbing automatisms, eventual reorientation	Odorless	Competitive inhibitor of acetylcholine muscarinic receptor		Support, intravenous fluids	Physostigmine salicylate (Antilirium) <sup>1</sup>	Persistent in soil and water and on contact surfaces. Contact hazard.

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
<b>Nerve Agents</b>								
Cyclohexyl sarin (GF) Sarin (GB) Soman (GD) Tabun (GA) VX	Most toxic of known chemical agents May be confused with organophosphate and carbamate pesticide poisoning Eyes: excessive lacrimation, miosis may be present and blurred vision Resp: rhinorrhea, bronchospasm, resp failure GI: hypersalivation, nausea, vomiting, diarrhea Skin: localized sweating Cardiac: sinus bradycardia Skeletal muscles: fasciculations followed by weakness, flaccid paralysis CNS: loss of consciousness, convulsions, apnea, seizures	Vapor: seconds Liquid: minutes or hours Symptom onset may be delayed up to 18 h, particularly for localized exposures.	GB, VX: none GA: fruity GD: camphor-like	Irreversible acetylcholinesterase inhibitors	Erythrocyte or serum cholinesterase activity to confirm exposure	Rapid establishment of patent airway Early administration of 2-PAM (pralidoxime [Protopam]) is critical to minimize permanent agent inactivation of acetylcholinesterase (i.e., "aging"). Benzodiazepines to control nerve agent-induced seizures Airway and ventilatory support as needed	Atropine and 2-PAM Additional doses until bronchial secretions are cleared and ventilation improved	Atropine, 2-PAM, and diazepam <sup>1</sup> are available in autoinjector kits through the US military. VX is a contact hazard.

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
<b>Pulmonary or Choking Agents</b>								
Acrolein Ammonia (NH <sub>3</sub> ) Chlorine (Cl) Chloropicrin (PS) Diphosgene (DP) Nitrogen oxides (NO <sub>x</sub> ) Perfluoroisobutylene (PFIB) Phosgene (CG) Sulfur dioxide (SO <sub>2</sub> )	Degree of water solubility of the agent influences onset and severity of respiratory injury. Eye and airway irritation, dyspnea, chest tightness, rhinorrhea, hypersalivation, cough, wheezing High-dose inhalation can cause laryngospasm, pneumonitis, and acute lung injury with delayed onset (≤ 48 h) of acute resp distress syndrome. Chest radiograph: hyperinflation, noncardiogenic pulmonary edema	Rapid or delayed 1–24 h; rarely up to 72 h	CG: freshly mown hay or grass			Supportive measures Specific treatment depends on the agent IV fluids for hypotension; no diuretics Ventilation with or without positive airway pressure Bronchodilators for bronchospasm Methylprednisolone <sup>1</sup> may be effective in preventing noncardiogenic pulmonary edema.	No specific antidote	Easily absorbed via mucous membranes of eyes, nose, oropharynx. May be confused with inhalation exposure to industrial chemicals (e.g., HCl, Cl <sub>2</sub> , NH <sub>3</sub> ). Not contact hazard.
<b>Riot Control Agents</b>								
Mace (CN) Tear gas (CS)	Metallic taste Burning and pain on mucosal membranes and skin Eyes: irritation, pain, tearing, blepharospasm Airways: burning in nose and mouth, respiratory discomfort, bronchospasm (may be delayed 36 h) Skin: tingling, erythema	Immediate	CN: apple blossom CS: pepper	SN2 alkylating agents	No specific laboratory tests	Supportive care Irrigation as necessary Persons with asthma, emphysema might need oxygen, inhaled bronchodilators, steroids, assisted ventilation. Lotions, such as calamine <sup>1</sup> for persistent erythema		Not contact hazard

**TABLE 1** Quick Reference Chart on Chemical Weapon Agents—cont'd

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
	Nausea and vomiting are common. CN can cause corneal opacification.							
<b>Vesicant or Blister Agents</b>								
General	Clinical effects depend on extent and route of exposure.	Effects may be delayed, appearing hours after exposure		Intracellular enzyme and DNA alkylating agents		Immediate decontamination within 2 min if able Supportive care Thermal burn-type treatment Symptomatic management of lesions		Primary liquid hazard. May be confused with skin exposure to caustic irritants (e.g., NaOH, NH <sub>3</sub> ). Persistent contact hazard.
Sulfur mustard (H) Distilled mustard (HD)	Skin: erythema and blisters (may be delayed ≤ 8 h), pruritus Eye: irritation, conjunctivitis, corneal damage, lacrimation, pain, blepharospasm Resp: mild to marked acute airway damage, pneumonitis within 1–3 days, respiratory failure GI effects (nausea, vomiting, diarrhea) may be present Bone marrow stem cell suppression leading to pancytopenia and increased susceptibility to infection Fever, sputum production	Delayed 2–48 h	Garlic, horseradish, or mustard			Skin: silver sulfadiazine <sup>1</sup> Eye: homatropine <sup>1</sup> ophthalmic ointment Pulmonary: antibiotics, bronchodilators, steroids Colony-stimulating factor may be helpful for leukopenia. Systemic analgesic and antipruritics Early use of PEEP or CPAP Maintain fluid and electrolyte balance (do not excessively fluid resuscitate as in thermal burns).	No specific antidote	Combination with lewisite (called mustard-Lewisite or HL) results in rapid effects of lewisite and delayed effects of mustard agents.

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
Lewisite (L)	<p>Skin: gray area of dead skin within 5 min, erythema within 30 min, blistering 2–3 h, immediate irritation or burning pain on contact, severe tissue necrosis</p> <p>Eye: pain, blepharospasm, conjunctival and lid edema</p> <p>Airway: pseudomembrane formation, nasal irritation</p> <p>Intravascular fluid loss, hypovolemia, shock, organ congestion, leukocytosis</p>	Immediate	Fruity or geranium				British anti-lewisite (BAL or dimercaprol)	More volatile than mustard. Damages eyes, skin, and airways by direct contact.
Phosgene oxime (CX)	Burning, irritation, wheal-like skin lesions, eye and airway damage, conjunctivitis, lacrimation, lid edema, blepharospasm	Immediate	Freshly mown hay	Urticant, nonvesicant agent	No distinctive laboratory findings	<p>Parenteral methylprednisolone<sup>1</sup> may be effective in preventing noncardiogenic pulmonary edema.</p> <p>Experimental: aerosolized dexamethasone<sup>1</sup> and theophylline<sup>1</sup> for pulmonary involvement</p>	No antidote	Vapor extremely irritating; vapor and liquid cause tissue damage upon contact.

