The molecular pathogenesis of pituitary tumors includes the inactivation of tumor suppressor genes, the activation of oncogenes, and the trophic effect of factors such as the hypothalamic releasing hormones. Approximately 40% of GH-producing tumors in whites harbor somatic point mutations of the  $\alpha$  subunit stimulatory G protein coupled to the GHRH receptor (GSP $\alpha$  mutations). This molecular alteration causes constitutive activation of the GHRH receptor, resulting in an increased transcription of the GH gene and the promotion of somatotroph proliferation. Acromegalic patients whose tumors harbor GSP $\alpha$  mutations usually have a more benign clinical course and appear to be more susceptible to management with somatostatin analogues. Nonwhite acromegalic populations, including persons of Japanese, Korean, and Mexican heritage, have a much lower prevalence of GSP $\alpha$  mutations.

Other molecular events should be present in GSP $\alpha$ -negative somatotrophinomas. Menin is a protein encoded by a tumor

**Figure 1** GH is regulated positively by GHRH and negatively by somatostatin. Fifty percent of circulating GH is bound to the GH binding protein, which represents the extracellular portion of the GH receptor. One molecule of GH dimerizes two molecules of GH receptor, and the ensuing signal transduction results in IGF-1 synthesis and secretion, which exerts negative feedback on GH secretion at the hypothalamic and pituitary levels. *Abbreviations:* ALS = acid-labile subunit; GH = growth hormone; GHRH = growth hormone-releasing hormone; IGF = insulin-like growth factor; IGFBP3 = insulin-like growth factor binding protein 3; IRS = insulin receptor S; JAK2 = Janus kinase 2; SRIH = somatostatin; SSTR = somatostatin receptor.

suppressor gene located on the short arm of chromosome 11. Inactivating mutations of *menin* are the molecular basis of type 1 multiple endocrine neoplasia (MEN1); however, GH-secreting tumors occurring out of this context do not have such genetic abnormalities. Inactivating mutations of other putative tumor-suppressor genes located relatively close to the *menin* locus have been described in several kindreds with familial acromegaly; however, they do not seem to play an important oncogenic role in the sporadic form of the disease. Other genetic alterations such as underexpression of GADD 45 $\gamma$  (growth arrest and DNA damage-inducible protein) and overexpression of the securing molecule PTTG (pituitary tumor transforming gene) have also been shown to be involved in the molecular pathogenesis of acromegaly. Although hereditary acromegaly is rare (less than 2% of the cases), familial somatotrophinomas account for 30% of the tumors seen in the syndrome of familial isolated pituitary adenomas. Patients with isolated familial somatotrophinomas are younger and usually have more aggressive tumors than subjects with sporadic acromegaly. Affected members do not show any molecular alterations in the MEN1 gene. However, 15% of 73 tested families harbor inactivating, germline mutations of the AIP (aryl hydrocarbon interacting protein) gene located on chromosome 11q13.3.

In more than 90% of cases, acromegaly is caused by a sporadic pituitary adenoma. In approximately 70% of these patients, these benign epithelial neoplasms are larger than 1 cm in diameter and are known as *macroadenomas*, whereas one-third of the patients harbor lesions smaller than 1 cm or *microadenomas*. One-third of the patients have tumors that cosecrete GH and prolactin (PRL) (mammosomatotroph cell adenomas). Real pituitary GH-secreting carcinomas, with documented metastasis as the irrefutable malignancy criterion, are exceedingly rare. On rare occasions, acromegaly results from GHRH-secreting neuroendocrine tumors, usually located in the lungs, thymus, or endocrine pancreas. In this scenario, the ectopically produced GHRH leads to hyperplasia of the somatotroph, with the consequent excessive production of GH. Even less common are GH-secreting tumors arising in ectopic pituitary tissue, usually located in the sphenoid sinus. A case of GH-secreting lymphoma has been reported.

### Clinical Manifestations

Acromegaly develops insidiously over many years. An 8- to 10-year delay in diagnosis has been estimated from the beginning of

the first symptom. Clinical characteristics are often attributed to aging. Symptoms and signs can be divided into those resulting from the compressive effects of the pituitary tumor and those that are a consequence of the GH and IGF-1 excess.

### Local Tumor Effects

Headache results from an increase in intracranial pressure and from the effects of GH itself; it is usually described as a dull pain that persists throughout the day. Occasionally, large tumors invading laterally into the cavernous sinuses give rise to cranial nerve syndromes, usually third and sixth. Visual field defects are relatively common with macroadenomas extending superiorly and compressing the optic chiasm. This usually results in different combinations of bitemporal homonymous hemianopia or quadrontopia.

### Consequences of the GH/IGF-1 Excess

#### *Skeletal Growth and Skin Changes*

A GH excess developing before the pubertal closure of epiphyseal bone leads to an acceleration of linear growth, and this results in gigantism. Once the patient is in adulthood, the GH/IGF-1 excess results in acral enlargement, which is manifested by increases in ring and shoe sizes as well as enlargement of the nose, supra-ciliary arches, frontal bones, and mandible (Figure 2). There is thickening of soft tissues of the hands and feet; hands are fleshy and bulky and the heel pad is increased. The skin is thickened due to the deposition of glycosaminoglycans and excessive collagen production. Hyperhidrosis and seborrhea occur in 60% of patients; skin tags (previously associated with colon cancer) and acanthosis nigricans are common.

#### *Musculoskeletal System*

Generalized arthralgias are present in the majority (80%) of patients. Degenerative osteoarthritis is more common than in the general population. Paresthesias of the hands and feet and a proximal painful myopathy are often reported. Nerve entrapment syndromes such as the carpal tunnel syndrome occur in nearly half of patients.

#### *Cardiovascular System*

Arterial hypertension is found in 30% of patients, and when associated with diabetes, it contributes to the increased mortality rate of the disease. Hyperaldosteronism with low renin levels and the resulting sodium retention play an important role in the pathogenesis of

**Figure 2** A and B, Skeletal growth and skin changes in acromegaly. (From Salmon JF: *Kanski's Clinical Ophthalmology*, 9th edition. Elsevier, 2020.)

hypertension, but other contributors such as an increased sympathetic tone are also present. Echocardiographic findings include left ventricular and septal hypertrophy with varying degrees of diastolic dysfunction. Symptomatic cardiac disease develops in 15% of patients and is usually due to coronary artery disease, heart failure, and arrhythmias. Although the existence of an acromegalic cardiomyopathy is still controversial, there are patients without hypertension and with angiographically normal coronaries, who develop severe congestive heart failure, in whom histologic evidence of subendocardial, subepicardial, and myocardial fibrosis and necrosis has been documented.

#### **Respiratory Abnormalities**

The majority of patients with acromegaly are affected by loud snoring. A significant fraction of these have sleep apnea (with both central and obstructive components) with significant drops in oxygen saturation, which can be complicated by arrhythmias, daytime somnolence, and chronic fatigue.

#### **Abnormalities in Glucose Metabolism**

Chronic GH hypersecretion creates a state of insulin resistance, and glucose intolerance has been reported in 30% to 50% of patients with acromegaly; the percentage with fasting hyperglycemia can be close to 30%, depending on the population. Hyperglycemia has correlated with GH concentrations in some studies and with IGF-1 levels in others. Although successful treatment of acromegaly, be it by surgical, pharmacological, or radiotherapeutical interventions, results in significant improvements in metabolic control, the prevalence of diabetes remains higher than in the general population.

#### **Abnormalities in Lipid Metabolism**

The classic lipid profile consists of diminished total cholesterol, along with elevated triglyceride concentrations. Intermediate-density lipoprotein (IDL) particles and lipoprotein(a) might also be elevated, and there is a higher percentage of the more atherogenic type II low-density lipoprotein (LDL).

#### **Bone and Calcium Metabolism**

Acromegaly is associated with hypercalciuria and hyperphosphatemia. High serum 25-hydroxyvitamin D<sub>3</sub> and urinary levels of hydroxyproline can be found, reflecting a state of increased bone turnover. Cortical bone mineral density is elevated, whereas trabecular bone mass is diminished.

#### **Neoplasia**

Retrospective studies suggested that colonic adenomatous polyps and adenocarcinoma were more frequent in acromegalic patients

than in the general population. Prospective studies have demonstrated that the risk, albeit smaller than previously thought, is real and probably justifies screening colonoscopy in these patients. Patients with uncontrolled acromegaly have a higher risk of recurrence of premalignant polyps and a higher mortality rate from colon cancer compared with subjects with biochemically controlled disease and the general population. Recently, an increased incidence of well-differentiated thyroid carcinoma has been documented.

#### **Associated Endocrine Abnormalities**

A euthyroid goiter is often found but seldom requires specific treatment. Hypopituitarism occurs variably, depending on the size and extension of the tumor and whether the patient has undergone surgery or radiation therapy. Hypogonadotropic hypogonadism is the most common pituitary deficiency, occurring in 20% of patients. A decreased libido is a common presenting complaint in both male and female patients with acromegaly; women often have menstrual and ovulatory disturbances and men complain of impotence.

Although an elevated PRL is common, it does not always reflect cosecretion of this hormone by the somatotrophinoma, but rather an interruption of the descending dopaminergic tone by the tumor compressing the pituitary stalk. Central hypocortisolism and hypothyroidism are less common.

GH-secreting pituitary adenomas are the second, after prolactinomas, pituitary tumor occurring in the context of MEN1 (multiple parathyroid adenomas, pituitary adenoma, and pancreatic islet cell tumors). Acromegaly can also develop in patients with the McCune-Albright syndrome (polyostotic fibrous dysplasia, café au lait spots, and endocrinopathies such as sexual precocity and autonomous thyroid nodules), and occurs in the context of the Carney complex.

#### **Mortality**

Life expectancy in patients with acromegaly is decreased by about 10 to 15 years, and the standardized mortality ratio is 1.5 to 2. Most patients die of cardiovascular causes, followed by cerebrovascular events, respiratory abnormalities, and neoplastic diseases. Hormonal control has a definite impact on survival. Lowering serum GH to less than 2.5 ng/mL results in reduction of the mortality rate to levels comparable with the general population. These safe GH levels were obtained using old radioimmunoassays, and there are no equivalent studies using ultrasensitive GH assays. IGF-1 levels have not been as good as GH as independent predictors of mortality.

Other factors associated with an increased mortality include advanced age and the presence of hypertension and diabetes. Mortality rate in acromegaly can be reduced to that seen on the general population when patients are treated using a multidisciplinary approach not only aiming at controlling the GH and IGF-1 levels but also focusing on the management of comorbidities.

### Biochemical Diagnosis

Due to the pulsatile nature of GH secretion, random determinations of this hormone are not useful in the diagnosis of acromegaly. The gold standard for the diagnosis is the measurement of GH after an oral glucose load of 75 g; current guidelines state that suppression to less than 0.4 ng/mL (using ultrasensitive assays) reliably excludes the diagnosis. Situations associated with decreased suppression of GH by glucose include puberty, pregnancy, use of oral contraceptives, uncontrolled diabetes, and renal and hepatic insufficiency.

IGF-1 levels reflect the integrated concentrations over 24 hours of GH and correlate well with clinical activity. Blood IGF-1 concentrations decrease with age, reflecting the parallel decline of the somatotrophic axis. There is a gender difference in IGF-1 (premenopausal women have lower levels than age-matched male subjects). Other conditions that lower IGF-1 levels include malnutrition, uncontrolled diabetes, and hepatic and renal failure. Normal ranges for IGF-1 should be established in each particular center based on age. The determination of other GH-dependent peptides such as IGFBP3 and ALS has not proved to be superior to IGF-1.

### Imaging

Pituitary magnetic resonance imaging (MRI) with gadolinium enhancement allows visualization of lesions as small as 2 or 3 mm in diameter. High-resolution computed tomography (CT) is a reasonable alternative, although it is much less sensitive. An ectopic source of GHRH should be suspected when the MRI is completely normal. In these rare cases, serum GHRH should be measured and the ectopic tumor should be sought, usually with high-resolution CT of the chest and abdomen.

### Treatment

The decision as to what therapeutic modality should be used has to take into account medical issues (cardiopulmonary comorbidities, size, and extension of the tumor) as well as the local characteristics of the treating center. The latter refers to the availability of pituitary surgeons and radiotherapeutic technologies as well as the economic feasibility of pharmacologic therapy.

### Surgery

Transsphenoidal surgery has been the traditional treatment for acromegaly and achieves biochemical cure (achievement of a post-glucose GH <1 ng/mL and normalization of IGF-1) in 80% to 90% of microadenomas. According to the latest published acromegaly consensus, biochemical cure is defined as a glucose-suppressed GH of 0.4 ng/mL as well as a normal age-adjusted IGF-1. Cure rates for macroadenomas are much lower (40%–50%), and invasive lesions have a very slight chance (<10%) of being cured by surgery. Even though surgery often fails to achieve a full biochemical cure, debulking the pituitary adenoma relieves optic chiasm compression and can result in a sufficient decrement of tumor mass (and therefore of GH production) to allow better results with either pharmacologic or radiotherapeutic regimens.

### Pharmacologic Therapy

Somatostatin analogues are the most commonly used medical treatment for acromegaly. Somatostatin inhibits GH secretion and somatotroph cell growth via its interaction with five different somatostatin receptor (SSTR) subtypes. The development of long-acting somatostatin analogues such as octreotide (Sandostatin) and lanreotide (Somatuline) overcame the pharmacologic difficulties of native somatostatin (short half-life, rebound GH secretion, and need for IV administration)

and resulted in a more potent inhibition of GH secretion. The most commonly used preparations are intramuscular octreotide LAR (long-acting repeatable) (Sandostatin LAR Depot) and subcutaneous lanreotide autogel (Somatuline Depot), which are administered every 4 weeks. Doses of octreotide-LAR range from 10 to 40 mg and those of lanreotide autogel from 60 to 120 mg, both administered every 4 weeks, although in specific patients the interval of injection can be increased to every 6 or even 8 weeks, thus diminishing the cost of therapy. Octreotide and lanreotide have very high affinities for SSTR-2 and to a lesser extent SSTR-5, which are precisely the most commonly expressed somatostatin receptors in GH-secreting adenomas.

When used after surgery has failed, somatostatin analogues can achieve a safe and a normal IGF-1 in 25% to 35% of patients. Primary treatment with somatostatin analogues is increasingly being used in patients with invasive tumors, when cardiopulmonary contraindications are present, and more recently as a result of the patient's or treating physician's preference. In these settings, biochemical success rates (achievement of a GH <2.5 ng/mL and normalization of IGF-1) have ranged between 30% and 80%, and more than 80% report significant relief of symptoms. More recent trials performed in unselected populations reveal that the real success rate lies between 25% and 35%. Tumor shrinkage occurs in 70% of primarily treated patients. Overall, treatment success is directly related to the abundance of SSTR-2 and SSTR-5 in the tumor. Lower pretreatment GH levels are also associated with a better response to somatostatin analogues. Side effects of somatostatin analogues, including nausea, abdominal pain, alopecia, and biliary sludge, occur in 20% of subjects. The currently recommended biochemical targets when treating patients with somatostatin analogues are the achievement of a GH of 1 ng/mL and an IGF-1 level within the normal age-adjusted range patients with somatostatin analogues is 1 ng/mL.

Pegvisomant (Somavert) is a GH mutant that prevents functional dimerization of the GH receptor, thus acting as an antagonist. Its use results in normalization of IGF-1 in more than 70% of patients, while increasing GH levels. Concern about adenoma growth due to the abolition of IGF-1 negative feedback on the tumoral somatotroph prevents its use in patients with very large lesions in close proximity to the optic chiasm. Transient elevations of liver aminotransferases can occur, although this seldom requires drug discontinuation. Pegvisomant does not compromise insulin secretion, as somatostatin analogues do. GH-receptor antagonists are expensive and should not be used as primary treatment; they are currently indicated in patients who are intolerant or have failed somatostatin analogue therapy.

Few patients respond marginally to difficult-to-tolerate large doses of bromocriptine.<sup>1</sup> Newer dopamine agonists, such as cabergoline,<sup>1</sup> are better tolerated and achieve biochemical control in 20% to 30% of patients. Combination treatment with cabergoline and octreotide appears to be promising in cases resistant to somatostatin analogues.

### Radiation Therapy

Both external-beam radiotherapy and radiosurgery are indicated in patients with persistent disease and a demonstrable tumor remnant who are either intolerant or resistant to pharmacologic treatment. Biochemical success occurs in 20% to 60% and requires many years to become apparent. Hypopituitarism, involving at least two axes, develops in more than 50% of patients within 10 years. Serious adverse effects such as brain necrosis and optic nerve damage seldom occur with the currently used techniques that minimize radiation to the normal surrounding tissues. With the currently available radiation techniques, radiotherapy is an effective and safe treatment alternative. The two major drawbacks of radiotherapy are the time it

<sup>1</sup>Not FDA approved for this indication.

takes to achieve biochemical control and the almost unavoidable induction of hypopituitarism.

Novel pharmacologic therapies are being developed, some of which will likely become useful particularly in patients who do not respond to current somatostatin analogues. These include the so-called “universal” somatostatin analogue pasireotide (Signifor LAR), which is capable of interacting not only with the SSTRs 2 and 5, but also with subtypes 1 and 3. Pasireotide seems to be slightly more effective than octreotide in achieving GH and IGF-1 targets; however, its major drawback is the worsening of hyperglycemia. Dopastatin<sup>5</sup> is a recently developed chimeric compound that behaves both as an analog and as a dopamine agonist; clinical trials had to be discontinued at early stages due to lack of efficacy. Oral octreotide, known as octreolin, is a new preparation of octreotide acetate attached to a transient permeability enhancer, which selectively allows the translocation of the somatostatin analog through the paracellular tight junctions. Oral octreotide (Mycapssa Delayed Release capsule), which was granted FDA approval in June 2020, has been shown to be as efficacious as the parenteral preparation in at least three phase III trials, including two open label non-inferiority studies and a more recent placebo-controlled trial.

<sup>5</sup>Investigational drug in the United States.

## ADRENOCORTICAL INSUFFICIENCY

Method of

Fabienne Langlois, MD; Elena V. Varlamov, MD; and Maria Fleseriu, MD

### CURRENT DIAGNOSIS

- An initial diagnosis of adrenocortical insufficiency (AI) is based in most cases on an evaluation of morning cortisol level(s), measured at 8 AM in patients who have a normal circadian rhythm.
- A morning cortisol level less than 3 µg/dL to 5 µg/dL supports an AI diagnosis, and a value greater than 15 µg/dL effectively rules out AI.
- To confirm the diagnosis, especially in cases with intermediate cortisol values, a high-dose (250 µg) cosyntropin (Cortrosyn) stimulation test is suggested with a normal cutoff peak cortisol greater than 18 µg/dL to 20 µg/dL at 30 or 60 minutes.
- Primary AI is characterized by elevated endogenous adrenocorticotrophic hormone (ACTH) levels and absence of mineralocorticoid hormones in addition to glucocorticoid (GC) deficiency; antibody screening and/or adrenal imaging is indicated.
- Secondary AI is characterized by an inappropriately normal or low endogenous ACTH level and low cortisol with preserved mineralocorticoid hormones. If an exogenous GC source/use is ruled out, pituitary hormone testing and magnetic resonance imaging (MRI) of the pituitary sella is appropriate.

### CURRENT THERAPY

- Oral hydrocortisone (Cortef) is the preferred form of steroid to attain physiologic replacement. Doses are usually 15 mg to 20 mg divided into two or three daily doses, with the highest dose in the morning.
- In case of physiologic stress—such as fever, severe infection, or minor surgery—doses should be doubled or tripled (depending on the type of stress or procedure) for the duration of the event.
- In patients with primary AI, fludrocortisone (Florinef), a mineralocorticoid, should be added to the treatment regimen, with a typical dose between 0.05 mg and 0.1 mg daily.
- For adrenal crisis in patients with known AI, administer bolus hydrocortisone injection (Solu-Cortef) 100 mg followed by 50 mg to 100 mg IV every 6 hours to 8 hours or continuous infusion of 200 mg/24 h along with substantial volumes of saline.
- Patients should wear a medical alert bracelet or necklace and have frequent education regarding AI, its treatment, and the prevention of adrenal crisis.

### Epidemiology

Primary adrenocortical insufficiency (AI), also known as Addison disease, has a prevalence of 100 to 140 cases per million persons. More than 90% of primary AI in the developed world is secondary to autoimmune adrenalitis, and is more common in women. Secondary AI caused by withdrawal of therapeutic glucocorticoid (GC) administration is the most prevalent; pituitary tumors and surgeries and opioid use are other common etiologies.

### Risk Factors

#### Primary Adrenocortical Insufficiency

A personal or family history of autoimmune disease (e.g., type 1 diabetes, Hashimoto disease, vitiligo, pernicious anemia) is a risk

factor for autoimmune adrenalitis. In the context of acute AI in the hospital, thrombosis and secondary adrenal hemorrhage must be ruled out and the possibility of heparin-induced thrombocytopenia (HIT) elicited if the patient is receiving parenteral anticoagulation. Miliary tuberculosis is the most frequent cause of primary AI in less economically developed countries. Infiltration in the context of malignancy is often due to a known metastatic cancer; other infiltrative diseases are rare.

### Secondary Adrenocortical Insufficiency

The most common risk factor for secondary AI is prolonged use of exogenous GC. In general, patients taking more than 5 mg of prednisone or the equivalent for longer than a few weeks are at risk for secondary AI. In some patients with GC receptor hypersensitivity, even smaller doses of GC other than oral (topical, injected, or inhaled) can also suppress the hypothalamic-pituitary-adrenal axis. Immunotherapy-related hypophysitis, most often related to inhibition of cytotoxic T-lymphocyte antigen-4 (CTLA-4), but also programmed cell death protein 1 (PD-1), and/or its ligand (PD-L1) induce AI, which is rarely reversible. Chronic opioid use, especially long-acting opioids, can also suppress central ACTH and induce AI.

Patients with tumors of the hypothalamic-pituitary region or a history of treatment of such tumors with surgery and/or radiation are at significant risk. Pituitary apoplexy occurs due to hemorrhage or infarction of the pituitary tumor and causes acute secondary AI. Autoimmune lymphocytic hypophysitis is more common in women and usually occurs in the third pregnancy trimester or postpartum. Pituitary ischemia due to severe blood loss postpartum is known as Sheehan syndrome. Patients with traumatic brain injury may experience transient or permanent AI in both the acute and/or recovery phase.

### Pathophysiology

Primary AI is characterized by complete destruction of the adrenal cortex, inducing deficits in all hormones: GC, mineralocorticoid, and androgens. With loss of cortisol feedback inhibition, ACTH will be markedly elevated. Secondary AI is the result of isolated low GC production; it is due a defect at the pituitary or hypothalamus level and results in low (or inappropriately normal) ACTH. Mineralocorticoid activity is maintained in secondary AI as it is controlled by the renin-angiotensin-aldosterone system.

### Prevention

There is no clinically practicable strategy for preventing primary AI. Opioids and GC-associated secondary AI may be prevented through judicious use of systemic GC and opioids, with efforts made to limit administration to the lowest effective dose for the shortest possible time.

### Clinical Manifestations

#### Primary Adrenocortical Insufficiency

The presentation of primary AI is sometimes dramatic, with a constellation of weakness, fatigue, anorexia, weight loss, nausea, abdominal pain, salt craving, and orthostatic hypotension. Symptoms start as subtle and nonspecific in some patients but may evolve rapidly in adrenal crisis, especially if a concomitant stress occurs. The skin and buccal mucosa are often hyperpigmented owing to the effect of excess ACTH on cutaneous melanocortin receptors. Hyponatremia and hyperkalemia (as a result of mineralocorticoid deficiency) are often present.

#### Secondary Adrenocortical Insufficiency

The presentation of secondary AI is more insidious, with weight loss, fatigue, nausea, and malaise as presenting features. This often leads to a delay in diagnosis. The production of mineralocorticoid is relatively intact in secondary AI, and as such potassium levels are usually normal. Hyponatremia may be present due to an increase in antidiuretic hormone. Hyperpigmentation is not present, reflecting normal or low ACTH levels. Other laboratory abnormalities are less common but hypoglycemia is occasionally observed, especially with concomitant growth hormone deficiency (GHD). Isolated ACTH deficiency is rare, and signs

and symptoms of other pituitary hormone abnormalities—such as hyperprolactinemia, central hypogonadism, GHD, or central hypothyroidism—may be present. Secondary AI may be masked by concomitant central hypothyroidism.

### Diagnosis

Morning cortisol levels (within 2 hours of waking up) of 3 µg/dL to 5 µg/dL or less has a relatively high predictive value for AI; a morning cortisol level greater than 15 µg/dL effectively rules out AI. To confirm the diagnosis of AI, a cortisol stimulation test is performed. Insulin tolerance testing has largely been replaced by stimulation testing with synthetic cosyntropin (ACTH—Cortrosyn, Synacthen). ACTH stimulation testing of cortisol is a reliable method of evaluating adrenal reserve. However, it should not be used in cases of acute secondary AI, such as apoplexy or after recent pituitary surgery, because adrenal atrophy must have occurred for the adrenal response to cosyntropin to be blunted. In high-dose ACTH testing, a cortisol level is checked before and at 30 and 60 minutes after 250 µg of cosyntropin has been administered intravenously. A peak cortisol level greater than 18 µg/dL to 20 µg/dL at 30 or 60 minutes defines a normal response. The low-dose (1 µg) test<sup>1</sup> measures cortisol 20 to 30 minutes after cosyntropin administration and may be more sensitive for the diagnosis of secondary AI. However, the high-dose (250 µg cosyntropin) test remains the standard. The above-mentioned cortisol cutoffs are based on laboratory methods using polyclonal antibody immunoassays. Newer assays (liquid chromatography mass spectrometry [LC-MS/MS]) and some monoclonal antibody immunoassays have reduced cross-reactivity with cortisol precursors and therefore result in 10% to 20% lower total cortisol levels. For example, lower stimulated cutoffs of 14 µg/dL to 17 µg/dL have been proposed. Additionally, one must consider total serum cortisol level, as this can be affected by diurnal rhythm and binding proteins, which are elevated in hyperestrogenic states and low in hypoalbuminemia. If the clinical picture is not concordant with the investigation, an endocrinology consult should be sought.

Once a diagnosis has been confirmed, a low or normal plasma ACTH level will indicate secondary AI; however, care must be taken with the methodology of the test, as some immunoassays for ACTH can give falsely low results if preanalytic precautions are not respected. An elevated ACTH level (more than twofold the upper limit of normal) typically indicates primary AI, and hyperkalemia, high plasma renin, and simultaneously low aldosterone levels will confirm associated mineralocorticoid deficiency. After the diagnosis of primary versus secondary AI has been established, an etiology should be sought (Boxes 1 and 2). Serology for antiadrenal (anti 21-hydroxylase) antibodies or evidence of other autoimmune diseases is useful in primary AI, given the very large fraction of these patients with autoimmune adrenalitis. In cases with absent antibodies, adrenal computed tomography imaging is indicated. Enlarged adrenal glands with high-density areas or calcification can suggest granulomatous disease or neoplasm. Acute hematoma or fluid collections around the adrenals during an acute adrenal crisis can indicate adrenal hemorrhage. Secondary AI is most often associated with chronic GC therapy but may be caused by a number of other diseases affecting the hypothalamic-pituitary region. If exogenous GC administration has been excluded, pituitary magnetic resonance imaging (MRI) and testing of the other pituitary axes are appropriate.

### Differential Diagnosis

Presentation of AI can be subtle (especially in secondary AI), and differential diagnosis is broad and includes a number of illnesses associated with fatigue, weight loss, and malaise as well as occult malignancies, renal or hepatic dysfunction, and electrolyte disturbances. In acute AI crisis, differential diagnosis includes other systemic illnesses associated with orthostatic hypotension and electrolyte abnormalities, including dehydration and distributive and septic shock. Fever can be part of an AI crisis, but an infectious process must be ruled out as the precipitating cause.

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** Causes of Primary Adrenocortical Insufficiency**Autoimmune**

Isolated  
Autoimmune polyglandular syndromes 1 and 2

**Infectious****Fungal**

Tuberculosis  
Histoplasmosis

**Viral**

Human immunodeficiency virus  
Cytomegalovirus

**Parasitic**

Syphilis  
Rarely bacterial

**Bilateral Adrenal Infarction****Hemorrhage**

Anticoagulation  
Sepsis (e.g., meningococemia)  
Trauma

**Thrombosis**

Thrombophilic condition (e.g., antiphospholipid antibody syndrome)  
Heparin-induced thrombocytopenia

**Neoplastic****Metastatic cancer**

Breast  
Colon  
Melanoma  
Lymphoma

Non-small cell lung cancer

**Infiltrative Diseases**

Hemochromatosis  
Primary amyloidosis  
Sarcoidosis

**Bilateral Adrenalectomy**

For bilateral tumors or intractable Cushing syndrome

**Familial or Genetic**

Classical congenital adrenal hyperplasia  
Adrenoleukodystrophy  
Familial glucocorticoid deficiency  
Adrenocorticotrophic hormone insensitivity syndromes  
X-linked adrenal hypoplasia (associated with DAX-1 mutation, may be of late onset)  
Triple-A or Allgrove syndrome (alacrimia, achalasia, adrenal insufficiency)

**Treatment**

GC replacement is recommended with oral hydrocortisone two or three times daily for primary AI and once or twice daily for secondary AI. One-half to two-thirds of the daily dose is given upon waking, and the dosage is roughly 15 mg to 20 mg/day (or 10 mg/m<sup>2</sup> to 12 mg/m<sup>2</sup> body surface area per day), typically 10 mg or 15 mg in the morning and 5 mg in the afternoon. Once-daily modified-release hydrocortisone is available in Europe and may better mimic the physiologic circadian rhythm of cortisol, but it is not yet available in the United States. Longer-acting GCs (prednisone, dexamethasone [Decadron]) may be used in patients who remain severely symptomatic in the evenings or early morning hours or who are unable to comply with a multidose hydrocortisone regimen. However, in such cases the risk of overreplacement is much higher.”

Patients should be instructed to increase this dosage according to physiologic stress, as doses should be doubled or tripled for the duration of the fever or intercurrent systemic illness. Day-to-day emotional stress does not require an increment in dosing. For surgery, GC parenteral doses should be administered according to the level of surgical stress, such as 25 mg for minor stress (e.g., cataract surgery),

**BOX 2** Etiologies of Secondary Adrenocortical Insufficiency**Iatrogenic/Medication**

Chronic steroid therapy, most often oral or parenteral, but could also be inhaled, topical, or injected  
Chronic opioid therapy  
Immunotherapy (CTLA-4 and PD-1/PDL-1 inhibitors)  
Drugs used for treatment of Cushing syndrome that can cause adrenal insufficiency  
Steroidogenesis inhibitors (ketoconazole, metyrapone, osilodrostat, mitotane, etomidate)  
Pituitary tumor directed drugs (pasireotide)  
Glucocorticoid receptor blockers (Mifepristone)

**Pituitary Injury**

Posttransphenoidal or transcranial surgery  
Radiation to the sella  
Infarction/hemorrhage (pituitary apoplexy, Sheehan syndrome)  
Traumatic brain injury

**Tumors of the Sella**

Pituitary adenoma  
Craniopharyngioma  
Meningioma  
Rathke cleft cyst  
Metastatic cancer

**Infiltrative/Inflammatory Diseases**

Sarcoidosis, tuberculosis, or other granulomatous diseases  
Lymphocytic hypophysitis  
Idiopathic adrenocorticotrophic hormone deficiency

**Congenital**

Genetic mutations in transcription factors (PROP-1, PIT-1, etc.)  
Midline defect  
Septo-optic dysplasia

50 mg to 75 mg for moderate stress (e.g., cholecystectomy), and 100 mg to 150 mg daily in divided doses for major stress (e.g., heart surgery).

Patients should wear a medical alert bracelet or necklace and should be dispensed hydrocortisone or dexamethasone injection with instructions for home self-administration in case of vomiting and inability to take oral doses. If symptoms do not improve within hours after injection, patients should seek urgent medical evaluation.

Mineralocorticoid replacement is indicated in most patients with primary AI, and fludrocortisone (Florinef) is the recommended medical therapy, with a typical dose between 0.05 mg and 0.1 mg once daily.

If a patient with known AI presents in adrenal crisis, hydrocortisone (Solu-Cortef) 100 mg bolus followed by 150 mg to 250 mg/day, divided every 6 to 8 hours or as a continuous 200 mg/24 hours intravenous (IV) infusion, is an appropriate initial therapy, with the dose tapered to an appropriate oral dose as the patient's condition improves. Aggressive hydration with a saline solution will help increase the intravascular volume, and high-dose GCs have some mineralocorticoid activity; thus mineralocorticoids are not required in the treatment of acute adrenal crisis.

In critical illness, the treatment of AI should not be delayed if diagnosis cannot be established and the patient is unstable. Baseline cortisol and ACTH levels should preferably be drawn prior to the initiation of treatment and should be interpreted as a stress value (i.e., should be >18 µg/dL). If in doubt, high-dose stress GCs are administered until testing is complete and cosyntropin stimulation testing may be delayed until the patient's condition improves because hydrocortisone has to be suspended at least 24 hours before testing. The controversial entity of suboptimal cortisol response during acute stress may be associated with worse outcomes, but no consensus exists for its diagnosis and treatment. Refer to [Table 1](#) for GC dosage recommendations.

**TABLE 1** Stress Dose Glucocorticoid Dosage Recommendations for Patients With Adrenal Insufficiency\*†

CLINICAL CONTEXT	MANAGEMENT
Minor surgical or medical stress (for example) Mild fever, colonoscopy, mild gastroenteritis, dental procedures	Hydrocortisone 25 mg/day OR twice the usual dose on days of stress
Moderate surgical or medical stress (for example) Cholecystectomy, pneumonia, severe gastroenteritis	Hydrocortisone 50–75 mg/day for 1–2 days followed by twice usual dose for 1–2 days, then resume the usual dose
Major surgical or medical stress (for example) Cardiopulmonary bypass, pancreatitis, vaginal delivery	Hydrocortisone 100–150 mg/day for 1–3 days followed by twice to thrice usual dose for 2–7 days, then resume usual dose
Adrenal crisis Critical illness (for example) Septic shock, hemodynamic instability	Hydrocortisone 100 mg bolus followed by 50–100 mg every 6–8 hours OR continuous infusion of 200 mg/24 h (or 0.18 mg/kg/day)

\*For an uncomplicated course, the glucocorticoid dosage should always be individualized according to patient's clinical status.

†Patients with primary adrenal insufficiency may require slightly higher doses compared with patients with secondary adrenal insufficiency and may benefit more from additional intravenous fluids to compensate for the lack of mineralocorticoids.

The replacement of dehydroepiandrosterone (DHEA) is controversial and not recommended for all patients by present guidelines. However, a trial may be warranted in selected cases of women with primary AI and persistent symptoms, including low libido and low energy. DHEA is available only as a dietary supplement and has not been approved by the US Food and Drug Administration (FDA).

### Monitoring

Patients should be interviewed and examined routinely for indicators of excess GC replacement, such as weight gain, striae, facial plethora, osteoporosis, or glucose intolerance; they should also be checked for under replacement if symptoms of AI persist. Cortisol levels and ACTH are not helpful in monitoring GC doses. Monitoring of mineralocorticoid status should include volume status, electrolytes, blood pressure, and occasionally serum renin levels. The development of hypertension, edema, or hypokalemia could mandate a dose reduction.

### Complications

Adrenal crisis in patients with known AI occurs at a rate of approximately six cases per 100 patient-years. Precipitating causes of adrenal crisis are mainly gastrointestinal infection and other infections, with other stressful events (pain, surgery, severe emotional distress, and pregnancy) occurring less commonly. Iatrogenic Cushing syndrome can develop if the dose of GC replacement is supraphysiologic long-term.

## CUSHING'S SYNDROME

Method of

Constantine A. Stratakis, MD, PhD

### CURRENT DIAGNOSIS

- Cushing's syndrome remains one of the most challenging diagnoses in endocrine medicine.
- Cushing's disease is caused by corticotropin (ACTH)-producing pituitary adenomas (corticotropinomas) and constitutes the most common cause of endogenous Cushing's syndrome, although its prevalence varies across different age groups.
- Growth failure in children, facial plethora and rounded face, central fat deposition, supraclavicular fat accumulation, buffalo hump, purple striae, thin skin, and proximal myopathy are relatively sensitive clinical features of Cushing's syndrome.
- Ectopic ACTH syndrome occasionally has an unusual presentation of rapid onset, severe weakness, and hypokalemia without classic symptoms of Cushing's syndrome.
- A urinary free cortisol test is the most cost-effective and reliable outpatient screening test.
- A 1-mg overnight dexamethasone screening test is less useful and more expensive than the urinary free cortisol test, but it provides a good alternative for patients in whom urinary collection is impossible or unreliable.
- Midnight salivary cortisol levels greater than 3.6 nmol/L (0.13 µg/dL) have a sensitivity and specificity of approximately 95% for the diagnosis of Cushing's syndrome.
- Undetectable ACTH levels (<1 pmol/L or <5 pg/mL) indicate a primary autonomous adrenocortical disease.
- Postcontrast spoiled gradient-recalled acquisition (SPGR) magnetic resonance imaging (MRI) is superior to conventional MRI for the localization of corticotropinomas in children and adults.
- Computed tomography (CT) is used to investigate adrenal disease in patients with ACTH-independent Cushing's syndrome. Usually, conventional MRI is less useful owing to motion artifacts.

## CURRENT THERAPY

- The initial therapy of choice for patients with Cushing's disease is transsphenoidal surgery of the pituitary gland to remove the responsible adenoma.
- Transsphenoidal surgery has a success rate greater than 80% in most experienced centers. Lower success rates and higher incidence of relapse are recorded in less-experienced centers.
- Laparoscopic adrenalectomy has become the treatment of choice for benign adrenal lesions with a diameter of less than 6 cm.
- In stages I to III adrenocortical carcinoma, complete tumor resection offers the best chance for cure.
- Mitotane (Lysodren), an adrenolytic agent, is used in the treatment of metastatic adrenocortical carcinoma and also as an adjuvant for tumors with a high risk of recurrence.
- Medical treatment with ketoconazole<sup>1</sup>, metyrapone<sup>1</sup>, aminoglutethimide (Cytadren)<sup>2</sup>, and mitotane<sup>1</sup> may be used to control hypercortisolism in preparation for surgery; medical adrenalectomy may also be used in cases of cyclic Cushing's syndrome.
- Pasireotide (Signifor) and mifepristone (Korlym) may be used for the treatment of Cushing's disease that cannot be cured by surgery and/or irradiation.
- The most effective treatment option for ectopic ACTH syndrome is resection of the tumor. Somatostatin analogues and various chemotherapeutic regimens have been used in the treatment of metastatic tumors.

## Definition and Epidemiology

Cushing's syndrome remains one of the most difficult diagnoses in endocrinology. By definition, Cushing's syndrome is a multisystem disorder that develops in response to glucocorticoid excess. Iatrogenic Cushing's syndrome is common, but endogenous Cushing's syndrome is a rare condition, with an estimated incidence of 0.7 to 2.4 per million population per year. The etiology of Cushing's syndrome may be excessive adrenocorticotropic hormone (ACTH) production from the pituitary gland, ectopic ACTH secretion by nonpituitary tumors, or autonomous cortisol hypersecretion from adrenal hyperplasia or tumors (Table 1). Cushing's disease refers to the subset of Cushing's syndrome cases caused by an ACTH-producing pituitary adenoma. Cushing's disease is the most common cause of spontaneous Cushing's syndrome in almost all ages, including older children and adolescents. Approximately 20% to 30% (with the exception of very young children) of endogenous Cushing's syndrome is caused by primary adrenocortical diseases that are not ACTH-dependent. Cushing's disease and adrenocortical adenomas occur more commonly in women, with a female-to-male ratio of 3–5:1.

## Pathophysiology

Cortisol inhibits the biosynthesis and secretion of corticotropin-releasing hormone (CRH) and ACTH in a negative-feedback loop that is tightly controlled. The hallmark of Cushing's syndrome is the absence of suppression of cortisol levels after low-dose dexamethasone (Decadron) administration owing to autonomous ACTH secretion by a tumor or autonomous glucocorticoid production by a primary adrenocortical disease. It is essential to understand that all diagnostic testing in Cushing's syndrome relies on the disturbance of this feedback mechanism, as revealed by dexamethasone, CRH (corticotropin ovine trifluate [Acthrel]), and all related testing.

ACTH-producing pituitary adenomas are microadenomas (<1 cm in diameter) in 80% to 90% of cases. Macroadenomas are rare and often invasive, with extension outside of the sella turcica. Chronic ACTH hypersecretion commonly leads to secondary adrenocortical hyperplasia.