**TABLE 1** Quick Reference Chart on Chemical Weapon Agents—cont'd

CHEMICAL AGENT	DIAGNOSTIC CONSIDERATIONS					TREATMENT CONSIDERATIONS*		
	SIGNS AND SYMPTOMS	SYMPTOM ONSET	ODOR	ACTION	TESTING	TREATMENT	ANTIDOTE	COMMENTS
<b>Vomiting (Arsine-Based) Agents</b>								
Adamsite (DM) Diphenylchlorarsine (DA) Diphenylcyanoarsine (DC)	Eyes: conjunctival irritation, tearing, and blepharospasm Airways: sneezing, mucosal lung irritation, edema, progressive cough, wheezing Cardiac: tachypnea, tachycardia GI: intestinal cramps, emesis, diarrhea Skin: erythema, edema at the site of dermal contact CNS: depression, syncope	All rapidly acting within minutes	DA: none DC: garlic DM: burning fireworks	Arsine gas depletes erythrocyte glutathione and causes hemolysis.	Chest radiograph to rule out chemical pneumonitis	Supportive care Monitor for hemolysis Wheezing or dyspnea: may need albuterol inhalation Eye irrigation (water, normal saline, lactated Ringer's) in patients with ocular exposure Treat repetitive emesis with IV hydration and antiemetics. Blood transfusion may be required. Exchange transfusion may be required. Hemodialysis may be useful in decreasing arsenic level and treating renal failure.		Primary route of absorption is through respiratory system.

\*Different situations can require different treatment and dosage regimens. Please consult other references as well as a regional poison control center (800-222-1222), medical toxicologist, clinical pharmacologist, or other drug information specialist for definitive dosage information, especially dosages for pregnant women and children.

†Available in Europe.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Investigational drug in the United States.

CNS, Central nervous system; CPAP, continuous positive airway pressure; CV, cardiovascular; GI, gastrointestinal; 2-PAM, pralidoxime (2-pyridine aldoxime methyl chloride); PEEP, positive end-expiratory pressure; resp, respiratory; SOB, shortness of breath.

## MONKEYPOX

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

The monkeypox virus is an *Orthopoxvirus*, the same genus as smallpox (variola) and cowpox (vaccinia). Monkeypox is a contagious zoonotic disease, and it is endemic in certain parts of Africa. It was first isolated in 1958 in Copenhagen from a colony of laboratory monkeys sent from Singapore for polio virus research. In 1970, the first proven case of human monkeypox was diagnosed in the Democratic Republic of the Congo. Despite being named *monkeypox*, African rodents such as Gambian pouched rats, dormice, and African squirrels, rather than monkeys, are considered to be the most likely reservoir of the virus.

There have been isolated cases and a few outbreaks of monkeypox in various countries including the United Kingdom and the United States. In 2003, the United States reported an outbreak of 71 probable cases (35 laboratory-confirmed) that resulted from direct contact with prairie dogs sold as pets. The prairie dogs were found to have been infected when they were housed with Gambian pouched rats imported from Ghana. There were no reported deaths in the 2003 outbreak. Cases in a 2018 outbreak in the United Kingdom were eventually traced back to travelers who had visited Nigeria.

In May 2022, cases of monkeypox were confirmed in the United Kingdom and traced to an individual who had traveled from Nigeria. Since then, tens of thousands of cases have been confirmed in North America, South America, Europe, Asia, Africa, and Australia. The majority of these cases had no history of travel to an endemic African country. The 2022 outbreak is considered to be the first example of widespread community transmission outside of Africa. On July 23, 2022, the World Health Organization declared this outbreak of monkeypox a Public Health Emergency of International Concern.

### Epidemiology

The eradication of smallpox in 1977 and the discontinuation of routine smallpox immunization paved the way for monkeypox to gain worldwide clinical relevance. This hypothesis was supported by a 2005–2007 study in the Democratic Republic of the Congo that reported a 20-fold increase in monkeypox compared with the incidence seen in the 1980s. Those who were not immunized for smallpox had a fivefold higher risk of monkeypox infection compared with those who were vaccinated.

The mortality risk associated with monkeypox varies with respect to the monkeypox strain or clade. Two distinct clades of monkeypox exist in different geographic regions of Africa. In Central Africa, where clade I is prevalent, the fatality rate has been reported to be approximately 11%, with deaths generally occurring during the second week of illness. Clade II, which has been isolated in West Africa, is associated with milder disease and a fatality rate of around 1%.

Outcomes in the United States are favorable. Of the initial 10,000 cases reported, there were no deaths. This may be a result of milder clade II, subclade IIb, infections and also could be related to a healthier patient population, greater availability of supportive medical care, and that most of the older adult population in the United States is vaccinated against smallpox.

As a zoonotic infection, animal-to-human transmission of monkeypox has been confirmed. Animal-to-human transmission can result from contact with infected papules, vesicles, pustules, or body fluids; ingesting infected meat; or bites and scratches.

A variety of animals, including nonhuman primates, and especially rodents, may contract monkeypox. Symptoms and severity of symptoms may differ among animals. Some may have symptoms that are mild, and others may have fever, upper respiratory illness, cough, and a papular-pustular rash. Animal-to-animal transmission may occur through the fecal-oral route, respiratory droplets, contact with wounds, and eating infected meat.

Human-to-human transmission occurs through exposure to infected skin lesions, body fluids, respiratory secretions, and fomites. The virus can be spread through small abrasions in the skin and mucous membranes. Sexual activity, largely among gay or bisexual men, is a frequently suspected route of transmission. The strong likelihood of sexually related transmission is supported by the findings of primary genital, anal, and oral mucosal lesions, which probably represent the inoculation site. Vertical transmission of monkeypox virus from mother to child has been proven.

Though the virus has been found in semen and vaginal secretions, it is uncertain if the disease can be transmitted through these fluids. It has not been determined if infected asymptomatic patients can spread the virus. A case of monkeypox in a health-care worker was possibly transmitted through a contaminated bedsheet used by a diseased patient.

### Risk Factors

Immunocompromised patients and children are at risk of complications. Risk factors for transmission include direct contact with infected lesions as well as through fomites including shared bedding, towels and utensils. In a United States study of 7500 cases of monkeypox from May 17 to July 22, 2022, 99% of the cases were male, and 94% reported recent male-to-male sexual or intimate conduct. Similar to data from other countries, 41% of these patients were HIV-positive. It is unknown if HIV infection increases a person's risk of acquiring monkeypox disease after exposure. Those who are not virologically suppressed with highly active antiretroviral therapy (HAART) may be at increased risk of severe disease.

At the onset of the 2022 outbreak, disease spread disproportionately among men who had sex with men. This suggested amplification of transmission through sexual networks.

### Pathophysiology

Monkeypox virus is a large, linear, double-stranded DNA virus with a genome size of around 190 kb. The virus replicates in the cytoplasm of vertebrate and invertebrate cells, although DNA viruses typically replicate and express their genomes in the nucleus. The virus invades the cell, replicates in the cytoplasm, and causes cell death.