Ectopic ACTH secretion is most often associated with small cell lung carcinoma, which accounts for half of the cases in adult patients with Cushing's syndrome. The ectopic ACTH syndrome

**TABLE 1** Etiology of Cushing's Syndrome in Older Children, Adolescents, and Young Adults\*

SYNDROME	% OF TOTAL
<b>ACTH-dependent</b>	
Cushing's disease	60–70
Ectopic ACTH syndrome	5–10
Ectopic CRH syndrome	<1
<b>ACTH-independent</b>	
Adrenocortical adenoma	10–15

Bilateral adrenocortical disease	5–10

\*In infants and younger children, the distribution is different.

Abbreviations: ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

causes severe hypokalemia and is usually underdiagnosed in patients during advanced stages of neoplasia. Other tumors causing the syndrome are bronchial, thymic, and pancreatic carcinoids; medullary thyroid carcinoma; pheochromocytoma; or other rare neuroendocrine tumors, especially in pediatric patients.

Adrenocortical tumors are more often adenomas that are usually smaller than 5 cm. Adrenocortical carcinomas are rare but very aggressive neoplasms; they most commonly occur as large nonsecreting abdominal masses at diagnosis, and only rarely does Cushing's syndrome develop.

Up to recently, only two types of primary adrenal hyperplasias that are ACTH-independent and cause Cushing's syndrome were known: primary pigmented nodular adrenocortical disease (PPNAD) and ACTH-independent macronodular adrenocortical hyperplasia, also known as massive macronodular adrenocortical disease.

Table 2 lists no fewer than six types of bilateral adrenocortical hyperplasias. They are divided into two groups of disorders, macronodular and micronodular hyperplasias, on the basis of the size of the associated nodules. In macronodular disorders, the greatest diameter of each nodule exceeds 1 cm; in the micronodular group, nodules are less than 1 cm. Although nodules less than 1 cm can occur in macronodular disease (especially the form associated with McCune-Albright syndrome), and single large tumors may be encountered in PPNAD (especially in older patients), the size criterion has biological relevance, because we rarely see a continuum in the same subject: most patients have either macronodular or micronodular hyperplasia. We use two additional basic characteristics in this classification of bilateral adrenocortical hyperplasias: presence of tumor pigment and status (hyperplasia or atrophy) of the surrounding cortex.

Pigment in adrenocortical lesions is rarely melanin; most of the pigmentation in adrenocortical adenomas and bilateral adrenocortical hyperplasias that produce cortisol is lipofuscin. The accumulation of lipofuscin-like material results from the progressive oxidation of unsaturated fatty acids by oxygen-derived free radicals in lysosomes. Lipofuscin pigmentation appears macroscopically as light brown to occasionally dark brown or even black discoloration of the tumor or hyperplastic tissue. Lipofuscin can be seen with a light microscope, but it is better detected by electron microscopy. Massive macronodular adrenocortical disease is a bilateral disease and may be caused by abnormal hormone receptor expression or activating mutations of G<sub>s</sub>α, which lead to stimulation of steroidogenesis. About 30% to 50% of the cases may be caused by ARMC5 mutations. Another cause of ACTH-independent Cushing's syndrome is primary pigmented nodular adrenocortical disease, usually associated with a syndrome of cardiac myxomas, lentiginos, and schwannomas (Carney's complex).

## Clinical Manifestations

The clinical presentation of Cushing's syndrome is variable and differs in severity (Table 3). Truncal obesity is the most common

**TABLE 2** Bilateral Adrenal Hyperplasias Causing Cushing's Syndrome

LESION	AGE GROUP	HISTOPATHOLOGY	GENETICS	GENE, LOCUS
<b>Macronodular Hyperplasias (Multiple Nodules &gt;1 cm Each)</b>				
Bilateral macroadenomatous hyperplasia	Middle age	Distinct adenomas (usually 2 or 3) with internodular atrophy	MEN1, FAP, MAS, HLRCS; isolated (AD); other	Menin, APC, GNAS, FH, ectopic GPCRs, ARMC5, PRKACA 5
Bilateral macroadenomatous hyperplasia of childhood	Infants, very young children	Distinct adenomas (usually 2 or 3) with internodular atrophy; occasional microadenomas	MAS	GNAS
ACTH-independent macronodular adrenocortical hyperplasia, also known as massive macronodular adrenocortical disease	Middle age	Adenomatous hyperplasia (multiple) with internodular hyperplasia of the zona fasciculata	Isolated, AD	Ectopic GPCRs; WISP2 and Wnt-signaling; 17q22-24, other; ARMC5, PRKACA 5
<b>Micronodular Hyperplasias (Multiple Nodules &lt;1 cm Each)</b>				
Isolated primary pigmented nodular adrenocortical disease	Children; young adults	Microadenomatous hyperplasia with (mostly) internodular atrophy and nodular pigment (lipofuscin)	Isolated, AD	PRKAR1A, PDE11A; PDE8B; 2p16; PRKACA 5 other
Carney complex-associated primary pigmented nodular adrenocortical disease	Children; young and middle aged adults	Microadenomatous hyperplasia with (mostly) internodular atrophy and (mainly nodular) pigment (lipofuscin)	CNC (AD)	PRKAR1A, 2p16; other
Isolated micronodular adrenocortical disease	Mostly children; young adults	Microadenomatous, with hyperplasia of the surrounding zona fasciculata and limited or absent pigment	Isolated, AD; other	PDE11A, PDE8B; other; 2p12-p16, other

**Abbreviations:** ACTH = adrenocorticotrophic hormone; AD = autosomal dominant; APC = adenomatous polyposis coli gene; cAMP = cyclic adenosine monophosphate; CNC = Carney complex; FAP = familial adenomatous polyposis; FH = fumarate hydratase; GNAS = gene coding for the stimulatory subunit alpha of the G-protein (Gsa); GPCR = G-protein-coupled receptor; HLRCS = hereditary leiomyomatosis and renal cancer syndrome; MAS = McCune-Albright syndrome; MEN1 = multiple endocrine neoplasia type 1; PDE8B = phosphodiesterase 8B gene; PDE11A = phosphodiesterase 11A gene; PRKAR1A = protein kinase, cAMP-dependent, regulatory, type I, alpha gene; WISP2 = Wnt1-inducible signaling pathway protein 1; Wnt = wingless-type MMTV integration site family.

clinical sign and is usually the initial manifestation in most patients. Growth failure in children is the most reliable sign of Cushing's syndrome, especially when combined with continuing weight gain. Other symptoms include central fat deposition, supraclavicular fat accumulation, buffalo hump, plethora, rounded face, purple striae, thin skin, proximal muscle weakness, hypertension, impaired glucose metabolism, gonadal dysfunction, and hirsutism (see Table 3). Diabetes mellitus and hypertension also develop. Osteoporosis, mood disorders, emotional lability and cognitive deficits are commonly observed. Proximal myopathy is common, especially in older patients. Ectopic ACTH syndrome caused by small cell lung cancer can have an unusual presentation characterized by rapid onset, severe weakness, and associated hypokalemia without classic symptoms of Cushing's syndrome. In contrast, ACTH-secreting carcinoids manifest with typical clinical manifestations.

## Diagnosis

### Confirmation of the Diagnosis

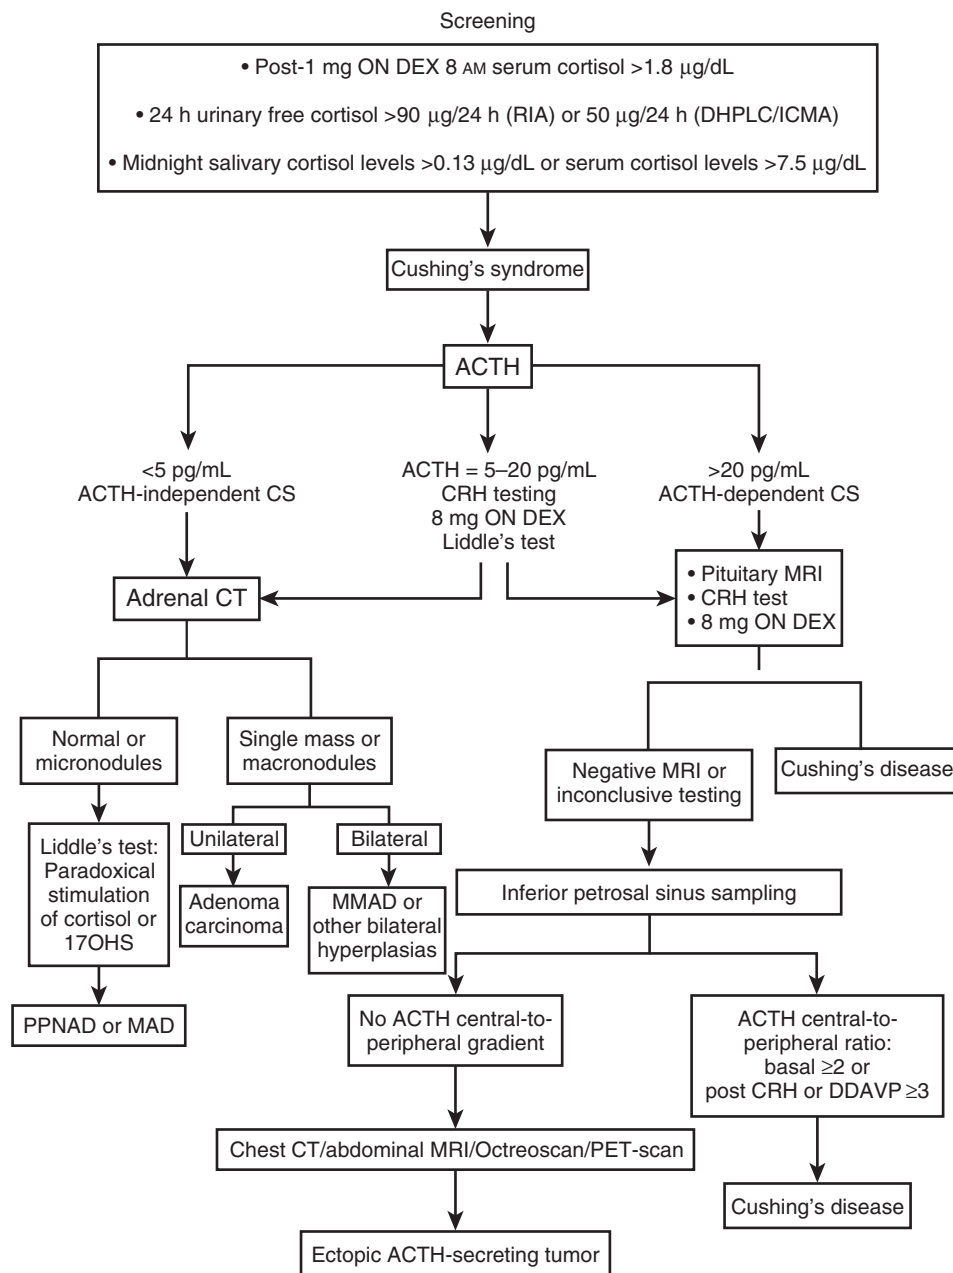

The initial evaluation should always include a careful clinical history and physical examination. Reliable symptoms and signs of Cushing's syndrome (see Table 3) should be present in any patient who undergoes evaluation for Cushing's syndrome; patients with no reliable symptoms and signs of Cushing's syndrome should not be investigated, as this often leads to unnecessary, extensive, and expensive testing. It is essential to investigate the use of exogenous glucocorticoids and other conditions that may be associated with mild hypercortisolism, such as alcoholism, anorexia nervosa, severe depression, and morbid obesity; these are pseudo-Cushing's states and are often difficult to exclude, especially in older or chronically ill patients.

The first task in the workup of any patient is documentation of hypercortisolism. On an outpatient basis, this is typically done through the urinary free cortisol test. This is the most cost-effective and reliable outpatient screening test. We typically recommend

**TABLE 3** Clinical Manifestations of Cushing's Syndrome

SIGNS AND SYMPTOMS	INCIDENCE (%)
Central obesity	97
Plethora	89
Moon facies	89
Decreased libido	86
Atrophic skin and easy bruising	75
Decreased linear growth	70–80
Menstrual irregularities	80
Hypertension	76
Hirsutism	56
Depression or emotional lability	67
Glucose intolerance/diabetes mellitus	70
Purple striae	60
Buffalo hump	54
Osteoporosis	50
Headache	10

collections over two or three consecutive days so that we avoid errors due to over- or undercollection that are not uncommon with single 24-hour studies. The results of the test need to be corrected for body surface area, as long as total creatinine excretion is normal. A 1-mg overnight dexamethasone test is less useful and more expensive, but it provides a good alternative for patients in whom urinary collection is impossible or unreliable. During these

**Figure 1** Algorithm for evaluating patients with Cushing's syndrome. *Abbreviations:* ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone; CS = Cushing's syndrome; CT = computed tomography; DDAVP = desmopressin; DHPLC = denaturing high-performance liquid chromatography; ICMA = immunochemiluminometric assay; MAD = micronodular disease; MMAD = massive macronodular adrenocortical disease; MRI = magnetic resonance imaging; 17OHS = 17-hydroxysteroids; ON DEX = overnight dexamethasone; PET = positron emission tomography; PPNAD = primary pigmented nodular adrenocortical disease; RIA = radioimmunoassay.

screening tests for hypercortisolism, patients should avoid any activation of the hypothalamic-pituitary-adrenal axis by stress, especially physical. The baseline measurements may be repeated as needed, because cyclic hypercortisolism often precedes overt Cushing's syndrome (Figure 1).

A 24-hour urinary free cortisol excretion of greater than 250 nmol per 24 hours (90 µg/24 hours measured by radioimmunoassay) is highly specific for the diagnosis of hypercortisolism. However, pseudo-Cushing's states are often associated with abnormal levels of 24-hour urinary free cortisol. Administration of 1 mg dexamethasone (15 µg/kg for children) at 11 PM results in suppression of the hypothalamic-pituitary-adrenal axis in normal persons and a fall in plasma and urinary cortisol levels. At 8 AM, serum cortisol should be less than 50 nmol/L (1.8 µg/dL). Unfortunately, dexamethasone is primarily metabolized by the cytochrome P-450 (CYP) system; several drugs, such as phenobarbital, carbamazepine (Tegretol), and rifampicin (Rifadin), that induce the activity of CYP3A4 can lead to false-positive tests. Oral contraceptives also interfere with serum cortisol levels owing to an increase in corticosteroid-binding globulin and by increasing dexamethasone metabolism. The test can only be interpreted if the serum dexamethasone levels reach the expected range; however, this additional requirement can make the test significantly more cumbersome and expensive.

Once hypercortisolism is suspected by the urinary free cortisol or the overnight dexamethasone test, the patient may undergo testing of the cortisol diurnal rhythm. The lack of circadian rhythm of cortisol is the earliest consistent biochemical abnormality of Cushing's syndrome, even in situations of cyclic or other atypical forms of Cushing's syndrome. Serum or salivary cortisol levels at midnight may be used for this test. Normally, the level of serum cortisol begins to rise at 3 to 4 AM and reaches a peak at 7 to 8 AM, falling during the day. A sleeping midnight serum cortisol level lower than 50 nmol/L (1.8 µg/dL) excludes the diagnosis of Cushing's syndrome, whereas a midnight serum cortisol higher than 207 nmol/L (7.5 µg/dL) is highly suggestive of Cushing's syndrome. This test does require inpatient admission. Salivary cortisol levels have an excellent correlation with serum cortisol levels and offer an easy and convenient outpatient way of evaluating circadian rhythm; saliva is also stable at room temperature (for up to 7 days). Midnight salivary cortisol levels greater than 3.6 nmol/L (0.13 µg/dL) have a sensitivity and specificity of approximately 95% for the diagnosis of Cushing's syndrome (see Figure 1).

After the biochemical confirmation of hypercortisolism, the next step is to investigate the source (see Figure 1). Baseline ACTH plasma levels greater than 2 to 5 pmol/L (>20–25 pg/mL) are diagnostic of ACTH-dependent Cushing's syndrome. On the

other hand, undetectable ACTH levels (<1 pmol/L or 5 pg/mL) indicate a primary autonomous adrenocortical disease. Values in between should be further investigated with dynamic testing.

### High-Dose Dexamethasone Testing

Oral dexamethasone is administered as 2 mg every 6 hours for 48 hours or as a single 8 mg (120 µg/kg for children) overnight dose. Urinary and serum cortisol levels are suppressed by more than 50% in most patients with Cushing's disease.

### Corticotropin-Releasing Hormone Testing

Synthetic ovine CRH (corticotropin ovine trifluate [Acthrel]), an analogue of human CRH is administered intravenously (100 µg), and plasma ACTH and cortisol levels are measured at 15-minute intervals during the next 60 minutes. Patients with Cushing's disease typically have an increase in ACTH or cortisol level of 35% and 22%, respectively. This test has a sensitivity of approximately 85% for the diagnosis of Cushing's disease, but it is often falsely positive in patients with adrenal, ACTH-independent Cushing's syndrome, who do not have a fully suppressed hypothalamic-pituitary-adrenal axis.

### Inferior Petrosal Sinus Sampling

None of the noninvasive tests are 100% accurate in distinguishing pituitary (Cushing's disease) from ectopic sources of ACTH. Inferior petrosal sinus sampling (IPSS) is indicated in all cases where an ACTH-dependent source of hypercortisolism is expected but the diagnosis of Cushing's disease versus an ectopic source remains uncertain. Typically, IPSS is done when the ovine CRH and dexamethasone tests are in disagreement or when the pituitary imaging by magnetic resonance imaging (MRI) is negative. An ACTH gradient of central-to-peripheral ACTH levels of 2 or more suggests Cushing's disease. When ovine CRH, human CRH, or desmopressin (DDAVP) testing is performed during IPSS, the diagnostic accuracy of IPSS increases. After ovine CRH stimulation, a central-to-peripheral ratio of ACTH levels of 3 or more suggest the diagnosis of Cushing's disease with specificity and sensitivity greater than 95%. The test is less useful for suggesting the tumor location (right versus left side of the pituitary gland).

### Imaging Studies

#### Pituitary Magnetic Resonance Imaging

Unfortunately, less than 50% of ACTH-producing pituitary adenomas are detectable with MRI, even with the use of contrast enhancement. Typically, we recommend against obtaining an MRI until ACTH dependency is established, because as many as 20% of the patients have an incidental pituitary microadenoma. To avoid false-negative and false-positive imaging, several centers have sought improved methods for MRI detection of ACTH-producing tumors. Our studies demonstrated that postcontrast spoiled gradient-recalled acquisition (SPGR) MRI in addition to the conventional T1-weighted spin echo was superior to conventional MRI for the diagnostic evaluation of corticotropinomas in both children and adults.

#### Adrenal Imaging

Computed tomography (CT) and MRI are used to investigate adrenal disease in patients with ACTH-independent Cushing's syndrome. Adrenal tumors larger than 6 cm are highly suspicious for adrenocortical carcinomas. The fat content contributes to the differentiation between benign and malignant adrenal tumors. Measurement of Hounsfield units (HU) in unenhanced CT is of great value in differentiating malignant from benign adrenal lesions. Adrenal lesions with an attenuation value of more than 10 HU in unenhanced CT or an enhancement washout of less than 50% and a delayed attenuation of more than 35 HU (on 10- to 15-min delayed enhanced CT) are suspicious for malignancy. MRI with dynamic gadolinium-enhanced and chemical shift technique is as effective as CT in distinguishing malignant from benign lesions. However, MRI is much less useful for detecting adrenal nodularity owing to motion artifacts. Thus, especially for detecting small unilateral adrenocortical adenomas or bilateral micronodular hyperplasia, we recommend a dedicated (thin-sliced) adrenal CT rather than MRI.

### Ectopic Adrenocorticotrophic Hormone Syndrome

High Resolution Chest-CT 7 and abdominal MRI are the recommended imaging procedures in patients with an IPSS that indicates a nonpituitary ACTH-producing source. Additionally, somatostatin receptor scintigraphy is a useful and complementary tool in the evaluation of patients with ectopic ACTH-dependent Cushing's syndrome. Recent studies have demonstrated a higher sensitivity of somatostatin receptor scintigraphy in comparison to CT or MRI for diagnosing occult ectopic tumors. Additional methods include PET-CT and FDG scans.

### Treatment

Untreated chronic hypercortisolism is associated with high morbidity and mortality owing to diabetes mellitus, hypertension, cardiovascular disease, thromboembolism, and suppression of the immune system. Cushing's syndrome should be treated effectively; patients should be closely monitored to rapidly detect recurrent disease.

### Treatment of Pituitary Corticotropinomas

#### Transsphenoidal Pituitary Surgery

The initial therapy of choice for patients with Cushing's disease is transsphenoidal surgery. This procedure is associated with low mortality and morbidity, but complications can include cerebrospinal fluid leaks, meningitis, hypopituitarism, and venous thromboembolism. The success rate for transsphenoidal surgery varies between 60% and 80%, but in experienced centers can be as high as 90% to 95%. Relapses are rare when surgery is performed in an experienced tertiary care center; it can be as high as 30% in less-experienced centers. Postoperative morning serum cortisol levels of less than 50 nmol/L (2 µg/dL) are highly predictive of remission and a low recurrence rate of less than 10% at 10 years.

After successful transsphenoidal surgery, glucocorticoid replacement therapy (hydrocortisone at 12–15 mg/m<sup>2</sup>/day; 20–30 mg daily in adults) is mandatory until the hypothalamic-pituitary-adrenal axis recovers from the chronic exposure to glucocorticoid excess; this usually takes place within a year after surgery. For recurrent disease, the choice of second-line therapy remains controversial. Repeat surgery can be successful when residual tumor is detectable on MRI imaging, but it carries a high risk of hypopituitarism. Irradiation is recommended in most cases where a tumor is not seen on MRI.

#### Radiotherapy

Radiotherapy has been used to suppress pituitary secretion of ACTH, but its success rate is variable (50% in some series). It can take as long as 5 years for a full effect; hypopituitarism develops in more than 70% of the patients over a period of 10 to 20 years after the therapy is completed. Stereotactic radiosurgery with gamma knife is associated with a more-rapid effect and a lower risk of hypopituitarism, but it has not been extensively studied.

### Medical Treatment to Control Secretion of Adrenocorticotrophic Hormone

Cushing's disease responds to the dopamine agonist cabergoline (Dostinex)<sup>1</sup> with a normalization of cortisol production in as many as 40% of the cases. The peroxisome proliferator-activated receptor  $\gamma$  (PPAR- $\gamma$ ) agonist rosiglitazone (Avandia)<sup>1</sup> was demonstrated to be effective in animal models, but it was unsuccessful in controlling ACTH oversecretion in patients with Cushing's disease. A new agent, SOM-230 (pasireotide [Signifor]), blocks both type 2 and type 5 somatostatin receptors and reduces ACTH secretion in vitro. Mifepristone (Korlym), a glucocorticoid receptor antagonist, recently became available for patients who failed surgical or irradiation therapies (see also below).

#### Bilateral Adrenalectomy

Bilateral adrenalectomy offers a definitive treatment that provides immediate control of hypercortisolism, but this surgery should be reserved for patients with Cushing's disease who have failed all other treatments. Bilateral adrenalectomy in active Cushing's disease often

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Medical Treatment for Hypercortisolism

MEDICATION	INITIAL DOSE	MAXIMUM DOSE	ADVERSE EFFECTS
Ketoconazole (Nizoral) <sup>1</sup>	100–200 mg bid/tid	1200 mg	Nausea, vomiting, abdominal pain, weakness, hypothyroidism, gynecomastia, hepatotoxicity, hypertriglyceridemia
Metyrapone (Metopirone) <sup>1</sup>	250 mg qid	6000 mg	Headache, alopecia, hirsutism, acne, nausea, abdominal discomfort, hypertension, weakness, leucopenia
Mitotane (Lysodren) <sup>1</sup>	500 mg tid	9000 mg	Nausea, vomiting, anorexia, diarrhea, ataxia, confusion, skin rash, hepatotoxicity
Aminoglutethimide (Cytadren) <sup>2</sup>	250 mg qid	2000 mg/d	Lethargy, nausea, anorexia, hypothyroidism, somnolence

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

leads to Nelson's syndrome, a condition characterized by unabated progression of a corticotropinoma (owing to the lack of negative feedback by cortisol), very high ACTH levels, and high morbidity.

### Treatment of Adrenal Disease

#### Adrenocortical Tumors

For adrenocortical tumors, the recommended treatment is surgical. Laparoscopic adrenalectomy has become the treatment of choice for benign adrenal lesions with a diameter of less than 6 cm. In stages I to III adrenocortical carcinoma, complete tumor removal by a well-trained surgeon offers by far the best chance for cure. Surgery often needs to be extensive, with en bloc resection of invaded organs, and regularly includes lymphadenectomy. Surgery for local recurrences or metastatic disease is accepted as a valuable therapeutic option and was associated with improved survival in retrospective studies. The overall 5-year survival in different series ranged between 16% and 38%. Median survival for metastatic disease (stage IV) at the time of diagnosis is still consistently less than 12 months.

Radiotherapy has been considered ineffective for treatment of adrenocortical cancer, but it can be indicated to control localized disease not amenable to surgery.

Mitotane (o,p'-DDD [Lysodren]) is the only adrenal-specific agent available for treating adrenocortical cancer. Mitotane is indicated in metastatic adrenocortical carcinoma and can also be used as an adjuvant for tumors with a high risk of recurrence. Mitotane exerts a specific cytotoxic effect on adrenocortical cells, leading to focal degeneration of the fascicular and particularly the reticular zone. In most patients, treatment should be initiated with a dose that does not exceed 1.5 g/day; this is then rapidly increased, depending on gastrointestinal symptoms, to 5 to 6 g/day. This high-dose regimen requires measurement of mitotane blood levels 14 days after initiation of therapy. The dose is then adjusted according to the medicine's plasma concentrations (which should be greater than 14 mg/L) and tolerance of the side effects. Because mitotane treatment induces adrenal insufficiency and increases the metabolic clearance of glucocorticoids, glucocorticoid replacement is indicated, often at higher than normal doses owing to increased clearance.

#### Cytotoxic Chemotherapy

Cytotoxic chemotherapy includes etoposide (VePesid)<sup>1</sup>, doxorubicin (Adriamycin)<sup>1</sup>, and cisplatin (Platinol)<sup>1</sup>, or streptozocin (Zanosar)<sup>1</sup> plus mitotane. Chemotherapy has limited efficacy for advanced adrenocortical cancer and is associated mainly with partial responses.

#### Bilateral Adrenal Hyperplasias

The treatment of choice for bilateral adrenal hyperplasias associated with ACTH-independent Cushing's syndrome is bilateral adrenalectomy. Patients require lifelong replacement therapy with glucocorticoids and mineralocorticoids, and they should be adequately educated about the risk of acute adrenal insufficiency.

<sup>1</sup>Not FDA approved for this indication.

### Treatment of Ectopic Corticotropin Syndrome

The choice of treatment for ectopic ACTH syndrome depends on tumor identification, localization, and classification. The most effective treatment option is surgical resection, although this is not always possible in metastatic disease or in the case of occult tumors. Because the ectopic ACTH syndrome is usually severe and occult tumors can become evident at imaging studies only during the follow-up, medical treatment to control hypercortisolism is often necessary. Bilateral adrenalectomy may be an option to be considered when the hypercortisolism cannot be controlled by other treatment options.

#### Medical Adrenalectomy

Several drugs that inhibit steroid synthesis are often effective for rapidly controlling hypercortisolism in preparation for surgery, after unsuccessful transsphenoidal surgery or removal of an adrenal tumor such as extensive cancer, or while awaiting the full effect of radiotherapy in recurrent Cushing's disease (Table 4).

Most experience with inhibitors of steroidogenesis has been with metyrapone (Metopirone)<sup>1</sup> and ketoconazole (Nizoral)<sup>1</sup>, two medications that appear to be more effective and better tolerated than aminoglutethimide (Cytadren)<sup>2</sup>. Metyrapone reduces cortisol and aldosterone production by inhibiting 11 $\beta$ -hydroxylation in the adrenal cortex. Ketoconazole is a broad-spectrum antifungal drug, which inhibits C17-20 desmolase, cholesterol side-chain cleavage, and 11 $\beta$ -hydroxylation. Ketoconazole is also associated with inhibition of testosterone biosynthesis and gynecomastia.

RU-486, or mifepristone (Korlym), is an antagonist of the progesterone and glucocorticoid receptors. Unexpectedly, the treatment of Cushing's disease with this glucocorticoid antagonist has been associated with increased ACTH secretion and consequent stimulation of cortisol production. RU-486 may be more useful in ectopic ACTH-producing tumors and in adrenal Cushing's syndrome, but its efficacy and potential side effects when administered chronically are currently unknown.

## DIABETES INSIPIDUS

Method of

Rami Mortada, MD

### CURRENT DIAGNOSIS

- Diabetes insipidus (DI) is a disorder of excess urine production (i.e., “diabetes”) that is dilute and tasteless (i.e., “insipidus”). DI contrasts with the concentrated and sweet urine in diabetes mellitus.
- Patients with DI present with polyuria and polydipsia; urine output is usually more than 40 mL/kg/day or more than 3 L/day.
- There are three subtypes of DI:
  - Central DI: due to relative or absolute lack of vasopressin
  - Nephrogenic DI: due to partial or total resistance to the renal antidiuretic effects of vasopressin
  - Dipsogenic DI (also called primary polydipsia): where polyuria is secondary to excessive, inappropriate fluid intake
- Initial labs should include plasma sodium and urine osmolality. Under normal physiologic conditions, the urine osmolality is less than 300 mOsm/L, but if the patient does not have sufficient fluid intake, the urine osmolality can be higher.
- The diagnosis is confirmed by examining urine output and osmolality. It can be followed by an assessment of renal response to the synthetic arginine vasopressin (AVP) analogue desmopressin (DDAVP).
- In primary polydipsia, urine concentration is normal in response to dehydration.
- In central DI, urine concentration does not increase appropriately with dehydration, but does respond to desmopressin (DDAVP). After dehydration in central DI, urine osmolality remains <300 mOsm/kg, and plasma osmolality is >290 mOsm/kg. Urine osmolality rises to >750 mOsm/kg after desmopressin.
- In nephrogenic DI, urine concentration does not increase appropriately with either dehydration or exogenous desmopressin.

### CURRENT THERAPY

- The treatment goal is to control polyuria and ensure electrolyte stability.
- In Central DI:
  - The mild form might not require treatment.
  - Significant polyuria can be treated with desmopressin in divided doses: nasal spray 5 to 100 µg/day; tablets 100 to 1000 µg/day; or parenterally 0.1 to 2.0 µg/day.
  - Overtreatment can cause hyponatremia.
- In Nephrogenic DI:
  - Urine output should not be expected to normalize after DDAVP administration.
  - Correct the culprit cause (hypercalcemia or lithium [Eskalith, Lithobid] cessation).
  - Follow a low-sodium, low-protein diet, as tolerated.
  - Hydrochlorothiazide<sup>1</sup> 25 to 50 mg/day may be taken either alone or in combination with indomethacin (Indocin) 25 to 50 mg twice daily.
  - Symptoms may respond partly to high-dose desmopressin (e.g., 4 mcg IM twice daily).
- Primary polydipsia is treated by limiting an excessive fluid intake.

<sup>1</sup>Not FDA approved for this indication.

### Physiology of Antidiuretic Hormone

Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), is a neurohypophysial hormone. It is a peptide hormone that promotes water retention by increasing the permeability of the kidney's collecting duct and distal convoluted tubule to water. It also increases peripheral vascular resistance, which in turn increases arterial blood pressure. In the clinical setting, the terms AVP, ADH, and vasopressin are used interchangeably.

Vasopressin is considered the main hormone involved in the regulation of water homeostasis and osmolality. The regulation and synthesis of vasopressin is under the influence of two systems: osmotic and pressure/volume status. In the case of osmoregulation, a small increase in plasma osmolality produces a parallel increase in vasopressin secretion; a small decrease in plasma osmolality causes a parallel drop in vasopressin.

Vasopressin is one among other hormones and systems that are involved in the regulation of volume and blood pressure. Other factors influence vasopressin production. For example, glucocorticoids inhibit secretion, whereas nausea and vomiting have a stimulatory effect.

### Pathophysiology of Diabetes Insipidus

The kidneys exercise one of their urine-concentrating abilities by promoting water retention. If the concentration of vasopressin is decreased, polyuria occurs and diluted urine is excreted. A decrease in total body water results in an increase in the plasma osmolality. If the physiologic response is intact, thirst is stimulated, which leads to an increase in water consumption and the correction of plasma osmolality. Therefore, unless there is a dysregulation in the thirst mechanisms or water consumption is limited due to a lack of availability (e.g., decreased level of consciousness, immobility, or physical restraints) severe dehydration does not develop.

### Clinical Causes

There are three subtypes of diabetes insipidus (DI).

- DI secondary to excess water intake (primary polydipsia)

Primary polydipsia is a disorder characterized by inappropriate excess fluid intake due to a disordered thirst sensation seen mostly in patients with psychiatric illnesses. A central defect in thirst regulation plays an important role in the pathogenesis of primary polydipsia. Such patients continue drinking even if the plasma osmolality falls below normal. It is not easy to achieve or maintain a low plasma osmolality because vasopressin secretion will normally be suppressed by the fall in plasma osmolality, resulting in rapid excretion of the excess water. If vasopressin regulation is intact, primary polydipsia should not lead to clinically important disturbances in the plasma sodium concentration unless hyposmolar fluid intake overwhelms the kidneys' ability to excrete excess water. Thus the serum sodium concentration is usually normal or slightly reduced in primary polydipsia. These patients may be asymptomatic or present with complaints of polydipsia and polyuria. In rare circumstances where water intake exceeds the kidneys' ability to excrete the water load of about 500 mL/hour, symptomatic severe hyponatremia might result in severe psychosis. Psychosis from hyponatremia in primary polydipsia is most commonly seen in institutionalized patients or in individuals attempting to dilute their urine to avoid a positive urine drug test.
- DI secondary to a decrease in or absence of vasopressin secretion (central DI)

Central DI may be caused by genetic anomalies of the vasopressin gene (Table 1). Familial neurohypophysial DI is characterized by the onset of DI with polyuria and polydipsia in childhood or early adulthood. The most common MRI finding in familial neurohypophysial DI is the progressive disappearance of the posterior pituitary bright spot in children. The normal pituitary bright spot seen on unenhanced T<sub>1</sub>-weighted MRI is thought to result from the T<sub>1</sub>-shortening effect of the

**TABLE 1** Central Diabetes Insipidus (DI) Etiologies

Idiopathic	Unknown etiology
Genetic	Familial neurohypophyseal DI, Wolfram's syndrome (autosomal recessive)
Mass effect	Craniopharyngiomas, primary germ cell tumors, metastatic tumors
Infiltrative diseases	Lymphoma, leukemia, sarcoidosis, amyloidosis
Autoimmune	Lymphocytic infundibuloneurohypophysitis
Trauma	Motor vehicle accident, closed head trauma
Surgical	Surgical intervention at the pituitary region

vasopressin stored in the posterior pituitary. The disappearance of the bright spot corresponds to the disappearance of vasopressin stores in the posterior pituitary. Wolfram's syndrome is a rare autosomal recessive syndrome manifested by DI, diabetes mellitus, optic atrophy, and deafness.

Central DI may be caused by mass lesions of the neurohypophysis, such as craniopharyngiomas, and primary germ cell tumors in childhood. DI can be the initial presentation. MRI often shows a thickened pituitary stalk and may show a hypothalamic mass. Metastasis to the pituitary usually is found with widespread metastatic disease and is twice as likely to involve the posterior pituitary than the anterior pituitary. DI can be associated with pituitary infiltration associated with lymphomas and leukemias.

In granulomatous disease that affects the hypothalamic-pituitary axis, there is usually clear evidence of disease elsewhere in the body. MRI shows an absence of the pituitary bright spot and widening of the hypothalamic-pituitary stalk. Lymphocytic infundibuloneurohypophysitis is a new, well-recognized cause of autoimmune DI, characterized by MRI appearance of a thickened hypothalamic-pituitary stalk and large posterior pituitary gland mimicking a pituitary tumor. Pituitary abscess is a rare cause of pituitary mass and DI. In situations where the cause is not easily diagnosed, an autoimmune process should be suspected. In some patients, the cause is idiopathic.

Central DI may be caused by surgery or trauma to the pituitary region. Vasopressin is normally secreted after any kind of surgical stress, and secretion is more pronounced after surgery to the pituitary region. Only a small percentage of patients undergoing pituitary surgery have permanent DI. A triphasic DI can occur after complete hypothalamic-pituitary stalk transection. The first phase is polyuric and appears within the first 24 hours after surgery. It is thought to be secondary to axonal shock with a resultant inability to release prefabricated vasopressin. The second phase is antidiuretic and starts on about day 6, after stalk injury. It is thought to be secondary to the unregulated release of vasopressin stores. The third phase, also polyuric, starts about day 12, after vasopressin stores have been depleted. It may result in permanent or partial DI or resolve to clinically asymptomatic disease.

The same patterns of DI that occur after pituitary surgery can be seen in patients who experience a closed head trauma. Three-quarters of traumatic induced DI are secondary to motor vehicle accidents. Trauma is usually severe and causes unconsciousness. There is a high association of anterior pituitary deficiency in association with DI induced by head trauma, so the possibility of central hypocortisolism should be considered and treated immediately. DI is reported in 50% to 90% of patients with brain death.

- DI secondary to the lack of renal response to vasopressin (nephrogenic DI)

Genetic anomalies resulting in a lack of renal response to vasopressin are caused by either a mutation in the V2 recep-

tors or a mutation of the aquaporin 2 water channels gene. The majority of the cases are X-linked recessive disorders in males. Newborns present with polyuria, vomiting, constipation, and failure to thrive. Symptoms usually occur within the first week of life.

Acquired nephrogenic DI can be caused by a kidney disease that distorts the architecture of the kidney and impairs its urine-concentrating ability (e.g., polycystic kidney disease, sickle cell disease). Decreased function of vasopressin or downregulation of aquaporin 2 channels can be caused by hypokalemia, hypercalcemia, and relief of bilateral urinary tract obstruction. Drugs such as lithium (the most common cause of drug-induced nephrogenic DI) and demeclocycline (used clinically to treat a syndrome of inappropriate ADH secretion) may cause nephrogenic DI.

### Clinical Manifestations

Patients with central DI typically present with polyuria, nocturia, and polydipsia. The serum sodium concentration in untreated central DI is often in the high normal range, which provides the ongoing stimulation of thirst that replaces urinary water losses. Moderate to severe hypernatremia can develop when thirst is impaired or if there is a lack of access to free water, such as the postoperative period in patients with unrecognized DI or infants with DI. For uncertain pathophysiologic reasons, patients with central DI may develop decreased bone mineral density at the lumbar spine and femoral neck, even if treated with desmopressin.

Nephrogenic DI in its mild form can be asymptomatic. Patients with moderate to severe nephrogenic DI, as with central DI, typically present with polyuria, nocturia, and polydipsia.

Primary polydipsia is the result of an abnormal compulsion to drink water. This disorder is most often seen in middle-aged women and in patients with psychiatric illnesses. The excessive water intake initially drives the excessive urination.

### Diagnosis

Polyuria must be distinguished from simple urinary frequency in the absence of excess urine volume. The initial diagnostic approach should be to confirm polyuria, defined as greater than 30 mL/kg or 3 L/day, with a urine osmolality measuring less than 300 mOsm/L. Simple metabolic causes such as hyperglycemia, uremia, and hypercalcemia should be excluded. A definitive diagnosis of DI requires testing of vasopressin production and action in response to osmolar stress. All forms of DI may be partial or complete. In primary polydipsia, the plasma sodium, blood urea nitrogen (BUN), and uric acid are relatively low. In other forms of DI, the plasma sodium and uric acid are relatively high and the BUN is relatively low.