Following viral entry through skin or mucous membranes, the monkeypox virus replicates at the inoculation site and then spreads to local lymph nodes. This is followed by a viremia that leads to viral spread and seeding at other sites.

The large size of the monkeypox virus readily generates an immune response. Genomic analysis reveals that the virus may be actively mutating and adapting to human host immune responses.

### Prevention

General safety measures such as use of personal protective equipment should be employed by healthcare workers and laboratory researchers who may come in contact with the monkeypox virus. Hospitalized patients with confirmed or suspected monkeypox should be isolated. Lesions should be covered by gloves, a gown, or a sheet. Routine cleaning and disinfection procedures should be followed, and special attention should be paid to soiled laundry because fomites may be a cause of monkeypox virus transmission. Intubation, extubation, and any procedures likely to spread oral secretions should be performed in an airborne infection isolation room. To date, there have been no cases of monkeypox transmitted by blood transfusion, organ transplantation or implantation, infusion, or transfer of human cells, tissues, or cellular or tissue-based products.

Patients and household members who are isolated at home should use face masks and gloves. Lesions should be covered, and good hand hygiene should be routine. Laundering linens and towels with detergent and water should be sufficient.

Activities that could aerosolize dried material from lesions (e.g., use of portable fans, dry dusting, sweeping, vacuuming) should be avoided. If possible, use a separate bathroom if there are others who live in the same household. Those infected with monkeypox should avoid contact with animals (specifically mammals), including pets.

Though it is uncertain if the disease can be transmitted through intercourse, it is recommended that condoms be used for 12 weeks after contracting the illness.

## Vaccinations

Immunization against smallpox will confer cross-reactive protection against monkeypox.

There are two available vaccines that can reduce the risk of developing monkeypox: the modified vaccinia Ankara (MVA) vaccine (JYNNEOS in the United States, IMVANEX in the European Union, and IMVAMUNE in Canada) and the ACAM2000 vaccine. Supplies of both vaccines are limited.

JYNNEOS is a live, nonreplicating MVA virus that was approved in 2019 by the U.S. Food and Drug Administration (FDA) for the prevention of monkeypox. JYNNEOS is administered subcutaneously as a two-dose series delivered 28 days apart. The standard FDA approved regimen involves a subcutaneous route of administration with an injection volume of 0.5 mL. In the context of the current national Public Health Emergency, an alternative regimen may be used for people age 18 years or older under an Emergency Use Authorization. This alternative regimen involves an intradermal route of administration with an injection volume of 0.1 mL. Experience with JYNNEOS is limited, but serious side effects are expected to be minor and rare. Booster doses are recommended. Since August 9, 2022, the standard regimen has been authorized for people younger than 18 years old under an Emergency Use Authorization. Peak immunity is expected to be reached 14 days after the second dose of JYNNEOS vaccine. Because JYNNEOS is based on a live, attenuated non-replicating orthopoxvirus, JYNNEOS typically may be administered without regard to timing of other vaccines. The JYNNEOS vaccine is recommended as an alternative to the older ACAM2000 vaccine.

ACAM2000 is a single-dose vaccine administered through the scarification (multiple puncture) technique. It requires 15 percutaneous jabs with a stainless-steel bifurcated needle that is dipped into the reconstituted vaccine. The technique produces a severe cutaneous reaction (development of a pustule or ulcer that will eventually scab over) known as a *take*, eventually leaving a dime-sized scar. This vaccination is a derivative of the Dryvax method that was used to eradicate smallpox worldwide. Some patients may prefer the proven effectiveness of the ACAM2000 vaccine over the newer JYNNEOS vaccine.

Because the ACAM2000 vaccine is a replicating virus, it has a number of contraindications: immunocompromise, age younger than 1 year, pregnancy, breastfeeding, atopic dermatitis and exfoliative skin conditions, known underlying cardiac disease or significant cardiac risk factors, and serious allergy to a vaccine component. Individuals should isolate after immunization with the ACAM2000 vaccine if potential close contacts have any of the aforementioned conditions. If possible, consider delaying other vaccines when administering ACAM2000, due to the reactogenicity profile of ACAM2000. Live vaccines and ACAM2000 should be separated by at least 28 days. Healthcare workers scheduled to receive an annual purified protein derivative (PPD) skin test for tuberculosis screening should not receive the skin test until more than 1 month after ACAM2000 vaccination.

Myopericarditis has been associated with the ACAM2000 vaccine. The risk of myopericarditis resulting from the JYNNEOS vaccine is uncertain. As a precaution, it is recommended that the mRNA SARS-CoV-2 vaccine be administered no sooner than 4 weeks after the ACAM2000 or JYNNEOS vaccine.

Adverse reactions to either vaccine should be reported to the Vaccine Adverse Event Reporting System.

## Preexposure Prophylaxis

The JYNNEOS vaccine has been recommended as preexposure prophylaxis (PrEP) to select persons at risk for orthopoxvirus infection in the occupational setting such as research laboratory personnel working with poxviruses, specialized clinical laboratory personnel performing diagnostic testing for orthopoxviruses, and designated response team members.

**TABLE 1** Interim Exposure Risk Assessment for Individuals Exposed to the Monkeypox Virus in a Community Setting\*

### High-Risk Exposure Characteristics

- Unprotected contact between an exposed individual's broken skin or mucous membranes and the skin lesions or bodily fluids from a patient with monkeypox (e.g., inadvertent splashes of patient saliva to the eyes or mouth of a person), or soiled materials (e.g., linens, clothing)

or

- Being inside the patient's room or within 6 feet of a patient with monkeypox during any medical procedures that may create aerosols from oral secretions (e.g., cardiopulmonary resuscitation, intubation) or activities that may resuspend dried exudates (e.g., shaking of soiled linens) without wearing a NIOSH-approved particulate respirator with N95 filters or higher and eye protection

### Intermediate-Risk Exposure Characteristics

- Unprotected contact between an exposed individual's intact skin and the skin lesions or bodily fluids from a patient with monkeypox, or soiled materials (e.g., linens, clothing)

or

- Activities resulting in contact between an exposed individual's clothing and the patient with monkeypox's skin lesions or bodily fluids, or their soiled materials (e.g., during turning, bathing, or assisting with transfer) while not wearing a gown

### Low/Uncertain Risk Exposure Characteristics

- Entry into the contaminated room or patient care area of a patient with monkeypox without wearing all recommended PPE, and in the absence of any exposures above

### No Risk Exposure Characteristics

- No contact with a person with monkeypox, their potentially infectious contaminated materials, or entry into their living space

\*Modified from Centers for Disease Control and Prevention: *Monitoring and risk assessment for persons exposed in the community* (website). <https://www.cdc.gov/poxvirus/monkeypox/clinicians/monitoring.html>.