Central DI usually has an abrupt onset resulting from destruction of more than 80% of vasopressin-secreting hypothalamic neurons. The etiology of polyuria is not always evident after history and laboratory tests are completed. In that case, a water restriction test (e.g., dehydration test or water deprivation test) is completed. The water deprivation test is an indirect assessment of the AVP axis, measuring renal concentrating capacity in response to dehydration. It can be followed by assessment of the renal response to the synthetic AVP analogue desmopressin to determine whether any defect identified in urine-concentrating ability can be corrected with AVP-replacement. Office testing is acceptable unless the patient cannot be watched closely. No food or water is allowed. The patient is watched for signs of dehydration and surreptitious water drinking. Baseline measurements include weight, plasma osmolality, sodium, BUN, glucose, and urine volume and osmolality. Weight, plasma osmolality, and urine osmolality are measured hourly. The test is ended if urine osmolality has not increased to more than 300 mOsm/kg for 3 consecutive hours, plasma osmolality has reached 295 to 300 mOsm/kg, or the patient has lost 3% to 5% of body weight. All initial measurements are repeated at the end of the water restriction test. Then, 5 units of aqueous AVP (Pitressin) is administered or 2 µg of desmopressin is given subcutaneously and the plasma osmolality,

**TABLE 2** Values Before and After Water Restriction

	INITIAL PLASMA OSMOLALITY	INITIAL PLASMA SODIUM	POSTTEST URINE/PLASMA OSMOLALITY	POSTTEST URINE/PLASMA OSMOLALITY+ADH
Normal	NL	NL	>1	>1
Central DI	High (high NL)	High (high NL)	<1	>1
Nephrogenic DI	High (high NL)	High (high NL)	<1	<1
Primary polydipsia	Low (low NL)	Low (low NL)	>1	>1

**TABLE 3** Treatment Options for Diabetes Insipidus

Central DI	Divide doses of two to three times per day: Desmopressin nasal spray 5–100 µg/day Desmopressin tablets 0.1–1 mg/day Desmopressin injection 0.1–2 µg/day
Nephrogenic DI	Low-salt, low-protein diet HCTZ <sup>1</sup> 25 mg one to two times per day Indomethacin <sup>1</sup> 25–50 mg bid Amiloride <sup>1</sup> 5–10 mg bid
Primary polydipsia	Water restriction to less than 1.5 L/day

<sup>1</sup>Not FDA approved for this indication.

sodium, BUN, glucose, and urine volume and osmolality are measured at 30, 60, and 120 minutes.

In primary polydipsia, urine concentration is normal in response to dehydration (Table 2).

In central DI, urine concentration does not increase appropriately with dehydration, but responds to desmopressin. Urine osmolality remains <300 mOsm/kg, accompanied by plasma osmolality >290 mOsm/kg after dehydration, and urine osmolality rising to >750 mOsm/kg after desmopressin administration.

In nephrogenic DI, urine concentration does not increase appropriately with either dehydration or exogenous desmopressin.

In practice, many results are indeterminate. If central DI is suspected, but the water deprivation test data are inconclusive, a reasonable approach is a therapeutic trial of 10 to 20 µg intranasal desmopressin per day with close monitoring of plasma sodium. If the diagnosis is confirmed, pituitary function testing and cranial MRI should follow.

### Treatment

The treatment goal is to improve polyuria and polydipsia symptoms while attempting to treat the etiologic factors (Table 3). This is achieved by appropriate correction of dehydration, if present, and replacing vasopressin or augmenting its effect on the target tissue.

Mild forms of central DI may not require pharmacologic treatment. Desmopressin effectively treats polyuria and polydipsia. Desmopressin comes in different forms, and dosages usually need to be divided.

Hyponatremia from plasma dilution can be avoided by skipping treatment for a short period on a regular basis (e.g., on Sunday). No second dose of desmopressin should be given unless the patient has urine output after the first dose.

Nephrogenic DI may respond to the removal of the offending agent (e.g., lithium) or correction of the underlying electrolyte disturbance (e.g., hypercalcemia or hypokalemia). Drug-induced nephrogenic DI, however, may persist after discontinuation of the drug.

Patients should be instructed to eat a low-sodium, low-protein diet, resulting in a decrease in urine output secondary to the drop in solute excretion. If symptomatic polyuria persists, hydrochlorothiazide<sup>1</sup> can be started. Hydrochlorothiazide presumably acts by inducing mild hypovolemia that induces an increase in proximal sodium and water reabsorption, thereby diminishing water delivery to the vasopressin-sensitive sites in the collecting tubules and reducing the urine output. Indomethacin (Indocin<sup>1</sup>) is an add-on medication if there is not enough response. Given that prostaglandins antagonize the action of vasopressin, indomethacin inhibits renal prostaglandin synthesis and subsequently decreases urine output.

Amiloride (Midamor)<sup>1</sup> might be more effective for lithium-induced nephrogenic DI. This drug closes the sodium channels in the luminal membrane of the collecting tubule cells. These channels constitute the mechanism by which filtered lithium normally enters the collecting tubule cells and interferes with the collecting tubule response to ADH.

The approach to primary polydipsia treatment is reduction in fluid intake. Desmopressin treatment should be avoided due to the risk of hyponatremia.

### Monitoring

Primary polydipsia is the most challenging of all types of DI to treat. It requires a multidisciplinary approach that frequently demands medical and psychiatric involvement.

In central DI, patients will require frequent follow-up to adjust desmopressin dosing. Once stable, patients can be seen less frequently to assess symptom control and to check plasma sodium levels to avoid overtreatment resulting in hyponatremia.

In nephrogenic DI, after the precipitating agent has been withdrawn, follow-up is needed to assess the reversibility of polyuria. If acquired nephrogenic DI becomes irreversible, patients might require prolonged pharmacological treatment. In both central and nephrogenic DI, the patient is advised to wear a medical alert bracelet stating the disease and the potential complications.

## DIABETES MELLITUS IN ADULTS

Method of

Kristine K. Grdinovac, MD; Candice E. Rose, MD, MS; and David C. Robbins, MD, MPH

### CURRENT DIAGNOSIS

- Established guidelines define diabetes as a fasting blood sugar  $\geq 126$  mg/dL or an HbA1c of  $\geq 6.5\%$  or a blood sugar  $\geq 200$  mg/dL 2 hours after a 75-g oral glucose load.
- Prediabetes is defined as a blood sugar of 100 to 125 mg/dL or an HbA1c between 5.7% and 6.4%.
- The diagnostic guidelines are derived from inflection points in the risk of acquiring complications at any given glucose elevation.
- People with prediabetes share a similar risk of cardiovascular disease (CVD) as those with diabetes. Thus, intervention with weight loss, exercise, and metformin<sup>1,2</sup> is very beneficial in this population.
- Early detection of complications can slow the progression to end-stage disease. Routine surveillance includes annual dilated eye examinations, foot inspection, measurement of microalbuminuria, and measurements of blood lipids and kidney and liver function.

<sup>2</sup>Not available in the United States.

### CURRENT THERAPY

- Treatment should be started early when signs of hyperglycemia appear, including prediabetes. The risks of complications are related to the lifetime duration of hyperglycemia.
- A standard glycemic treatment goal is an HbA1c below 7%. It is justified, in a few patients, to set a higher goal when factors such as age, desire to lose weight, catastrophic risk of hypoglycemia, concurrent disease, and/or other barriers are detected.
- Because the treatment of diabetes is largely focused on prevention of atherosclerotic disease, aggressive control of blood pressure and lipids is also recommended.
- Treatment of type 2 diabetes mellitus (T2DM) is fundamentally based on diet (weight loss) and exercise with the addition of drugs (or bariatric surgery) when treatment goals are not achieved. No patient should experience uncontrolled hyperglycemia for more than 3 months without the addition of more therapy.
- Metformin is usually the first-line drug. The ADA now considers glucagon-like peptide-1 (GLP-1) receptor agonists and sodium-glucose cotransporter 2 (SGLT2) inhibitors as possible first-line drugs.
- There are now many options for additional medications that may best fit a patient's disease characteristics, financial resources, and lifestyle. Some of the newer (and more expensive) medications are weight-neutral, may promote weight loss, and have shown to reduce the risk of atherosclerotic cardiovascular disease and deterioration in renal function.
- Assessment of glucose control includes periodic measurement of HbA1c, home blood glucose monitoring, and, when appropriate, continuous glucose monitoring.
- Treatment with insulin is an option that can be introduced at any time during the course of T2DM. The goal, ideally, is to normalize the blood sugar without significant or frequent hypoglycemia.

### Epidemiology

The increasing prevalence of diabetes in the United States and globally has been described as an epidemic or tsunami that has the potential to overwhelm medical systems worldwide. The number

of people who have been diagnosed with diabetes increased from 108 million in 1980 to about 422 million in 2014. The global prevalence has nearly doubled during the same period, from 4.7% to 8.5%. About 34.2 million or 10.5% of Americans are known to have diabetes, and a nearly equal number have the disease but are undiagnosed. The prevalence increases with age, reaching 26.8% of the population 65 years of age or older. Women have a slightly higher prevalence than men, and the disease disproportionately affects people of Hispanic and Asian descent and non-Hispanic Blacks. Not surprisingly, the proportion of people with undiagnosed diabetes is also greatest among those of color and in the lower socioeconomic strata.

In the United States, the yearly incidence of prediabetes (defined as a fasting blood sugar of 100 to 125 mg/dL or HbA1c 5.7% to 6.4%) is estimated to be approximately 35%. On average, 1 in 10 prediabetic patients will become diabetic every year.

The risk factors for diabetes clearly include an interaction of genetic susceptibility and environmental triggers, including obesity. For example, among diabetic patients, 89% are overweight or obese. The U.S. National Health Interview Survey has shown a striking impact of obesity on the risk of acquiring the disease. Among nearly 800,000 respondents, the lifetime risk of diabetes was approximately 7.6% among underweight men and 70.3% for those who were very obese. The effect of increasing weight on the risk of diabetes is linear, with those having a body mass index (BMI) above 30 having at least a fivefold increase in the risk of acquiring diabetes. Central or intraabdominal accumulation of fat has also been shown to be more highly correlated with diabetes than with subcutaneous fat. Thus, individuals of the same body composition who have a predominance of central or intraabdominal fat are much more likely to have insulin resistance, hypertension, diabetes, and dyslipidemia. Intraabdominal fat, in contrast with subcutaneous fat, produces more free fatty acids, inflammatory cytokines, hormones associated with insulin resistance, and reduced amounts of insulin sensitizers such as adiponectin.

The widely used BMI cutoff points for overweight (25 to 30 kg/m<sup>2</sup>) and obesity ( $>30$  kg/m<sup>2</sup>) are good markers for diabetic risks among non-Hispanic whites and African Americans. However, among Asians and Hispanics, diabetes incidence increases at much lower BMIs, possibly triggered by a more potent impact of central adiposity on insulin resistance and hyperglycemia. In the Diabetes Prevention Program (DPP), a BMI cutoff point of 22 kg/m<sup>2</sup> rather than 25 kg/m<sup>2</sup> was used to identify Asian participants at increased risk for diabetes. These differences should be kept in mind when counseling or treating patients of different ethnicities.

In addition to obesity, a variety of other risk factors include smoking, hypertension, hypercholesterolemia, and, most importantly, physical inactivity. Of these associated risk factors, it is clinically important to recognize that even a modest increase in physical activity and a small reduction in body weight are the only nonpharmacologic interventions prospectively shown to reduce the risk of acquiring or even occasionally reversing diabetes (as shown in the DPP).

The genetics of type 2 diabetes mellitus (T2DM) are complex and incompletely understood despite huge studies seeking the gene variations that increase risk of diabetes. Large population studies have found over 120 gene variants that account for the risk of T2DM, but their contribution is small (about 3% to 10%), and with few exceptions, any given gene variant is practically useless in assessing risk for a particular individual. Thus although weight, waist circumference, and age are clinically useful markers of risk, genetic testing is not yet a clinical tool to predict diabetes. The predominant factors responsible for the diabetes phenotype are environmental rather than genetic. Curiously, identical monozygotic twins show a strong diabetes concordance (76%), even when the twins are raised separately from one another.

### Diagnosis and Classification of Diabetes and Prediabetes

The definitions of diabetes and prediabetes are based on standardized and discrete markers of hyperglycemia. On the other

hand, the complications of diabetes, most notably atherosclerosis and microvascular disease, are more or less linearly related to the exposure to hyperglycemia over time rather than appearing with any given marker of glycemia. For example, one accepted definition of diabetes is a fasting blood sugar of 126 mg/dL or higher. However, a marked increased risk of CVD is found at lower concentrations of blood glucose. Prediabetic persons, whose fasting blood sugar may range from 100 to 125 mg/dL, have nearly the same incidence of atherosclerotic heart disease as patients assigned a standardized diagnosis of diabetes.

The standard definitions of diabetes are largely based on inflection points in the risk of complications versus a given increment in glycemia. Diabetes then is defined as any of the following abnormalities:

- Hemoglobin A1c 6.5% or higher
- Fasting plasma glucose 126 mg/dL or higher
- A 2-hour glucose of 200 mg/dL or higher after a 75-g oral glucose load (oral glucose tolerance test)

It must be noted that there is some controversy over these values. Not all newly diagnosed individuals will have abnormalities in all three criteria. Furthermore, it is unsettled whether one test better predicts complications than another. Some experts insist that a patient should have at least two abnormal criteria, but this may delay justified clinical intervention and add cost and inconvenience. It is our recommendation to accept any one abnormality as a criterion for a diagnosis of diabetes and justification to begin lifestyle and possibly drug interventions.

The accepted classification of diabetes is, like the laboratory diagnosis, useful but imperfect. *The common phenotype of all types of diabetes is hyperglycemia* and a variety of more subtle abnormalities related to insulin deficiency or insulin resistance such as dyslipidemia, increased tissue oxidation, and macro- and microvascular disease, among others.

## Diabetes Is Classified into Four Categories

### Type 1 Diabetes

In most cases, type 1 diabetes mellitus (T1DM) is caused by an autoimmune destruction of the insulin-producing beta cells. About 95% of such patients have autoantibodies (glutamic acid decarboxylase-65 [GAD-65], anti-zinc transporter protein, and anti-islet cell antibodies) that mark the gradual (sometimes over many years) or rapid destruction of the beta cells. The result is a complete or near-total loss of endogenous insulin and life-sustaining dependence on insulin therapy. In general, antibody-positive persons who have all three antibodies and those with higher titers become diabetic more quickly than those with low titers of one or two antibodies.

Differentiating T1DM from T2DM can sometimes be a diagnostic challenge. *The age of onset* of T1DM peaks in the mid-teens but is not a reliable diagnostic tool because incident T1DM is seen throughout the human lifespan. Similarly, *thinness* is no longer a reliable phenotype of T1DM since so many individuals are obese. *Ketoacidosis* used to be considered a hallmark of T1DM, but a subset of T2DM patients presents with ketoacidosis, recovers with treatment, and can be successfully treated with oral agents (Flatbush diabetes). The diagnosis can sometimes be even more perplexing because some new-onset T1DM patients will not require insulin for several months after presenting with ketoacidosis. This so-called *honeymoon phase* of diabetes usually lasts less than 6 months.

When the diagnosis is unclear, we occasionally measure C-peptide and glucose simultaneously and the GAD-65 antibody to more clearly differentiate a T1DM patient from the more common T2DM (see definition later in this chapter). Those patients with very low C-peptides in the presence of elevated glucose and the positive anti-GAD-65 antibody are almost always type 1, and insulin treatment is needed from the outset.

### Type 2 Diabetes

T2DM accounts for about 95% of the worldwide burden of the disease. The pathophysiology of the disease is fundamentally a

simultaneous deficiency in the amount of insulin needed to overcome the insulin resistance, resulting in hyperglycemia, an event that most commonly occurs during midlife. However, the condition is increasingly manifest in childhood or early adolescence in concert with epidemic obesity and inactivity. Adolescent T2DM, now accounting for a significant proportion of diabetes in youth, appears to be a particularly aggressive form of the disease with high risk of late complications.

The cause of the hyperglycemia is complex and multifactorial. There is a progressive nonautoimmune loss of insulin production thought to be caused by aging, loss of beta cells from inflammation and oxidative stress, a genetically programmed loss with age, or, for lack of a better term, *pancreatic exhaustion*. Resistance to insulin is also an essential aspect of the disease that may be detected long before hyperglycemia. The vast majority of patients with T2DM are obese or at least have increased amounts of central fat. Many students of T2DM argue that there are many subtypes or genotypes that share a similar clinical presentation, and future classification schemes may account for those differences. About 5% of the T2DM population are thin, and the cause of their noninsulin-dependent diabetes is not so clear.

### Gestational Diabetes

Gestational diabetes (GDM) is typically diagnosed in the second or third trimester of pregnancy on the basis of a 50-g oral glucose tolerance test in women who were not known to be diabetic pre-pregnancy. GDM carries an increased risk of pregnancy complications (hypertension, preeclampsia, large birthweight infants), and treatment with diet, metformin<sup>1</sup>, or insulin is commonly used. Importantly, 50% to 80% of women who had GDM will suffer from T2DM within a decade of their pregnancy.

### Specific Types of Diabetes Due to Other Causes

This category may account for as much as 5% of clinical diabetes and should not be overlooked. We remind our residents to think of these “other” forms of diabetes on the first visit with every phenotypically type 2 patient. These include cystic fibrosis, glucocorticoid-induced diabetes, Cushing syndrome, hemochromatosis, certain anticancer drugs (e.g., checkpoint inhibitors, alpelisib [Piqray]), and monogenic forms of diabetes. The monogenic forms of diabetes can be manifested in the first 3 months of life. Later in life, an autosomal dominant form of non-insulin-dependent diabetes termed maturity-onset diabetes of youth (MODY) is seen. MODY may account for a few percent of the “type 2” diabetic population and is suspected when there is onset of diabetes in the late teens or early adulthood. Genetic testing is commercially available for these polymorphisms and can identify common subtypes that are responsive to high-dose sulfonylurea medication.

### Clinical Manifestations

Most patients with T2DM are discovered by elevated glucose on an incidental blood test. Population screening is generally inefficient except among those at very high risk. Otherwise, presenting symptoms include polyuria, polydipsia, nocturia, blurred vision, and/or weight loss resulting from catabolism. Although the peak incidence of T2DM is in midlife, there is an increasing and disturbing increase in the incidence of T2DM in children and adolescents, especially those belonging to racial and ethnic minorities. This is undoubtedly correlated with childhood obesity.

Less frequently, patients can initially present with diabetic ketoacidosis (DKA) or nonketotic hyperosmolar hyperglycemic state (HHS). This typically occurs in combination with some inciting factor, such as infection, stress, or myocardial ischemia. Patients have hyperglycemia, marked dehydration, electrolyte derangements, and altered levels of consciousness and are at increased risk of death. Other common conditions that are highly

<sup>1</sup>Not FDA approved for this indication.

correlated with the development of diabetes include polycystic ovarian syndrome, GDM, toxemia of pregnancy, and delivery of infants over 8 lb at birth (large for dates).

Most commonly, T2DM has an insidious onset, and patients can remain asymptomatic for several years, only being diagnosed unexpectedly through routine laboratory workup. Aging, sedentary behaviors, and obesity may tip the balance between insulin action and insulin resistance, resulting in clinical hyperglycemia. At the time of diagnosis, however, asymptomatic patients may already have significant microvascular and/or macrovascular diabetic complications because there is often a long prodrome of hyperglycemia.

Without a doubt, the most common sign of insulin resistance is simply obesity (a large waist or high waist-to-hip ratio) or increased accumulation of central fat, a finding that occurs in 90% to 95% of T2DM patients. Other signs may include acanthosis nigricans, a velvety, hyperpigmented thickening of the skin, typically seen at the nape of the neck and within intertriginous areas such as the axilla (Figure 1). Skin tags around the base of the neck are recognized as a sign of insulin resistance. Necrobiosis lipoidica is a granulomatous skin disorder that is prevalent in up to 65% of patients. It appears as reddish-brown to yellow-brown oval-shaped plaques with central atrophy and telangiectasias that frequently ulcerate (Figure 2).

### Long-Term Implications of Glycemic Control

Atherosclerotic cardiovascular disease (ASCVD), stroke, and peripheral vascular disease are the major causes of morbidity and mortality in persons with diabetes. The Framingham study estimated that the relative risk of ASCVD among diabetic patients was three- to fivefold higher than in the nondiabetic cohort, even when accounting for smoking, hypertension, and dyslipidemia. Diabetes itself is an independent risk factor for ASCVD, and multiple studies suggest a correlation between effective glycemic control and risk mitigation of CVD and mortality. Other risk factors for ASCVD include hypertension, dyslipidemia, tobacco use, and family history.