## Postexposure Prophylaxis

JYNNEOS and ACAM2000 may be used for postexposure prophylaxis (PEP). Exposures in both community and healthcare settings should be assessed to determine the risk of monkeypox virus transmission.

The Centers for Disease Control and Prevention (CDC) has established guidelines for PEP based on assessment of the risk of transmission resulting from the exposure. Risk may be defined as *high*, *intermediate*, *low*, or *none* (Table 1). For patients with high-risk exposure, PEP is recommended. For those with intermediate-risk exposure, initiation of PEP is a clinical decision based on determination of the patient's risk-benefit ratio. If the degree of risk is low, PEP is not recommended. Monitoring for symptoms of disease is recommended for all individuals with any degree of exposure. Monitoring and PEP are not recommended if there has been no exposure. The need for PEP should be made in consultation with public health authorities.

The CDC has broadened the criteria for PEP, defined as Expanded Post-Exposure Prophylaxis (PEP++). PEP++ is recommended for any of the following persons:

- People who are known contacts to someone with monkeypox who are identified by public health authorities—for example, via case investigation, contact tracing, or risk exposure assessment
- People who are aware that a recent sex partner within the past 14 days was diagnosed with monkeypox
- Certain gay, bisexual, or other men who have sex with men, or transgender and gender diverse people who have sex with men

and have had any of the following within the past 14 days: sex with multiple partners (or group sex); sex at a commercial sex venue; or sex in association with an event, venue, or defined geographic area where monkeypox transmission is occurring. If administered within 4 days of exposure, PEP with JYNNEOS may prevent disease. If given between days 4 and 14 of exposure, vaccination is thought to reduce the symptoms of monkeypox but not prevent the disease.

**Pregnancy/Breastfeeding**

Monkeypox can pose considerable risks to the fetus. Miscarriages, stillbirth, preterm birth, and neonatal monkeypox have been reported when pregnant women contract monkeypox. Fetal ultrasound monitoring is recommended in cases of maternal monkeypox virus infection, and subsequent management should be based on the presence of ultrasound anomalies such as fetal hepatomegaly or hydrops. The sensitivity of molecular detection of monkeypox virus in the amniotic fluid is unknown. By analogy with cytomegalovirus, toxoplasmosis, and Zika virus infections, it is likely that monkeypox virus is shed in the amniotic fluid when the fetal kidneys produce sufficient urine (i.e., after 18 to 21 weeks’ gestation).

While most nonpregnant adults with monkeypox experience mild illness, those with the infection who are pregnant, recently pregnant, or breastfeeding should be prioritized for treatment. These individuals may be at increased risk of severe disease and transmitting infection to the fetus or newborn. Following consultation with the CDC, tecovirimat should be considered for first-line treatment. Animal studies have suggested the risk of teratogenicity from brincidofovir and cidofovir.

JYNNEOS can be offered to people who are pregnant or breastfeeding who are otherwise eligible. The risks and benefits of JYNNEOS should be discussed with the patient using shared decision making.

ACAM2000 is a replicating viral vaccine licensed for prevention of smallpox. Vaccination with ACAM2000 is contraindicated in people who are pregnant or breastfeeding, due to risk of pregnancy loss, congenital defects, and vaccinia virus infection in fetuses and newborns.

Given the risk of neonatal transmission of monkeypox virus from close contact and the potential for severe disease in newborns, direct contact between a mother in isolation for monkeypox and her newborn is not advised.

**Children**

Covering lesions and trying to prevent scratching are especially important in children because of the risk of auto-inoculation and the risk of spreading the pox to the eyes. Maintenance of hydration is important. Fluid intake may be limited because of mouth lesions and general malaise, and fluid loss may be significant as a result of multiple and open lesions. Children should be closely monitored for complications and severe illness. Though most cases will resolve without a problem, treatment should be considered for children in the groups noted in Table 2.

**Clinical Manifestations**

In patients with classic monkeypox, the incubation period from time of exposure to clinical illness is usually 5 to 13 days, but it may be up to 21 days.

The clinical manifestations of monkeypox are usually mild, and patients may have subclinical infection or be asymptomatic. In rare situations, patients may develop life-threatening illness. The duration of symptoms is usually 2 to 4 weeks. Most patients recover without specific treatment. Common prodromal symptoms include headache, fatigue, fever, chills, myalgias, backache, and sore throat. After 1 to 2 days, mucosal lesions develop in the mouth closely followed by skin lesions on the face and extremities (including palms and soles). More lesions tend to be on the head and extremities than on the trunk. Skin lesions may appear in crops at the site of inoculation or be generalized. The rash may or may not spread to the rest of the body, and the total

**TABLE 2** High-Risk Children and Adolescents with Monkeypox to be Considered for Treatment\*

- Those with complications (e.g., pneumonia, sepsis, ocular lesions, cellulitis, or abscess)
- Those with severe disease (e.g., hemorrhagic disease, confluent lesions, encephalitis, airway obstruction caused by lymphadenopathy, or other conditions requiring hospitalization)
- Children and adolescents at risk of severe disease, including:
  - Children under 8 years of age
  - Children and adolescents with immunocompromising conditions
  - Children and adolescents with a history or presence of atopic dermatitis or other active exfoliative skin conditions (e.g., eczema, burns, impetigo, varicella zoster, herpes simplex, severe acne, severe diaper dermatitis with extensive areas of denuded skin, psoriasis, or Darier disease [keratosis follicularis])
  - Children and adolescents with aberrant infections, such as those involving the eyes, face, or genitals

\*Children and adolescents, especially those with high-risk conditions, who have been exposed to persons with suspected or confirmed monkeypox may be eligible for PEP with vaccination, antiviral medication, or immune globulin. Antiviral medications, primarily tecovirimat, can be considered for use as monkeypox PEP in unusual circumstances (e.g., when vaccine is contraindicated due to an allergy to vaccine components). The effectiveness of antiviral medications as monkeypox PEP is unknown. Modified from Centers for Disease Control and Prevention: *Clinical considerations for monkeypox in children and adolescents*. Available at: <https://www.cdc.gov/poxvirus/monkeypox/clinicians/pediatric.html#print>. Updated August 22, 2022.

number of lesions may vary from a few to thousands. Over the following 2 to 4 weeks, the lesions evolve in 1- to 2-day increments through macular, papular, vesicular, and pustular phases. Lesions are characterized as firm, deep-seated, and 2 to 10 mm in size. Lesions are often described as painful until the healing phase when they become itchy. The evolution of the lesions may vary. They may evolve in the same stage on the same area of the body, or different areas of the body may have lesions at different stages of development. Lesions remain in the pustular phase for 5 to 7 days before crusts begin to form. Healing lesions may itch. Crusts form and desquamate over the subsequent 7 to 14 days, and the condition resolves around 3 to 4 weeks after symptom onset in most cases. Patients are no longer considered infectious after all crusts have sloughed off and the lesions have reepithelialized.

Other symptoms may include conjunctivitis, cough, dyspnea, nausea, vomiting, dysphagia, and photophobia. Lymphadenopathy may occur in the postauricular, submandibular, cervical, axillary, and/or groin nodes. Lymphadenopathy is a feature that distinguishes monkeypox from smallpox.

During the current global outbreak, lesions often occur in the genital and anorectal areas or in the mouth. Rash is not always disseminated across many sites on the body and may be confined to only a few lesions or only a single lesion. Rash does not always appear on palms and soles. Rectal symptoms (e.g., purulent or bloody stools, rectal pain, or rectal bleeding) have been frequently reported.

**Diagnosis**

A history of exposure and the natural history of the patient’s illness, such as the onset and progression of symptoms and appearance of the rash, are helpful in making a probable diagnosis. The diagnosis can be most easily confirmed by polymerase chain reaction testing of fluid from open lesions. Two swabs from each lesion (in general, 2–3 lesions should be sufficient) should be collected for testing. Using two sterile synthetic swabs (including, but not limited to polyester, nylon, or Dacron) with a plastic, wood, or thin aluminum shaft, swab the lesion vigorously to collect adequate DNA. Do not use cotton swabs.

Diagnosis may also be confirmed through the use of electron microscopy, culture, and immunohistochemical analysis. Genomic sequencing may be used in some situations. The use

of serum IgM and IgG antibody testing may provide supportive information. Histopathologic diagnosis is nonspecific.

### Differential Diagnosis

The differential diagnosis of monkeypox includes other poxviruses, particularly smallpox and chickenpox. Other conditions to be considered in the differential diagnosis include hand, foot, and mouth disease; herpes zoster; herpes simplex; measles; impetigo; scabies; candidiasis; dermatitis herpetiformis; Orf; bullous disease; insect bites; contact dermatitis; and drug eruptions. The symptoms during the prodromal period may be similar to influenza, COVID-19, and other viral respiratory illnesses. Symptoms may be particularly variable in patients with HIV or other types of immunocompromise. Papules, vesicles, and pustules may be present in the genital and perianal areas and can be confused with sexually transmitted illnesses such as herpes, syphilis, chancroid, or lymphogranuloma venereum.

### Treatment

Treatment of monkeypox is usually aimed at reducing symptoms. In rare situations, supportive treatment is required for those who suffer from severe disease. Currently, there is no proven antiviral treatment specific for monkeypox. Certain high-risk individuals should be considered for antiviral treatment with agents approved for the treatment of smallpox (tecovirimat or brincidofovir). These high-risk individuals include those with severe disease, those who are immunocompromised, children younger than 8 years of age, individuals with atopic dermatitis or exfoliative skin conditions, pregnant mothers, and breastfeeding women.

Tecovirimat (TPOXX, ST-246) is a potent inhibitor of an orthopoxvirus protein required for the formation of infectious virus particles that are essential for dissemination within an infected host. Tecovirimat was approved for the treatment of smallpox under a regulation known as the Animal Rule. Under the Animal Rule, efficacy is established on the basis of adequate and well-controlled studies in animal models of the human disease or condition of interest. The CDC, in partnership with the FDA, has made it easier for healthcare providers to access tecovirimat treatment under the Expanded Access Investigational New Drug protocol. Tecovirimat can be administered as an oral drug or an intravenous injection based on weight of the patient. The duration of treatment is 14 days. Tecovirimat is well tolerated; the most common side effects are headache and nausea.

Brincidofovir (Tembexa, CMS001) is an oral drug approved by the FDA for treatment of smallpox in adults, children, and neonates. Its effectiveness against monkeypox in humans is not proven, though in vitro and animal studies have demonstrated its effectiveness against orthopoxviruses. Brincidofovir is a pro-drug of cidofovir (Vistide), an antiviral medication used to treat cytomegalovirus retinitis in patients with AIDS. However, the use of cidofovir can result in renal toxicity and other adverse events.

The vaccinia immune globulin intravenous (VIGIV) may be considered for use in patients with severe disease. The VIGIV

should also be contemplated as a prophylactic measure for those with T-cell immunodeficiency who are exposed to monkeypox and in whom vaccination is contraindicated.

Because of the developing evidence base to support these therapies and because treatment of monkeypox will evolve with time, consultation with state health department authorities and the CDC Emergency Operations Center (1-800-488-7100) is recommended before initiation of treatment. Updated information regarding indications for treatment of monkeypox can be found on the CDC website (<https://www.cdc.gov/poxvirus/monkeypox/clinicians/treatment.html>).

### Complications

Serious complications of monkeypox are rare and include pneumonia, sepsis, encephalitis and, particularly in the immunocompromised and children, death. Secondary infections of the monkeypox lesions may occur. Corneal infection with loss of vision has been reported. Monkeypox can be transmitted to the fetus during pregnancy, and newborns may contract it through close contact during and after birth. Miscarriages and stillbirth have been associated with monkeypox contracted during pregnancy.

- Anosmia, in COVID-19, 664
- Anovulatory cycles, causes of, 1197, 1198t
- Antacids, for hiccups, 27
- Antepartum care, 1255  
 common concerns of antenatal period, 1259–1261  
 current diagnosis of, 1255b  
 current therapy for, 1255b  
 domestic violence screening and counseling in, 1256  
 education for, 1257–1258  
 examination, 1256–1257  
 first visit and early care, 1256–1258  
 follow-up, 1258  
 laboratory studies in, 1257, 1257t  
 potential indications for high-risk referral in, 1256b  
 tests of fetal well-being in, 1261–1262, 1261b  
 weeks' gestation  
 15 to 20, 1258  
 20 to 35, 1258–1259, 1259b  
 36 to 41, 1259
- Anterior cruciate ligament injuries, 982, 982f
- Anterior drawer test, for ACL laxity, 982, 982f
- Anterior uveitis, 536–537, 536t  
 red eye caused by, 528
- Anthralin, for psoriasis, 1099
- Anthrax, 547–549, 1496t–1501t  
 background of, 550  
 clinical manifestations of, 550–551