Treatment of hyperglycemia and associated cardiovascular risk factors has clearly been shown to be beneficial in diabetes. Several landmark trials examined the role of intensive glycemic control and ASCVD outcomes. One study, widely quoted and sometimes misinterpreted, seemed to suggest the opposite, that those assigned to very tight control experienced increased risk of death. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study evaluated the effect of tight glycemic control (HbA1c <6.0% vs. HbA1c of 7% to 7.9%) on the outcomes of nonfatal myocardial infarction (MI), nonfatal stroke, and CVD death. The trial was stopped early because of increased mortality in the intensive therapy group. However, a subset analysis showed that patients with no history of CVD events prior to the study and baseline HbA1c less than 8% had a statistically significant reduction in CVD events. Hypoglycemia did not account for the increased deaths, and the majority of excess deaths were among those who had long-term poor control and were unable to achieve tight control, even when assigned to the aggressive arm of the study.

The Action in Diabetes and Vascular Disease: Preterax and Diamicon MR Controlled Evaluation (ADVANCE) trial aimed to lower HbA1c  $\leq 6.5\%$  in the intensive arm and measured microvascular plus macrovascular (nonfatal MI, nonfatal stroke, CVD death) outcomes. Notably, very few patients were using insulin at the start of this study, but criteria for all participants included having vascular disease or a risk factor for vascular disease. Ultimately, there was no increase in ASCVD mortality or overall mortality between the two arms. The Veteran Affairs Diabetes Trial (VADT) evaluated the value of intensive glycemic control for the primary outcomes of nonfatal MI, nonfatal stroke, CVD death, hospitalization for heart failure, and revascularization. Results of this study showed more CVD deaths in the intensive therapy group than the standard arm, although not statistically significant.

**Figure 1** Acanthosis nigricans is a common examination finding of insulin resistance. It presents as a hyperpigmented, velvety, gray-to-brown thickening of the skin folds at the posterior neck and intertriginous folds. From James WD, Elston D, Treat J, Rosenbach M. *Andrews' diseases of the skin: clinical dermatology*, 13th ed., Philadelphia, 2020, Elsevier.

**Figure 2** Necrobiosis lipoidica is a granulomatous skin disorder that is prevalent in up to 65% of patients with diabetes. It appears as reddish-brown to yellow-brown oval-shaped plaques with central atrophy and telangiectasias that frequently ulcerate.

At first glance, these studies suggest that very intensive control of diabetes may lead to increased mortality rather than improved cardiovascular outcomes. It is important to note that in all three trials, ASCVD risk factors were treated aggressively in all participants. All three studies also demonstrated more hypoglycemia in the intensive therapy groups than standard therapy groups. Hypoglycemia, however, did not explain the increased mortality in the intensively treated patients. The studies enrolled many patients who were older (mean age 60 to 66), with a long duration of diabetes (8 to 12 years) and already established CVD or known risk factors. Further subset analyses of each of these trials revealed significant benefits of intensive glycemic control for ASCVD outcomes in those patients with shorter duration of diabetes, lower initial HbA1c at entry, and/or absence of known CVD. We do not see the data from these studies as justification for not attempting tight glycemic control in most patients. *Thus intense glycemic control may be more likely to benefit younger*

**TABLE 1** Treatment Options for Overweight and Obesity in Type 2 Diabetes

TREATMENT*	BMI CATEGORY (KG/M <sup>2</sup> )		
	25.0–26.9 (OR 23.0–24.9 <sup>†</sup> )	27.0–29.9 (OR 25.0–27.4 <sup>†</sup> )	≥30.0 (OR ≥27.5 <sup>†</sup> )
Diet, exercise, and behavioral therapy	Yes	Yes	Yes <sup>†</sup>
Pharmacotherapy—weight-loss medications for selected patients	No	Yes	Yes <sup>†</sup>
Metabolic surgery (vertical gastropasty or modified Roux-en-Y)	No	No	Yes <sup>†*</sup>

\*Asian Americans in italics.

<sup>†</sup>For obese patients with comorbidities.

BMI, Body mass index.

*patients with shorter duration of diabetes in whom tight control prevents the development of future ASCVD complications.*

Intensive glycemic control also reduces the risk of microvascular complications (retinopathy, nephropathy) in T2DM. As with macrovascular disease, microvascular disease may be present at the time of initial diagnosis of T2DM. Several pivotal trials demonstrated benefits of intensive versus standard blood glucose control on major microvascular outcomes in T2DM. The UK Prospective Diabetes Study (UKPDS) showed the significant impact of early, intensive glycemic control by demonstrating a 25% reduction in the development of microvascular complications in those with newly diagnosed T2DM. At the 10-year follow up, there was continued benefit in reducing microvascular risk as well as risk for MI and death from any cause, demonstrating that early, intensive control of glycemia can provide lasting positive effects on microvascular and macrovascular outcomes.

### Prevention

Several large, randomized controlled trials have shown that behavior and lifestyle changes are highly effective in preventing T2DM. The strongest evidence comes from the DPP. This trial showed a reduction in incidence of T2DM among prediabetic enrollees by 58% over 3 years. The lifestyle intervention goals of the DPP were to attain and maintain a weight loss of 7% minimum and 150 minutes of physical activity per week, similar in intensity to brisk walking. Few patients actually achieved these modest goals, but the benefit was seen among most patients assigned to lifestyle changes alone. Similarly, modest reduction in weight has a significant protective effect on the progression to diabetes. The DPP study also included a metformin-only arm, and these patients also had a reduction in the incidence of diabetes (about 25%). It has been estimated that prediabetic patients following lifestyle suggestions *and* daily metformin<sup>1</sup> may have the lowest risk of diabetes over time compared with control groups and those receiving intensive lifestyle intervention only or daily metformin only.

### General Medical Management

When caring for the typical T2DM patient, many providers face noncompliant patients with complex problems who show, over time, little progress in overcoming their disease. The treatment of diabetes is perhaps unique in medicine because it relies heavily on changes in patient lifestyle and adherence to complex regimens and imposes heavy economic burdens. The 20-minute clinic visit is unsuited for patients with multiple complaints, and after these visits providers often feel unsuccessful, frustrated with the patients, or worn out from nagging patients to adhere to their regimens.

It is important to find and practice an approach to these patients that focuses on problem solving rather than threatening, using praise for small changes, setting reasonable goals, and constantly reminding oneself that there are little victories in many patient visits that can be a source of personal reward (Table 1). In our clinic, we rely heavily on the techniques of motivational interviewing, adapted to a short clinic visit, to help the patient identify

and solve problems. In addition, we find that motivational interviewing helps the *provider* share in a sense of success, even if that change is small but in the right direction.

### General Goals

The treatment of diabetes is goal driven. Although there are discrete goals for average glycemia (HbA1c), blood pressure, and lipid levels, the American Diabetes Association (ADA) recognizes that the goals can be adjusted for a given patient's risks for hypoglycemia, duration of disease, presence of certain comorbidities, established vascular complications, patient preferences, and available resources and system support (Table 2).

### Glycemic Goals

Assessment of glycemic control centers around HbA1c and self-monitoring blood glucose (SMBG) values. The average HbA1c correlates well with the SMBG in most instances, although certain situations, such as increased red blood cell turnover, hemoglobinopathies, or recent blood transfusions, may cause discordant results. It is also important to recognize there may be ethnic differences for HbA1c values, as studies have shown higher HbA1c values in African Americans than in Caucasians with the same mean glucose. HbA1c should be measured at least quarterly in patients who are not meeting glycemic goals or twice yearly in those who achieve HbA1c targets.

The ADA recommends an HbA1c target of less than 7% in most nonpregnant adults, suggesting that an even more stringent target HbA1c of less than 6.5% may be appropriate for some patients if it can be achieved without significant hypoglycemia or adverse effects. Conversely, the HbA1c goal may be loosened to less than 8% for patients who are at high risk of hypoglycemia, have limited life expectancy, have advanced complications of diabetes, or have long-standing disease. These guidelines encourage providers to individualize HbA1c goals for each patient, taking patient characteristics as well as risks and benefits into account. Similarly, the Veteran's Affairs/Department of Defense guidelines suggest shared decision making and individualized HbA1c goals, with more aggressive HbA1c goals for patients with a long life expectancy and absent or mild microvascular complications and relaxed HbA1c goals for those with limited life expectancy and significant comorbidities.

In contrast, the American College of Physicians (ACP) recommends that clinicians target an HbA1c of 7% to 8% for most patients with T2DM, with deescalation of pharmacologic therapy for any patients achieving an HbA1c less than 6.5%. The authors of this section do not agree with these guidelines and instead choose to follow the ADA guidelines for HbA1c targets because HbA1c targets closer to 8% put patients at risk for developing more macrovascular and microvascular complications. Although the authors do believe that HbA1c goals should be individualized and relaxed when indicated, we target A1c values of less than 7% without hypoglycemia, especially in younger patients with early diagnosis of T2DM, in an attempt to provide the greatest protection against future macrovascular and microvascular complications.

**TABLE 2** Decision Factors in Selecting Glycemic Goals

DECISION FACTORS	HBA1C <7%	HBA1C >7%–8%
Consequences of hypoglycemia	Low risk of severe hypoglycemia, patient senses hypoglycemia, has access to good support system	High risk, hypoglycemia unawareness, lives alone
Duration of diabetes	Short; tight control early in the disease promotes reduction in complications over time	There is little evidence that tight control late in the disease alters outcome
Life expectancy	Long	Short; reduction in macro- and microvascular diseases seen after years or decades of good glycemic control
Life-shortening comorbidities	Absent	Patients with life-limiting comorbidities may justifiably have glycemic goals that avoid extreme highs and lows
Well-established comorbidities such as retinopathy, nephropathy, neuropathy	Absent. However, improvement in retinopathy and delay in progression of neuropathy are recognized benefits of tight control	Many comorbidities such as end-stage renal disease, moderate-severe ischemic vascular disease, severe peripheral or autonomic neuropathy
Patient preferences	Highly motivated, strong support	Prefers less burdensome therapy, voices resistance to treatment; obstacles potentially modifiable over time
Available resources	Readily available, good health insurance, strong social network	Limited resources, including cost of medication, poor social support, and so on. The provider can choose low-cost medications (human insulins, sulfonylureas, metformin) to attempt to reach glycemic goals

Home SMBG testing remains a mainstay for patients to evaluate and manage blood glucose levels. Patients who are on multiple daily injections (MDIs) of insulin should perform SMBG fasting, before meals, and at bedtime, which is typically three to four checks per day. For patients only on basal insulin, with or without other noninsulin agents, SMBG should be performed at least once daily, ideally fasting. It can be argued that SMBG may not provide added benefit for non-insulin-treated patients, although periodic testing would still be useful to guide treatment and document hypoglycemia. Other studies have found improved glycemic control in patients without insulin therapy who still perform multiple SMBG tests per week. The ADA does not outline specific guidelines for SMBG for patients who are not on MDI.

With advances in technology, continuous glucose monitors (CGMs) are a commonly used tool to assess glucose values (Figure 3). Benefits of CGM include little to no need for SMBG, thus minimizing fingersticks, and continuous data that may alert the patient to glycemic trends and alarm for both high and low blood glucose values. Some CGMs may also be paired with insulin pumps to implement real-time data for basal insulin pump algorithms. Reports can be generated that include multiple data points not achieved with simple SMBG, such as percentage of time CGM is active, glycemic variability, and glycemic patterns over a 24-hour time frame.

A relatively new concept that is included in CGM reports is glycemic “time in range” (TIR), which accounts for the percentage of time a patient is within a desired glucose target. The TIR has a strong correlation with the HbA1c value, and it is typically reported as the *glucose management indicator* (GMI) on CGM reports. In using TIR to assess control, we strive for values of 70% or higher with a coefficient of variation of less than 30%.

The most important principles in the treatment of hyperglycemia can be succinctly summarized as follows:

- Start it early in the disease (arguably even in the prediabetic stages).
- Do not delay additional treatment when glycemic goals are not attained. In our practice, we consider additional interventions every 3 months until the patient’s glucose goals are attained.

There is strong empirical evidence supporting these principles. The Epidemiology of Diabetes Interventions and Complications (EDIC) study clearly showed that poor control early in the disease increased the prevalence of complications many years later, even if tight control was implemented at some later, intermediate time point. This delayed risk for complications is called *metabolic memory*. Evidence

from practice patterns is that patients with poor glycemic control often stay that way for years as they promise better adherence to weight loss and exercise and negotiate with clinicians who themselves might be fearful of adding medications, especially insulin.

### Monitoring

Much like driving a car without a speedometer, a diabetic patient who is unmonitored is at risk of undetected poor control and wide swings in blood sugar. There is little credible evidence that a patient can feel blood sugar highs and lows even when trained in behavioral clinical trials. Before choosing how a patient must be monitored, it is important to determine the frequency needed. The Diamicron MR in NIDDM Assessing Management and Improvement Control (DINAMIC-1) study randomized patients taking a sulfonylurea between no monitoring versus twice-weekly fingerstick testing groups. There was a small but significant difference in A1c between the groups (0.25%). Other studies show that patients doing more frequent testing report a lower score on measures of quality of life while achieving comparable HbA1c levels.

Nevertheless, there are many patients who benefit from frequent monitoring. Those include patients using insulin, those at risk for hypoglycemia, and perhaps a subset who insist on close monitoring as frequent reassurance that they are being properly treated. We have also observed some benefits related to self-learning. Some patients learn which foods produce high excursions in postprandial glucose and self-correct their diet over time based on these data.

### Fingerstick Monitoring

The precision and accuracy of available over-the-counter (OTC) monitors are adequate to make safe clinical decisions. In general, the choice of a monitor is based on cost, insurance reimbursement, and features such as memory and the ability to upload stored results for clinical review. We find this latter feature especially useful to detect patterns of diurnal glycemia.

### Continuous Glucose Monitoring

CGM offers a tremendous benefit and is extremely useful, if not necessary, in patients treated with insulin. CGM is now recommended for all patients with diabetes on MDIs, continuous subcutaneous insulin infusions, and other forms of insulin therapy. Several devices are available (various Freestyle Libre systems [Abbott, Abbott Park, IL], Dexcom G6 [Dexcom Inc., San Diego, CA], and Medtronic Guardian Connect [Medtronic, Minneapolis,

**Figure 3** The report from a continuous glucose monitor contains valuable information. The time of day is along the x-axis, and blood glucose is along the y-axis. On the right, average glucose, sensor usage, and time in range is documented. The clinician can see that the patient is within the glycemic goal 57% of the time, above goal 40% of the time, and hypoglycemic 3.4% of the time. The GMI is the Glucose Management Indicator, which correlates to an average A1c. In addition, the graph shows a pattern of overnight hyperglycemia (*black boxes* on or above the *dashed white line* of 180 mg/dL) and daytime euglycemia (*dark gray boxes* between the *white dashed lines* of 180 mg/dL and 70 mg/dL). Further information is gained by discussing daily habits and eating patterns with patients. This enables the provider to see an overall picture of glycemic control and make changes accordingly. Photo provided by the authors, de-identified patient report.

MN]). They are all placed on the skin. The Eversense E3 CGM (Ascensia Diabetes Care, Basel, CH) is implanted under the skin and can store glucose data for up to 6 months. Insurance carriers often limit use to patients treated with at least four shots of insulin daily or insulin pumps. The most common devices are small, self-adherent to the skin, shower resistant, easy to apply, and provide continuous readings for 10 to 14 days. Most of the devices have audible low-glucose alarms, a feature useful for patients at risk for hypoglycemia without symptoms (hypoglycemic unawareness). Transmitted data can also alert the patient to trends in blood glucose levels, with directional arrows signaling the rate of increasing or decreasing blood glucose, and notify the patient to act accordingly. The majority of CGMs do not require calibration with fingersticks, and all of them can upload their data to a smartphone or independent reader, which can, in turn, be reviewed both by the patient, a family member, or clinician. “Professional” CGMs are clinic-based and can include blinded or real-time data collection for clinicians. A useful Internet site that accommodates this process with Health Insurance Portability and Accountability Act (HIPAA) compliance is Tidepool ([tidepool.org](http://tidepool.org)). We consider the availability of continuous glucose monitoring a major advance in patient care.

### Frequency of Clinical Visits

The standard frequency of visits for T2DM patients is every 3 to 6 months. We shorten this interval in patients who are in poor control as needed to prevent acute complications. The recommended interval is set, in part, on the duration needed to measure a stable change in HbA1c, which is about 3 months. Other recommendations include the following:

- Actions taken with each visit
  - Blood pressure (orthostatic if indicated)
  - Height, weight, vital signs
  - HbA1c if results are not available within the past 3 months
  - Skin examination
- Annual visits
  - Fundoscopic examination by eye specialist
  - Comprehensive foot examination
  - Laboratory examination to include lipid profile, liver function tests, and spot urine microalbumin/creatinine

- As indicated: electrolytes, B<sub>12</sub>, platelet count if considering fatty liver, nonalcoholic steatohepatitis (NASH), or nonalcoholic fatty liver disease (NAFLD)
- Podiatry
  - We generally refer patients to podiatry when there is evidence of reduced blood flow, infection, deformities (claw toes, Charcot foot), heavy calluses, bunions, or neuropathy as determined by errors in sensing the 10-g fiber and loss of vibratory or position sensations. We also use these findings to order custom-fitted shoes that can prevent more serious foot disease.
- Diabetic education/nutrition
  - We find the partnership with a certified diabetes care and education specialist (CDCES, previously known as a *certified diabetes educator* [CDE]) and/or nutritionist invaluable. Even among patients who feel fully informed, an *annual* visit can reinforce good behaviors, inform patients of new treatments, offer inroads to group and formal education, and occasionally assist in management of insulin doses depending on the regulations defining the scope of practice of diabetes educators.
- Cardiology
  - A routine referral to cardiology is not required despite the fact that the majority of T2DM patients will die of ASCVD. Cardiology visits are recommended in patients who plan on starting an intensive exercise program and those with traditional signs of ischemic heart disease (IHD). Keep in mind that diabetic patients are thought to manifest fewer symptoms of IHD, thus the threshold for referral and testing is arguably lower than for many other patients.

### Early Detection of Complications

Although the ultimate goal of treatment is prevention of complications, a secondary aim is to find complications and treat them appropriately.

### Hypertension

The definition of hypertension for diabetic patients varies between systolic values of less than 130 and 140 mm Hg. Currently, the ADA sets a threshold of less than 140/90 mm Hg for diagnosing

hypertension. We recommend three measurements in a seated patient over 15 minutes and using the average of the final two values as the recorded value.

#### Treatment

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are usually the drugs of first choice.

#### Retinopathy

Ophthalmoscopic examination by primary care and diabetes specialists has poor sensitivity and is not considered part of the required examination. A dilated eye examination by a qualified eye specialist is recommended in T2DM patients every year and in T1DM patients annually after 5 years of disease.

#### Neuropathy

Autonomic neuropathy is common among T2DM patients and is usually first detected by the loss of R-R wave variability on a long-lead electrocardiogram (ECG). Less commonly, it can take the form of gastroparesis, alternating diarrhea and constipation, or orthostatic hypotension. Peripheral neuropathy can take the form of distal, symmetrical dysesthesias, hypesthesia, progressive loss of touch or vibration sensations, and heat-cold insensitivity. These patients are at risk of amputation, foot infection, and bony deformities (Charcot foot).

#### Treatment

We reserve treatment for patients in whom the symptoms interfere with sleep or daily activities because drugs relieve symptoms but do not alter the course of the disease. Treatment choices for peripheral painful neuropathy include selective serotonin reuptake inhibitors (SSRIs), gabapentin (Neurontin),<sup>1</sup> pregabalin (Lyrica), anticonvulsants, transcutaneous electrical nerve stimulation (TENS), and, ultimately, narcotics. Gastroparesis is treated primarily on the basis of symptoms rather than studies of timed gastric emptying. Small, frequent meals and a vegetarian diet are better tolerated, and there has been some success with erythromycin,<sup>1</sup> metoclopramide (Reglan), or linacotide (Linzess)<sup>1</sup> to stimulate motility.

#### Foot Disease

Guidelines suggest a thorough annual foot examination. We include pulses, an estimation of capillary refill, and a 10-point (5 points each foot) 10-g fiber test. Vibration sensitivity using a tuning fork is very hard to judge, although it can be included in the examination, especially if using a 256-cps fork. Patients at risk should be instructed to do a daily foot examination, using a mirror to examine the plantar surface, and should promptly report early signs of infection, sores, or deformities.

#### Treatment

Prevention is preferable to treatment. Custom shoes should be prescribed to patients with deformities, poor circulation, or neuropathy. Referral to podiatry is needed.

#### Dyslipidemia/Hyperlipidemia

Prevalence of hypercholesterolemia in diabetes is about the same as in the general population. However, at any given level of cholesterol, diabetic patients are about two to three times more likely to suffer from or die from an atherosclerotic event than nondiabetic individuals. Understandably, some diabetologists consider their practice focus on glycemic control as another cardiovascular risk factor, and their practice is mostly “preventive cardiology.”