- Anthrax (*Continued*)  
   current therapy of, 549b  
   diagnosis of, 549b, 551  
   epidemiology of, 550  
   pathophysiology of, 550  
   pregnancy and, 552

   prognosis of, 552  
   specimen collection for, 551  
   supportive care for, 551  
   treatment for, 551–552
- Anthrax immune globulin intravenous (AIGIV), 552
- Anti IgE, for rhinitis, 59–60
- Antibiotics  
   for acne vulgaris, 1044  
   for acute pyelonephritis, 1168, 1168t  
   for bacterial meningitis, 555–556, 555t–557t  
   for bronchitis, 872  
   for bursitis, 979  
   for *Campylobacter* infection, 586  
   for cat scratch disease, 565t  
   for cholera, 571b  
   for *Clostridioides difficile* colitis, 562  
   for common bacterial skin infections, 1054t  
   for conjunctivitis, 525, 526t  
   for diverticulitis, 210, 210t  
   for GABHS pharyngitis, 54  
   hypersensitivity reactions to, 80–81  
   for infective endocarditis, 138, 138b, 140t  
   for influenza, 613  
   for invasive bacterial skin infections, 1055t  
   for legionellosis, 914, 914t  
   for lung abscess, 916  
   for *Mycoplasma pneumoniae*, 967  
   for necrotizing skin and soft tissue infections, 650  
   for nontyphoidal salmonellosis, 588  
   for osteomyelitis, 655, 655t  
   for otitis externa, 519, 520t  
   for otitis media, 523, 524t  
   for plague, 658  
   for Q fever, 668  
   for rat-bite fever, 671  
   for relapsing fever, 674  
   for rhinosinusitis, 531  
   for salmonellosis, 679–680, 680t  
   for shigellosis, 588  
   for staphylococcal food poisoning, 588  
   for stingrays, envenomations and, 1403t  
   for travelers' diarrhea, 1479  
   for viral meningitis, 819  
   for Whipple's disease, 265  
   for yellow fever, 718
- Antibody test, for peptic ulcer disease, 217
- Anti-calcitonin gene-related peptide monoclonal antibodies, 754
- Anticholinergics  
   for asthma, 882t–883t  
   intoxication, 1421–1422  
   for Parkinson disease, 778t  
   for urgency urinary incontinence, 1176
- Anticoagulants  
   for disseminated intravascular coagulation, 429  
   monitoring, 959  
   for STEMI, 92, 93t  
   for venous thromboembolism, 956–958
- Anticoagulation  
   ACC/AHA recommendations for, in mitral valve prolapse, 144t  
   for ischemic cerebrovascular disease, 747–748  
   for pulmonary embolism, 3  
   for venous thromboembolism, 169
- Anticonvulsants, for hiccups, 26
- Antidepressants  
   for bulimia nervosa, 850  
   for hiccups, 26  
   for pain, 44t  
   for spine pain, 63
- Antidiuretic hormone, 364  
   physiology of, 298
- Antidote kit, for cyanide intoxication, 1430
- Antidotes, for poisonings, 1409, 1410t–1414t
- Antidromic AVRT, 159, 159f
- Antiemetics, 47t  
   for hiccups, 26  
   for nausea and vomiting, 19  
   for salmonellosis, 679  
   for vestibular neuritis, 12
- Antiepileptic drugs (AEDs), 785  
   characteristics of, 789–793  
   dosage and side-effect profile of, 790t  
   in elderly patient, 793–794  
   for pain, 44t  
   in women, 793
- Antifibrinolytics, for disseminated intravascular coagulation, 431
- Antihistamine H<sub>1</sub> antagonists, for anticholinergic agent intoxication, 1422
- Antihistamines  
   for anaphylaxis, 74  
   for angioedema, 80  
   for erythema multiforme, 1080  
   for insect stings, 70  
   for otitis media, 523–524  
   for serum sickness, 85  
   for urticaria, 1129  
   for vestibular neuritis, 12
- Antihypertensives, classes of, 130t–133t
- Antiinflammatory agents, for cystic fibrosis, 906
- Anti-influenza therapy, 966, 966t
- Antimalarials, 631–632, 631t  
   chemoprophylaxis with, 635, 636t  
   in pediatric patient, 635  
   in pregnancy, 635  
   for systemic lupus erythematosus, 991
- Antimetabolites, for uveitis, 539t
- Antimicrobial susceptibility, of typhoid fever, 710
- Antimicrobials  
   for acute cholangitis, 192  
   for Lyme disease, 625, 626t  
   for sepsis, 683  
   for urinary tract infection, 1194  
   for whooping cough, 715
- Antinuclear antibodies (ANAs), in scleroderma, 993
- Antioxidants, for  $\beta$ -thalassemia, 502
- Antiphospholipid antibodies, 992  
   Q fever and, treatment of, 668t
- Antiplatelet therapy  
   for angina pectoris, 100–102  
   for ischemic cerebrovascular disease, 747–748  
   for STEMI, 90–92
- Antipruritic therapies, for pruritus, 56
- Antipsychotics  
   for delirium, 833t  
   for hiccups, 26  
   for schizophrenia, 869t–870t
- Antireflux surgery, for GERD, 222
- Antiresorptive therapy, for primary hyperparathyroidism, 346  
   with cinacalcet, 346
- Antiretroviral therapy, for HIV infection, 597–601, 602t–603t  
   adverse drug reactions and drug-drug interactions, 601–603  
   current recommendations for, 597, 599t, 602t–603t  
   initiation of, 597
- Antiretroviral therapy, for HIV infection (*Continued*)  
   long-acting injectable, 600  
   monitoring response to, 600–601, 600t  
   selection of, 597–600
- Antiseizure medicines, for peripheral neuropathic pain, in spine, 63
- Antithrombotic-associated intracerebral hemorrhage, 742
- Antithrombotic drugs  
   for ischemic cerebrovascular disease, 749  
   for multisystem inflammatory syndrome in children, 1336t, 1337  
   for peripheral artery disease, 151–152
- Antitoxins  
   for anthrax, 552  
   for botulism, 586
- Antivert. *See* Meclizine