In contrast with relatively normal cholesterol levels, patients with poorly controlled diabetes display elevated triglycerides (TGs) and lowered high-density lipoproteins (HDLs); this pattern is referred to as *diabetic dyslipidemia*. The recent changes in ADA lipid treatment guidelines are now in synchrony with those of the American

Heart Association (AHA) in that they focus more on risk than on concentrations of blood lipids, with the exception of suggesting annual measurements of blood lipids. For patients with diabetes without preexisting CVD, the current ADA recommendations for starting pharmacologic therapy are (1) an LDL cholesterol level of  $\geq 130$  mg/dL (3.35 mmol/L) and (2) a goal of less than 100 mg/dL (2.60 mmol/L) for LDL cholesterol. The AHA risk guidelines are also applied to the diabetic population. Treatment of hypertriglyceridemia is suggested with TG levels greater than 200 to 400 mg/dL, but recognizing that the most effective treatment may be weight loss and improved glycemic control. Pharmacologic therapy is usually reserved for those with TGs greater than 400 mg/dL. Severe hypertriglyceridemia ( $>1000$  mg/dL) carries the risk of pancreatitis and is treated with aggressive insulin management and severe caloric restriction. Markedly elevated triglycerides often plummet with fasting, and we frequently use this approach in hospitalized patients until the triglycerides are less than 500 mg/dL while simultaneously treating the hyperglycemia with insulin. Statin treatment of diabetic patients is very rewarding and has a very low number needed to treat (NNT) to prevent a cardiovascular event. The Justification for the Use of Statins in Primary Prevention: An Intervention Trial Evaluating Rosuvastatin trial (JUPITER) study, for example, showed that one cardiovascular event per 5 years was prevented with every 18 patients treated with rosuvastatin.

#### Treatment

Diet and drug treatment follow AHA guidelines. Diabetic dyslipidemia (low HDL, elevated TG) is responsive to improved glycemic control and weight loss. We generally reserve the use of fibrates to those in whom TGs exceed 400 mg/dL. The more potent statins (rosuvastatin [Crestor], atorvastatin [Lipitor]) are favored in patients with hypertriglyceridemia.

#### Depression

The prevalence of depression among diabetic patients is thought to triple that of the general population. We screen every patient on every visit with a modified Patient Health Questionnaire-9 (PHQ-9). Depression is correlated with poor diabetic control, and ameliorating depression with medication or therapy is associated with an improvement in glycemic control. It has been argued that depression may be both a cause of poor control and a result of it.

#### Treatment

Ideally, we prefer to combine antidepressant medications with sessions with a skilled therapist. Group diabetic visits have been shown to be helpful and efficient.

#### Nephropathy

Diabetes is still the most common cause of renal failure in the United States, and it may be largely preventable by tight glycemic control and attainment of normal blood pressure. Screening should include a yearly spot urine test for microalbumin/creatinine. We consider any value above 30 mcg/mg creatinine indicative of nephropathy, even in the context of a normal glomerular filtration rate (GFR).

#### Treatment

The presence of microalbuminuria should trigger the prescription of an ACE inhibitor or ARB regardless of the presence of hypertension. These drugs, among others, have been shown to delay end-stage renal disease (ESRD) and slow the decrease in GFR. Sodium-glucose cotransporter 2 (SGLT2) inhibitors are also now recognized to have a benefit in stabilizing or delaying diabetic renal disease. We also carefully follow GFR and refer to nephrology when there is any rapid or otherwise unexplained increase in serum creatinine or a decrease in adjusted GFR to 30 mL/min or less.

#### Fatty Liver Disease (NASH, NAFLD)

It is estimated that about 60% of patients with T2DM have fatty livers or NAFLD, steatosis unrelated to causes other than the metabolic disturbances of T2DM. Seventeen percent of the

<sup>1</sup>Not FDA approved for this indication.

T2DM patients will progress to liver fibrosis, a potent risk factor for hepatocellular carcinoma (HCC). HCC is at least two to three times more prevalent among diabetic patients than in the general population. NAFLD is now the leading cause of cryptogenic cirrhosis. Diagnosis of NAFLD is suspected by the presence of elevated serum transaminases, and suspicion is further raised by using one of several scoring systems (FIB4, NAFLD, or *Hepcalc*, a smartphone app) and ordering physiologic tests that measure loss of liver elasticity, such as the Fibroscan. We therefore include a platelet count in our routine annual laboratory tests to calculate the NAFLD or FIB4 and use an *indeterminate* or *likely* score as the basis for referral to hepatology.

### Treatment

Weight loss, improved metabolic control, and many diabetic medications such as pioglitazone (Actos),<sup>1</sup> the glucagon-like peptide 1 (GLP-1) receptor agonists, SGLT2 inhibitors, DPP4 inhibitors, and metformin<sup>1</sup> may offer some benefit.

### Hypoglycemic Unawareness

It is estimated that about 10% of deaths in T1DM are related to hypoglycemia. A small subgroup of patients loses the adrenergic response to hypoglycemia (usually a blood glucose <60 mg/dL) and are at risk for catastrophic events such as automobile accidents, neurologic decline, and trauma. Such patients must have flexible, elevated glycemic goals. Beta blockers may contribute to the risk, and alternative drugs should be considered in such patients.

### Treatment

Later in this chapter we discuss the use of glucagon (GlucaGen, Gvoke, Baqsimi) and the “rule of 15” in the treatment of various degrees of low blood sugar. These patients may derive many benefits from continuous glucose monitoring, especially with devices that have audible alarms when blood sugar trends down sharply. Cognitive behavioral therapy designed to teach at-risk patients to detect early clues to hypoglycemia reduces the frequency of hypoglycemic events. Some studies suggest that adrenergic symptoms reappear in some patients after increasing glycemic goals for a few months.

### Erectile and Sexual Dysfunction

Erectile dysfunction (ED) is common among diabetic men, and the clinician should not hesitate to ask if it is a problem during a visit. Surprisingly, unlike other complications, it is not clear if better glycemic control delays or prevents ED. It is also unknown if diabetic women suffer from sexual dysfunction, although some claim that dryness on arousal is more common.

### Treatment

Many men respond to tadalafil (Cialis) or sildenafil (Viagra), both of which are now available in generic form. When this fails, we refer to an experienced urologist who can consider intrapenile injections and prosthetic devices.

### Lifestyle

BMI should be calculated at least annually, although it is useful to do at each visit. This can be calculated as weight in kg divided by height in meters squared ( $\text{kg}/\text{m}^2$ ) or electronically in the electronic medical record (EMR) or online calculator. BMI should be classified as underweight (<18.5  $\text{kg}/\text{m}^2$ ), normal (18.5 to 24.9  $\text{kg}/\text{m}^2$ ), overweight (25 to 29.9  $\text{kg}/\text{m}^2$ ), or obese (>30  $\text{kg}/\text{m}^2$ ). In general, higher BMIs increase the risk of all-cause mortality and CVD and reduce quality of life. Weight-loss goals and intervention strategies should then be discussed (see Table 1).

### Diet

A variety of eating patterns are acceptable for management of T2DM. There is no one preferred eating plan, as it should be

individualized for each person. Referral to a registered dietitian nutritionist (RD/RDN) is recommended for all people with diabetes, prediabetes, and GDM to educate and help plan a diet with specific caloric and metabolic goals. Patients with diabetes should have medical nutrition therapy (MNT) with an RD/RDN at the time of diagnosis and as needed throughout their lives.

Reduced overall carbohydrate intake and emphasis on carbohydrates that are high in fiber and minimally processed are recommended. An eating plan emphasizing monounsaturated and polyunsaturated fats and fewer processed foods (Mediterranean-style diet) has been shown to improve glucose metabolism and lower CVD risk. In reality, a diet that is lower in calories and that the patient enjoys enough to continue can cause weight loss.

### Exercise

As mentioned previously, 150 minutes per week of moderate to vigorous-intensity exercise improves insulin sensitivity, has been shown to reduce body fat, and is recommended for most patients with T1DM or T2DM. Ideally, this activity is spread over at least 3 days, with no more than 2 days in a row without exercise. Prolonged sitting has negative effects on postprandial blood glucose levels and should be avoided. People with T2DM should decrease the amount of time sitting and other sedentary behaviors. For sedentary activity lasting 30 minutes or longer, a 3-minute (minimum) break of walking, stretching, or isometric exercise is encouraged for improved glycemic control. Resistance training should be done two to three times per week for improved strength as well as improved glycemic control. Even light activities such as housework, gardening, parking farther away, and taking the stairs all have a beneficial impact on weight and blood glucose values. If your patients do not like to “exercise,” encourage an increase in normal physical activities.

### Weight Loss

Treatment of obesity can delay or prevent the development of T2DM and can be very helpful in the treatment of T2DM. Behavioral therapy, including diet and physical activity, to achieve and maintain weight loss of 5% or more is recommended for patients with T2DM who are obese or overweight. Behavioral therapy should include frequent follow-up with a focus on behavioral strategies, diet changes, and physical activity. For many patients, a calorie deficit of 500 to 750 kcal/day will help achieve this goal. This allows for approximately 1200 to 1500 kcal/day for women and 1500 to 1800 kcal/day for men, although this depends on baseline body weight. Eating plans should be individualized for weight loss while still providing adequate protein, fat, and carbohydrates. Long-term weight maintenance programs are recommended for patients who have achieved their short-term weight loss goal. These programs should include a high level of self-monitoring, including habits, food choices, and portion sizes; they should also continue to encourage a high level of physical activity (at least 200 minutes/week) and at least a weekly body weight check. If a body weight check is done at home, it should be done after using the bathroom first thing in the morning for consistency. Very-low-calorie diets (800 kcal/day or less) are an option for some people but should be short term (3 months) and prescribed by trained practitioners with close medical follow-up. These patients still need long-term comprehensive weight maintenance counseling.

### Drugs That Are Associated with Weight Loss

Medications for treatment of diabetes that are associated with modest weight loss include metformin, SGLT2 inhibitors, amylin mimetics, and alpha-glucosidase inhibitors. GLP-1 receptor agonists such as semaglutide (Ozempic, Rybelsus), dulaglutide (Trulicity), liraglutide (Victoza), and exenatide (Bydureon) produce, on the average, the greatest amounts of weight loss, averaging about 1 lb per month.

<sup>1</sup>Not FDA approved for this indication.

### Drugs That Are Weight-Neutral or Cause Weight Gain

Dipeptidyl peptidase 4 inhibitors (the “gliptins”) are weight-neutral. Sulfonylureas, thiazolidinediones (TZDs), and insulin often cause weight gain, but the amount of weight gain is often overestimated, and the benefit of glucose reduction probably counterbalances the modest weight gain associated with their use.

### Drugs Used Specifically for Weight Loss

The U.S. Food and Drug Administration (FDA) has approved a handful of medications to be used in conjunction with diet and exercise for short-term and long-term treatment of obesity. Most of these medications have been shown to improve glycemic control in patients with diabetes and delay progression to diabetes in those at risk. Several of the GLP-1 agonists are formulated in combination with basal insulin in a pen and can be administered in a single injection.

Several medications are FDA approved for long-term weight loss in patients with a BMI 27 kg/m<sup>2</sup> or greater with at least one obesity-associated comorbid condition (T2DM, dyslipidemia, or hypertension). These medications are orlistat (Alli, Xenical), phentermine and topiramate (Qsymia), bupropion and naltrexone (Contrave), liraglutide (Saxenda), and semaglutide (Wegovy). Phentermine (Adipex) is also approved for short-term weight loss. These medications can be helpful for patients in adhering to diet and lifestyle changes. The importance of this adherence cannot be overstated as patients will gain back the lost weight once the medication is stopped if they have not adopted diet and lifestyle changes to continue to promote weight loss or maintenance. Providers should be knowledgeable about the potential risks and benefits of these medications to prescribe appropriately to patients. These medications are contraindicated in women who are pregnant or trying to conceive. We urge our patients to use these in combination with a structured weight-loss program that emphasizes both short-term weight loss and maintenance.

A recent addition to potential medications for weight loss is the dual GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) receptor agonist tirzepatide (Mounjaro).<sup>1</sup> This novel agent has demonstrated substantial and sustained weight loss in trial participants, some with a reduction of over 20% body weight after 72 weeks. However, to date it has not been approved by the FDA for weight loss.

### When to Consider Bariatric Surgery

Bariatric surgery, sometimes referred to as *metabolic surgery* because of its weight-loss effects and treatment of T2DM, has been shown in some studies to provide better glycemic control and control of diabetes complications than medical treatment of T2DM. It should be recommended as an option to treat T2DM in patients with a BMI great than or equal to 40 kg/m<sup>2</sup> or those with a BMI 30 to 39.9 kg/m<sup>2</sup> with comorbidities who have tried but not achieved weight loss with other methods. Younger age, shorter duration of diabetes, better glycemic control, and nonuse of insulin are all predictors of reversal of T2DM with bariatric surgery. Bariatric surgery has been thought of as a “last resort” but should really be considered earlier in the course of the disease. Randomized trials have shown diabetes remission rates of 30% to 60% following Roux-en-Y gastric bypass. However, over 5 to 10 years, diabetes recurrence rates are 35% to 50% but generally with improved glycemic control and less need for medications.

### Pharmacologic Therapy

Along with lifestyle modifications, metformin remains the first-line agent for the treatment of T2DM because of its known effectiveness, lack of hypoglycemic effects, low cost, and relatively safe clinical profile. GLP-1 receptor agonists and SGLT2 inhibitors are now also considered reasonable but expensive alternatives. For patients not meeting glycemic targets with metformin alone, the ADA advises an individualized approach in selecting appropriate

pharmacologic therapy and escalation of treatment to achieve glycemic goals for patients with T2DM. Many agents now offer added benefits for protection against ASCVD and progression of diabetic kidney disease (DKD) as well as additional weight-loss effects. A patient-centered approach should guide treatment, considering the potential for additional risk factor reduction, mitigating weight gain, hypoglycemia risk, cost, and patient preference (Figure 4). A1c should be checked every 3 months, with escalation of care if targets are not achieved. However, intensification of care, including initiation of insulin, should not be delayed in patients with markedly uncontrolled glycemia.

After metformin, providers must then consider whether patients are at risk for or have established ASCVD, heart failure, or established DKD. As such, a glucagon-like protein 1 (GLP-1) receptor agonist or SGLT2 inhibitor should be second-line therapy. If a patient does not have high risk or established ASCVD, heart failure, or DKD, second-line agents should be initiated on an individualized basis, accounting for other variables such as weight reduction, hypoglycemia, and cost.

### Noninsulin Agents

#### Metformin

Metformin is a biguanide that inhibits hepatic glycogenolysis and gluconeogenesis. It improves insulin sensitivity in muscle and fat. It can lower A1c by 1.0% to 1.5% on the average, but it occasionally can be very effective, even in new-onset patients with rather high HbA1c levels. Metformin is inexpensive with good efficacy and no risk of hypoglycemia. It is usually weight-neutral and may even provide modest weight loss. Metformin has cardiovascular benefits.

Common adverse effects include gastrointestinal upset, which can be minimized by taking metformin with a meal instead of before a meal or by using the extended-release formula. Gradual titration up to full dose also reduces gastrointestinal side effects, especially when taken with meals. Metformin is associated with a reduction in vitamin B<sub>12</sub> but rarely with a deficiency. Lactic acidosis is a very rare but catastrophic complication of metformin, usually occurring in patients with significant reduction in GFR.

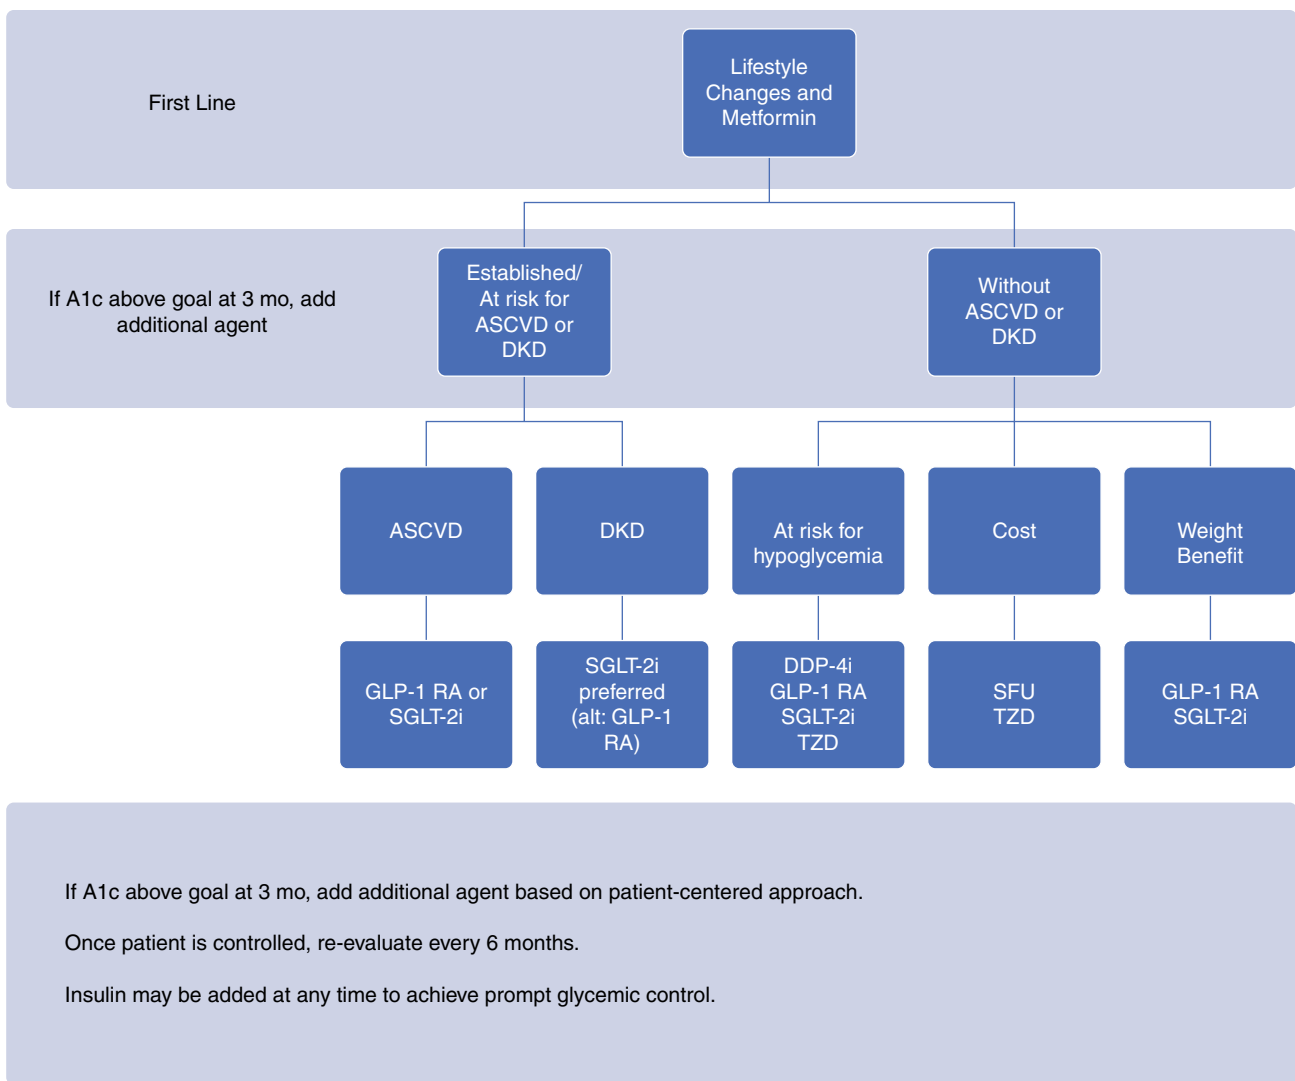

Metformin has often been inaccurately accused of causing renal damage, and there is little to no evidence to support this belief. The FDA has approved metformin for use in patients with eGFR greater than 30 mL/min/1.73 m<sup>2</sup>. The authors typically give a reduced dose of metformin for eGFR less than 60 mL/min/1.73 m<sup>2</sup>. As metformin is renally cleared, it should be withheld for 48 hours after iodinated contrast administration to avoid contrast-induced nephropathy. Metformin should be avoided in unstable or hospitalized patients with acute heart failure because of the increased risk of lactic acidosis and worsened myocardial dysfunction. Metformin should be continued as long as it is tolerated and there are no contraindications, even as additional agents including insulin are added. Of note, there is probably little benefit in the use of metformin in T1DM,<sup>1</sup> although it may be beneficial for patients with concomitant insulin resistance caused by overweight/obesity.