 current therapy for, 1131b  
 diagnosis of, 1131–1132, 1131b  
 epidemiology of, 1131–1133  
 evaluation of, 1131–1132  
 pathophysiology of, 1131  
 treatment of, 1129–1130, 1132–1133
- Ventilation/perfusion (V/Q) scanning, for pulmonary embolism, 955
- Ventricular arrhythmia, 153  
 STEMI and, 94
- Ventricular septal defect (VSD), 111–112, 111f
- Ventricular tachyarrhythmias (VTAs), 121–122
- Ventricular tachycardias, 157, 160  
 long-QT syndrome and, 160  
 structural heart disease and, 160
- Ventricular-assist devices (VAD), microangiopathic hemolytic anemia and, 435
- Verapamil (Calan, Calan SR)  
 for hypertension, 130t–133t  
 for hypertrophic cardiomyopathy, 135
- Verrucae plana. *See* Flat warts
- Verrucae vulgaris. *See* Common warts
- Verrucous carcinoma, of vulva, 1249
- Vertebral osteomyelitis, 655
- Vertigo, Ménière's disease and, 517
- Very-low-density lipoproteins (VLDLs), 335–336
- Vesicant or blister agents, 1512t–1517t
- Vestibular migraine, 10b
- Vestibular neuritis, 10b  
 dizziness in, 10, 11t  
 Ménière's disease and, 516
- Veteran Affairs Diabetes Trial (VADT), 303
- Vfend. *See* Voriconazole
- Viagra. *See* Sildenafil
- Vibracyclin. *See* Doxycycline
- Vibrio cholerae*, 568  
 acute diarrhea caused by, 183  
 in foodborne illnesses, 582t–584t
- Vibrio parahaemolyticus*, in foodborne illnesses, 582t–584t
- Vibrio vulnificus*, in foodborne illnesses, 582t–584t
- VICP. *See* Vaccine Injury Compensation Program
- Victoza. *See* Liraglutide
- Video-assisted lobectomy, for lung cancer, 921
- Video-assisted retroperitoneal debridement (VARD), for acute pancreatitis, 175
- Video-assisted thoracoscopic surgery (VATS), for lung cancer, 918
- Vigabatrin (Sabril), as antiepileptic drugs, 792
- Viloxazine (Qelbree), for attention-deficit/hyperactivity disorder, 1303t, 1304
- Viperid envenomations, 1460–1463  
 clinical effects of, 1461  
 duration of, 1461  
 epidemiology and recognition of, 1460–1461  
 severity of, 1461
- Viral conjunctivitis, 525, 526f
- Viral encephalitis, 1496t–1501t
- Viral hemorrhagic fevers, 1496t–1501t
- Viral meningitis, 818–822  
 clinical manifestations of, 819, 820t–821t  
 complications of, 819–821  
 current therapy for, 818b  
 diagnosis of, 818b, 819  
 differential diagnosis of, 819  
 epidemiology of, 818  
 pathophysiology of, 818  
 prevention of, 818–819  
 treatment of, 819
- Viral orchitis, 1181
- Viral pharyngitis, 53
- Viral pneumonias, 963–968
- Viral respiratory infections, 871–873, 968–970  
 current diagnosis of, 968b  
 current therapy for, 968b  
 diagnosis of, 871, 871b  
 differential diagnosis of, 871–872  
 therapy for, 871b, 872–873
- Viral rhinosinusitis, 8
- Virazole. *See* Ribavirin
- Viread. *See* Tenofovir
- Virtual reality, in stroke patient, 784
- Viruses  
 acute diarrhea caused by, 183  
 in foodborne illnesses, 589
- Visceral leishmaniasis (VL), 615
- Visceral pain, palliative and end-of-life care for, 45
- Vision assistance, 542
- Vision enhancement, 542
- Vision loss, four aspects of, 541, 541f

- Vision rehabilitation, 540–545  
 blindness and, 542–543, 543f  
 comprehensive, 541–542, 542f  
 current diagnosis of, 540b  
 current therapy for, 540b  
 neural processing problems in, 544  
 optical problems in, 543  
 patient-centered functional priorities in, 544–545  
 retinal problems in, 543–544  
 techniques and devices for, 543
- Vision substitution, 542
- Visual dysfunction, 544
- Visual impairment, 514, 544  
 in stroke patient, 784
- Vital signs, medical toxicology and, 1404, 1405t
- Vitamin B<sub>12</sub>  
 deficiency  
 anemia, 472, 473t  
 treatment of, 474  
 malabsorption, 263
- Vitamin C, for COVID-19, 660
- Vitamin D, 1342  
 for COVID-19, 660  
 for osteoporosis, 1010  
 supplements, 1159
- Vitamin K, 1342  
 antagonist therapy, for venous thromboembolism, 956
- Vitamin K1 (Aqua Mephyton), for common poisonings, 1410t–1414t
- Vitamin K-dependent multiple deficiencies, 447t
- Vitiligo, 1109
- Vocal cord cancer, 32
- Vocal fold paralysis, 30, 30f  
 phonotraumatic lesions, 30–31, 31f
- Vocal tics, 739
- Voice timbre, 323
- Voice training, gender affirming  
 care, 324
- Voiding dysfunction, urinary tract infections  
 and, in infants and children, 1374
- Volume expanders, for newborn resuscitation, 1372t
- Volume overload, in chronic kidney disease, 1150
- Vomiting (arsine-based) agents, 1512t–1517t
- von Willebrand disease (vWD), 445–446  
 acquired, 446  
 clinical presentation of, 445  
 clinical variants of, 445t  
 diagnosis of, 445, 447t  
 in pregnancy, 446  
 treatment of, 446
- von Willebrand factor (vWF), 440, 442–443, 475, 504, 505f
- Voriconazole (Vfend), for coccidioidomycosis, 903
- Vorinostat (Zolinza), for cutaneous T-cell lymphomas, 1063
- Vraylar. *See* Cariprazine
- VTAs. *See* Ventricular tachyarrhythmias
- VTE. *See* Venous thromboembolism
- Vulva, blunt trauma to, 1172
- Vulvar cancers, 1248–1249
- Vulvar neoplasia, 1247–1250  
 benign cystic neoplasms, 1247  
 benign solid neoplasms, 1247–1248  
 current therapy for, 1247b  
 diagnosis of, 1247b  
 intraepithelial, 1248, 1248t  
 invasive vulvar lesions, 1248–1250, 1249t
- Vulvovaginal candidiasis (VVC), 1251t  
 pathophysiology of, 1251  
 treatment for, 1252–1253, 1253t
- Vulvovaginitis, 1250–1254  
 clinical manifestations for, 1251, 1251t  
 current treatment for, 1250b  
 diagnosis of, 1250b, 1251–1252, 1251t, 1252f  
 differential diagnosis for, 1252  
 epidemiology of, 1250  
 pathophysiology of, 1250–1251  
 prevention for, 1251  
 risk factors for, 1250  
 treatment for, 1252–1254, 1253t
- VVC. *See* Vulvovaginal candidiasis
- vWD. *See* von Willebrand disease
- vWF. *See* von Willebrand factor
- VX, 1512t–1517t
- Vyzulta. *See* Latanoprostene bunod

- Wakix. *See* Pitolisant
- Waldenström macroglobulinemia, 468
- Walled-off pancreatic necrosis (WOP), 176
- Warfarin (Coumadin)  
 anticoagulation, guidelines for, 418b  
 for mitral valve prolapse, 144  
 for pulmonary embolism, 3  
 for venous thromboembolism, 169–170, 957–958, 958t
- Warts (verrucae), 1110–1113  
 clinical manifestations of, 1111–1112  
 current therapy for, 1110b  
 diagnosis of, 1110b  
 differential diagnosis of, 1112  
 epidemiology of, 1110–1112  
 pathophysiology of, 1110  
 risk factors for, 1112  
 treatment of, 1137–1138, 1112  
 home remedies for, 1112–1113  
 office-based, 1138  
 over-the-counter, 1113  
 patient education for, 1138
- Wasps, allergic reactions to, 69
- Water, renal handling of, 364, 364t
- WBGT. *See* Wet-bulb globe temperature
- Wegener’s granulomatosis, 1065t
- Weight, after bariatric surgery, 381
- Weight gain  
 in antenatal period, 1259  
 drugs that are weight neutral or causing, 309
- Weight loss  
 for diabetes mellitus, 308–309  
 drugs associated with, 308  
 drugs used specifically for, 309  
 for osteoarthritis, 1004–1005  
 for snoring and OSA, 801–802, 801t  
 in ulcerative colitis and Crohn disease, 237t
- Weight-supported treadmill training, in stroke patient, 781
- Wellbutrin. *See* Bupropion
- Wells rule, 2t
- WES. *See* Whole-exome sequencing
- Western equine encephalitis, 1496t–1501t
- Wet-bulb globe temperature (WBGT), heat-related illness in, 1391
- WGS. *See* Whole-genome sequencing
- Wheal and flare response, in histamine-induced pruritus, 56

- Whipple’s disease, 265
- Whipworm, 253
- Whole blood donors, 415
- Whole-body phosphate deficit, of DKA, 317
- Whole-bowel irrigation, in decontamination, 1407
- Whole-brain radiotherapy, for metastatic brain tumors, 736
- Whole-exome sequencing (WES), 1483–1484  
 for mitochondrial disease, 1331–1332
- Whole-genome sequencing (WGS), 1483–1484
- Whooping cough (pertussis), 714–716  
 clinical symptoms of, 715  
 current therapy for, 714b  
 diagnosis of, 714b, 715  
 epidemiology of, 714  
 microbiology and pathophysiology of, 715  
 prevention of, 715  
 transmission of, 714–715  
 treatment of, 715, 716t
- Wide complex tachycardia, differential diagnosis for, 157, 158f
- Wild-type allele, 1481
- Willis Ekbom disease, 1365–1366
- Wilson disease, microangiopathic hemolytic anemia and, 435
- Wolff-Parkinson-White (WPW) syndrome, 157, 159f
- Women’s health  
 abnormal uterine bleeding, 1197–1198  
 amenorrhea, 1199–1202  
 benign breast disease, 1205–1208  
 cancer of  
 breast, 1209–1212  
 endometrium, 1212–1215  
 contraception, 1219–1223  
 endometriosis, 1226–1228  
 female sexual dysfunction, 1228–1230  
 infertility, 1231–1232  
 menopause, 1233–1236  
 ovarian cancer, 1237–1239  
 pelvic inflammatory disease, 1240–1241  
 premenstrual syndrome, 1242–1245  
 seizures and epilepsy in, 793  
 urinary tract infections, 1202–1204  
 uterine leiomyoma, 1245–1247  
 vulvar neoplasia, 1247–1250  
 vulvovaginitis, 1250–1254
- World Allergy Organization (WAO), 71–72  
 subcutaneous immunotherapy systemic reaction grading system by, 73t
- Wrist actigraphy, monitoring, in sleep disorders, 797
- X**
- Xalatan. *See* Latanoprost

- Xolair. *See* Omalizumab
- Xopenex. *See* Levalbuterol
- Xpovio. *See* Selinexor
- X-ray  
 in antenatal period, 1261  
 of osteochondral ankle injuries, 981–982, 981f  
 of osteochondral knee injuries, 983–984, 983f  
 of posterior cruciate ligament injuries, 982  
 of proximal interphalangeal joint dorsal dislocation, 984, 984f–985f  
 of scaphoid fracture, 984–985, 986f  
 of spondylolisthesis, 988–990, 989f–990f  
 of spondylolysis, 988–990, 988f
- Xylocaine. *See* Lidocaine

## Y

Yellow fever, 714–716, 1496t–1501t  
clinical manifestations of, 718  
complications of, 718–719  
current therapy for, 716b  
diagnosis of, 716b, 718  
differential diagnosis of, 718  
epidemiology of, 716–717  
pathophysiology of, 717  
prevention of, 717–718  
risk factors for, 717  
treatment of, 718  
vaccine, 1476  
Yellow jackets, allergic reactions, 70  
*Yersinia enterocolitica*, 420  
acute diarrhea caused by, 183  
*Yersinia pestis*, 1496t–1501t  
in plague, 657  
*Yersinia* spp., in foodborne illnesses,  
582t–584t, 588  
Yodoxin. *See* Iodoquinol  
Yoga  
for dysmenorrhea, 1224  
for postpartum depression, 1273  
Youth, gender affirming care  
and, 324

## Z

Zafirlukast (Accolate), for asthma, 883t–885t  
Zaire ebolavirus, 578  
Zaleplon (Sonata), for insomnia, 800t  
Zanaflex. *See* Tizanidine  
Zanamivir (Relenza)  
for influenza, 613, 613t, 969  
Zebeta. *See* Bisoprolol  
Zenker diverticulum, 207, 207f  
Zestril. *See* Lisinopril  
Ziagen. *See* Abacavir  
Ziconotide (Prialt), for pain, 40  
Zidovudine (Retrovir), 605  
Zika virus disease, 719–723  
clinical manifestations of, 721  
complications of, 722  
diagnosis of, 721–722  
differential diagnosis of, 722  
epidemiology of, 719  
monitoring for, 722  
pathophysiology of, 720  
prevention of, 720–721, 721f, 721t  
risk factors for, 719–720  
treatment of, 722  
Zileuton (Zyflo), for asthma, 883t–885t  
Zinc, for COVID-19, 660

Ziprasidone (Geodon)  
for schizophrenia, 869t–870t  
for Tourette syndrome, 741t  
Zithromax. *See* Azithromycin  
Zoledronate (zoledronic acid, Reclast)  
for osteoporosis, 1010–1011, 1010t  
for Paget's disease of bone, 1013–1014  
Zolinza. *See* Vorinostat  
Zollinger-Ellison syndrome, 266  
Zoloft. *See* Sertraline  
Zolpidem (Ambien), for insomnia, 800t  
Zonegran. *See* Zonisamide  
Zonisamide (Zonegran), as antiepileptic  
drugs, 790t, 792  
Zostavax (zoster vaccine live), for herpes  
zoster infections, 713  
Zoster sine herpette, 1133  
Zosyn. *See* Piperacillin-tazobactam  
Zovirax. *See* Acyclovir  
Zulresso. *See* Brexanolone  
Zurampic. *See* Lesinurad  
Zydelig. *See* Idelalisib  
Zyflo. *See* Zileuton  
Zyloprim. *See* Allopurinol  
Zyprexa. *See* Olanzapine  
Zytiga. *See* Abiraterone

ClinicalKey®

# Confidence is ClinicalKey

Evidence-based answers, continually updated

The latest answers, always at your fingertips

A subscription to ClinicalKey draws content from countless procedural videos, peer-reviewed journals, patient education materials, and books authored by the most respected names in medicine.

Your patients trust you. You can trust ClinicalKey.

Equip yourself with trusted, current content that provides you with the clinical knowledge to improve patient outcomes.