#### Sodium-Glucose Cotransporter 2 Inhibitors

SGLT2 is expressed in the proximal renal tubule and mediates reabsorption of the majority of the glucose load filtered through the kidneys. SGLT2 inhibitors block renal glucose reabsorption, thus promoting excretion of glucose and sodium via glucosuria and lowering blood glucose levels in patients with T2DM. The glucose-lowering effects are independent of insulin, beta-cell function, and insulin sensitivity, thus offering an additional pathway for glucose regulation with low risk of hypoglycemia when used without insulin. These agents lower A1c by 0.5% to 1.0%. Although it is appealing to use these drugs among T1DM patients, the risk of normoglycemic ketoacidosis and lack of FDA approval makes this risky, in our opinion.

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**Figure 4** The choice of oral agents is based on many factors including the patient's financial resources and risk or presence of complications. In this figure, we show a decision tree based on the presence or absence of major complications. ASCVD, Atherosclerotic cardiovascular disease; DPP-4i, dipeptidyl peptidase 4 inhibitor; DKD, diabetic kidney disease; GLP-1 RA, glucagon-like peptide 1 receptor agonist; SGLT-2i, sodium-glucose cotransporter 2 inhibitor; TZD, thiazolidinedione. Modified from the ADA Standards of Medical Care in Diabetes, 2020.

Several landmark trials have demonstrated a significant benefit of the SGLT2 inhibitors for both ASCVD risk and DKD. The Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients (EMPA-REG OUTCOME) was the first pivotal trial showing reduced composite outcomes for cardiovascular death, nonfatal MI, or nonfatal stroke with the use of empagliflozin (Jardiance). There was a significant relative risk reduction in rates of cardiovascular death by 38%, all-cause mortality by 32%, and hospitalization for heart failure by 35%. As a result of this trial, empagliflozin received FDA approval for reduction of cardiovascular death in adults with T2DM and CVD. The Canagliflozin Cardiovascular Assessment Study (CANVAS) demonstrated reduction in cardiovascular events, but not cardiovascular death, in patients with T2DM at high risk for CVD in the canagliflozin (Invokana) group when compared with the placebo group. Subsequently, the Evaluation of the Effects of Canagliflozin on Renal and Cardiovascular Outcomes in Participants with Diabetic Nephropathy (CRE-DENCE) trial showed a 30% risk reduction for composite end-stage kidney disease, doubling of serum creatinine level, or death from renal or cardiovascular causes as well as a lower risk of cardiovascular events in patients of the canagliflozin group compared with patients in the placebo group. The Dapagliflozin Effect on Cardiovascular Events randomized

double-blind controlled (DECLARE-TIMI 58) trial evaluated time to first event for cardiovascular death, MI, or ischemic stroke, which was reduced in the dapagliflozin (Farxiga) arm when compared with the placebo arm. Although the mechanisms responsible for these clinical outcomes are not well-described, SGLT2-inhibitor-related natriuresis is proposed to account for a favorable effect on blood pressure, while altered myocardial metabolism and weight loss could account for additional benefits to reduction in CVD-related mortality.

Along with the cardiovascular and renal benefits of this drug class, SGLT2 inhibitors also contribute to very modest weight loss. Unfortunately, they can be expensive, and there is a risk of hypoglycemia if used in combination with insulin or sulfonylureas. Because they are renally cleared, considerations for renal dose adjustment are required. There is also an FDA black-box warning for the risk of amputations with canagliflozin, a finding that has not been uniformly supported in subsequent studies. There is an increased risk of bone fractures with long-term use (canagliflozin), euglycemic DKA, genitourinary and other infections, volume depletion, slight elevation of LDL cholesterol, and Fournier gangrene. The marked benefit in cardiac and renal protection of these drugs must be balanced against the risks of euglycemic DKA, increased urinary tract infections (UTIs) (about 10% in women, >5% in men), and intolerance caused by dehydration.

In balance, 90% to 95% of patients prescribed this class of drugs tolerate them well (see [Table 2](#)).

### **Glucagon-Like Peptide 1 Receptor Agonists**

The GLP-1 receptor agonists are, with one exception, injectables that act through several mechanisms, including increased insulin secretion in response to hyperglycemia, reduction of gastric emptying, reduction of inappropriate glucagon secretion, and potentially slowing the loss of beta-cell function over time. On the average, they lower HbA1c by 1.0% to 1.5%. This class of medications promotes significant weight loss by enhancing a sense of early satiety and has a low risk of hypoglycemia when used as monotherapy because of its glucose-dependent mechanism of action. These agents have historically been injectable, but recently a new oral GLP-1 receptor agonist (semaglutide [Rybelsus]) was approved.

Like the SGLT2 inhibitors, this class of medications has also demonstrated significant risk reductions in ASCVD and DKD. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial included subjects at risk for CVD and found that liraglutide significantly reduced cardiovascular death, nonfatal MI, or nonfatal stroke, as well as all-cause mortality relative to placebo. Based on the LEADER data, the FDA approved liraglutide (Victoza) for the reduction of major cardiovascular events and cardiovascular deaths in adults with T2DM and CVD. Additional studies have shown benefit of GLP-1 receptor agonists in cardiovascular outcomes. The Trial to Evaluate Cardiovascular and Other Long-Term Outcomes with Semaglutide in Subjects with T2DM (SUSTAIN-6) showed statistically significant reductions in nonfatal MI, nonfatal stroke, or cardiovascular death in the semaglutide (Ozempic) group. An additional meta-analysis of seven GLP-1 receptor agonist cardiovascular outcome trials found that this drug class reduced major adverse cardiovascular events by 12%, all-cause mortality by 12%, and hospitalization for heart failure by 9%. There was also a 17% reduction in a composite of various renal outcomes.

The most common side effects of these agents include mild injection-site reactions, abdominal cramping, and nausea and vomiting, which are typically transient and lessened by gradual dose up-titration. There is a risk of hypoglycemia if used in combination with insulin or sulfonylureas. This class of medications has been found to increase the incidence of benign and malignant C-cell tumors in rodents and is contraindicated in patients with a personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia 2A or 2B. There have also been post-marketing reports of acute pancreatitis in association with GLP-1 receptor agonists, and they should not be initiated in patients with a history of pancreatitis. Although there are reports of increased incidence of pancreatic cancers and neuroendocrine tumors, a causal relationship has not been established, and the FDA cites insufficient evidence to confirm this risk. Like the SGLT2 inhibitors, these medications may be costly, especially for patients without insurance. The drugs may be poorly tolerated in patients with gastroparesis or previous bariatric surgery. One preparation has been approved for oral use (semaglutide [Rybelsus]) but with a loss of efficacy compared with the injected compound.

### **Glucose-Dependent Insulinotropic Polypeptide and Glucagon-Like Peptide-1 Receptor Agonist**

Tirzepatide (Mounjaro) is a novel agent that combines both a glucose-dependent insulinotropic polypeptide (GIP) and a glucagon-like peptide-1 (GLP-1) receptor agonist as a once-weekly injection for the treatment of T2DM. The GIP is part of the incretin family of hormones. Its main role is to stimulate insulin secretion, and it also inhibits apoptosis of pancreatic beta cells and promotes proliferation. The combination of GLP-1 and GIP agonists seems to promote greater efficacy in the management of T2DM and significant weight reduction. A multicenter trial demonstrated substantial weight loss in participants over the course of 72 weeks. A 5% weight reduction was achieved by at least 85% of participants. Impressively, at least one-half of the participants achieved a weight loss of 20% body weight with higher doses. Its

safety profile is comparable to the GLP-1 receptor agonist class. Tirzepatide was recently approved by the FDA for the treatment of T2DM in adults. Although currently costly, this medication is an exciting advancement in the treatment of T2DM and obesity.

### **Dipeptidyl Peptidase 4 Inhibitors**

The dipeptidyl peptidase 4 (DPP-4) inhibitors work by inhibiting the degradation of incretin hormones (like GLP-1) and thus increasing the half-life to increase insulin secretion in a glucose-dependent manner and decrease glucagon secretion. They lower A1c by 0.5% to 1.0%. They are weight-neutral and do not contribute to hypoglycemia if used as monotherapy. This class of medications is generally well-tolerated, but a few patients complain of upper respiratory symptoms and joint pain. There is a risk of hypoglycemia if used in combination with insulin or sulfonylureas. This class can still be used in renal failure with appropriate dose adjustments. One drug in the class, linagliptin (Tradjenta), is hepatically metabolized, and no dose adjustment is needed in patients with poor renal function. Like the more potent GLP-1 receptor agonists, the DPP-4 inhibitors can be associated with pancreatitis. There is no additive benefit with a DPP-4 inhibitor with GLP-1 receptor agonist, and the combination should be avoided, with preference usually for the GLP-1 receptor agonist. A dose reduction is indicated for patients with renal impairment. Of note, the ADA suggests that DPP-4 inhibitors (except saxagliptin [Onglyza]) may be considered in patients with heart failure<sup>1</sup> because saxagliptin may potentially exacerbate underlying myocardial dysfunction. There is a role for these agents when there is a compelling need to minimize hypoglycemia, when weight neutrality is desired, or in case of significant renal failure.

### **Thiazolidinediones**

TZDs are insulin sensitizers that increase insulin sensitivity in muscle and fat. Pioglitazone (Actos) and rosiglitazone (Avandia) are currently available. They are potent in lowering A1c by 1.0% to 1.5%. They are not associated with hypoglycemia. Pioglitazone may reduce CVD and triglycerides. These medications may cause weight gain in the form of both volume retention and increase in fat mass. There is an FDA black-box warning against the use of these agents in congestive heart failure. They are also associated with an increased risk of bone fractures and small relative risk of bladder cancer with long-term use (pioglitazone). Pioglitazone can also raise LDL cholesterol. There is a role for these agents when patients do not want to use an injectable medication, when cost is an issue, or when there is a need to minimize hypoglycemia. We frequently use them in the uncommon thin type 2 diabetic patient and, anecdotally, seem to have favorable results. Most clinicians avoid the use of TZDs in patients who are already taking insulin because of the risk of edema and congestive heart failure (CHF).

### **Secretagogues**

Sulfonylureas stimulate beta-cell insulin secretion from the pancreas. They can lower HbA1c by 1.0% to 1.5%. These medications are initially effective and inexpensive. However, the authors typically do not prescribe these medications unless cost is an issue. Sulfonylureas lose their efficacy because they result in beta-cell loss over time and also cause weight gain, potentially contributing to further insulin resistance. Newer agents, such as the SGLT2 inhibitors and GLP-1 receptor agonists, preserve islet cell function, maintain their efficacy, and have shown both cardiovascular and renal protective benefits. Sulfonylureas also have a risk of hypoglycemia and should be taken with food. Caution should be used with hepatic or renal impairment.

### **Other Agents**

Other less used agents include amylin agonists (pramlintide [Symlin]), bile acid sequestrants (cholestyramine resin [Questran],<sup>1</sup> colesevelam [Welchol]), and dopamine receptor agonists

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Noninsulin Treatment for Adults with Type 2 Diabetes: Factors to Consider for a Patient-Centered Approach

	EFFICACY	WEIGHT CHANGE	ASCVD BENEFIT	DKD BENEFIT	HYPOGLYCEMIA RISK	COST
Metformin	High	Neutral/modest loss	Benefit	Benefit	None	Low
SGLT2 inhibitor	High	Loss	Benefit	Benefit	Low	High
GLP-1 receptor agonist	High	Loss	Benefit	Benefit	Low	High
DPP-4	Low	Neutral	Neutral	Neutral	Low	High
TZD	High	Gain	Potential benefit	Neutral	None	Low
SFU	Intermediate	Gain	Neutral	Neutral	High	Low

ASCVD, Atherosclerotic cardiovascular disease; DKD, diabetic kidney disease; DPP-4, dipeptidyl peptidase 4; GLP-1, glucagon-like peptide 1 receptor; SFU, sulfonylurea; SGLT, sodium-glucose cotransporter 2; TZD, thiazolidinedione. Modified from the ADA Standards of Medical Care in Diabetes 2021.

(bromocriptine [Cycloset]). The authors use these infrequently given their cost, modest impact on glycemia, and relative inconvenience for the patient. See Table 3 for a summary of prescribing noninsulin medications.

### Insulin

Insulin is often thought of as the drug of last resort for T2DM. It has a narrow therapeutic window in that the glucose targets are near the threshold for hypoglycemia. Patients have sometimes been preconditioned with fear of insulin, having been threatened by well-intentioned providers saying, for example, “If you don’t lose weight, you will need to go on insulin.”

Transitioning a patient to insulin requires a fair amount of patient education, a valuable resource especially among small, isolated practices. Patients offer their own resistance seeing the cost, inconvenience, and pain. Insulin injections are sometimes seen as a mark of final deterioration in their disease and associated with catastrophic events: “My uncle lost his leg when he was put on insulin.”

Arguably, insulin can be introduced at any stage of diabetes. There is some evidence that early introduction of insulin may preserve islet cell function, but long-term studies have not confirmed or rejected that concept. Conceptually, we see insulin administration as hormone replacement just as giving levothyroxine to a hypothyroid patient. We avoid using insulin as a threat, which may only increase resistance to it when it is finally needed. In practice, insulin is usually prescribed when diet and exercise, oral medications, and perhaps GLP-1 agonists have failed to achieve treatment goals. One should not delay its use when it is needed, keeping in mind the concept of *metabolic memory* discussed earlier in this chapter; the longer patients are hyperglycemic, the more likely they are to have complications in the future.

### Conceptual Approach to Insulin Administration in Type 2 Diabetes Mellitus

The primary motivation for using insulin is to achieve the treatment goal. This may go beyond reaching the desired HbA1c threshold because being an average, it does not reflect glucose variability. Evolving concepts suggest that large variations in glucose, even after meals, add to the risk of complications. Thus, TIR (percentage of time that the patient has a blood sugar of 70 to 180 mg/dL) is a concept that will likely move from the domain of the specialist to internal medicine and family practice. Whether the clinician uses a basal-bolus approach (premeal short-acting insulin with a long-acting background insulin) or combinations of regular and neutral protamine Hagedorn (NPH) insulin, the intent is to mimic the postmeal excursions in insulin and to provide a constant background of insulin action. See Table 4 for a summary of insulin preparations.

### First Steps

The most common approach to initiation of insulin is to start with a single shot of basal insulin. A conservative approach is to start with 0.2 U/kg and to titrate the dose up until the patient is sleeping without hypoglycemia and waking up with acceptable blood glucose levels (typically 80 to 130 mg/dL). There are a variety of clinically tested titration protocols that allow the patient to adjust to basal insulin without further consulting the provider. These are called *treat-to-target* (TTT). For glargine (Lantus, Basaglar) and detemir (Levemir) insulin, we suggest adding 1 unit per day to the initiating dose until the overnight and fasting targets are reached. Similarly, if the patient experiences overnight hypoglycemia, we reduce the dose by 1 unit. When prescribing ultra-long-acting insulins such as glargine 300 U/mL (Toujeo) and degludec (Tresiba), we modify the TTT by changing the dose by 2 units at 5-day intervals because the pharmacodynamic half-lives of these preparations approach 36 to 40 hours.

### Next Steps

A single dose of basal insulin can achieve an HbA1c of less than 7% in at least 50% of T2DM patients. If this target is not reached, we frequently move to a dosing scheme termed *basal-plus-one*. In this case, we add short-acting insulin before the largest meal of the day. Typically, this additional dose can be estimated by dividing the basal insulin dose by one-third and adding that amount as the plus-one premeal dose. The goal of this regimen is to achieve a blood sugar of less than 180 mg/dL 2 hours after the meal. This maneuver will bring HbA1c into the target range in about one-half of patients who fail to be well controlled on a single dose of basal insulin.

### Multiple Daily Injections or Basal-Bolus Therapy

MDI is used in many T2DM patients and is the standard of care in T1DM. There are a number of approaches that can be adapted for a given patient’s lifestyle and motivation. A helpful statistic is that short-acting insulin in most well-controlled insulin-using patients accounts for 40% to 60% of the total daily dose (TDD).

### Fixed Dose Plus Sliding Scale

In this instance, the patient is prescribed a certain number of units of insulin before each meal and given a table to add insulin if the premeal glucose level is above a certain threshold. This might be acceptable in a patient who has regular meals or refuses to learn more complex premeal dose calculations. Endocrinologists frequently dislike the term *sliding scale* because it is often misused to justify giving no premeal insulin when the premeal glucose level is normal. Premeal insulin is given primarily to act on the content of the meal.

### Small, Medium, Large

A conceptually simple approach is to assign three premeal doses based on the size of the meal or more specifically the amount of carbohydrate in the meal. Many patients learn to use this dosing scheme with reasonable results.

### Carbohydrate Counting with a Correction Factor

This is the gold standard of calculating a premeal dose. It allows for the greatest meal flexibility but at the expense of learning to calculate the grams of carbohydrate in a meal and reliably testing the fingerstick blood glucose before the meal. In addition to working with a nutritionist, a good reference for the carbohydrate content of foods is *Calorie King*, as a paperback or free mobile phone app. Here are the steps needed to calculate carbohydrate ratio (grams of carbohydrate per unit of insulin) and the correction factor (how much insulin to take to correct for premeal hyperglycemia).

- **Estimate the total daily dose (TDD):** Typically, this is about twice the number of units used as basal insulin. Alternatively, a starting TDD for patients with T2DM is approximately 0.5 units/kg.
- **Estimate the carbohydrate ratio:**  $500/\text{TDD} = \text{grams of carbohydrate requiring a unit of premeal insulin}$
- **Estimate the correction factor:**  $1600/\text{TDD} = \text{mg/dL that blood glucose will lower with 1 unit of insulin typically given with any elevation above 140 mg/dL}$ . Patients will often remember this number as, for example, “1 extra unit for every \_\_\_ mg/dL above 140.” The 140 mg/dL target can be adjusted up when there is concern about hypoglycemic unawareness or if overall goals are higher than the conventional standards. It can also be expressed as a simple formula:

$$([\text{blood glucose before the meal}] - 140) / \text{correction factor} = \text{units needed to treat the premeal hyperglycemia}$$

These formulas provide estimates and give the patient a starting point. Some patients find that they need different insulin dose factors at different meals. In any case, the criteria for success are that patients avoid hypoglycemia between meals and reach their glucose target before the next meal.

### Other Factors Affecting Insulin Requirements

#### Exercise

Exercise can have a marked effect on glucose utilization and insulin sensitivity. The exercising muscle takes in glucose as needed provided that there is *some* insulin in the blood. The glucose transporter on the muscle membrane responds somewhat independently of insulin to local depletion of glucose and glycogen by accelerating glucose transport. In addition, regular exercise reduces insulin requirements both by increasing the efficiency of muscle glucose transport, improving intramuscular energy utilization, reducing insulin resistance, and increasing lean body mass/reducing body fat.

We recommend that patients reduce short-acting insulin in anticipation of exercise. Thus, for example, the premeal short-acting insulin at lunch would be reduced in anticipation of exercise before the evening meal. The amount of the reduction is variable and depends primarily on the duration and intensity of the exercise. We initially suggest decreasing the premeal insulin by one-third, but in long-duration and high-intensity exercise premeal insulin can be reduced drastically or even eliminated in some cases. Patients should have documented education on the impact of exercise on glycemia and must have a source of rapid-acting carbohydrate readily available to them. In the case of children or adolescents, this might mean educating coaches and teachers on the signs and treatment of hypoglycemia.

The window of vulnerability to exercise-induced hypoglycemia extends beyond the time of exercise. During postexercise rest, muscles may continue to take up large amounts of glucose to replete glycogen stores, and hypoglycemic episodes can occur as long as 24 hours after a bout of vigorous exercise.

#### Sick Days

A common and unfortunate misconception held by some patients is that they do not need insulin if they do not eat. This may be true

for some T2DM patients, but many will suffer uncontrolled hyperglycemia and sometimes catastrophic metabolic dysfunction when insulin is withheld for prolonged periods. In some patients, insulin requirements increase during illness because of the stress response. Thus, insulin-using diabetic patients should increase the frequency of blood glucose monitoring, take their basal insulin, and use short-acting insulin. The following are some guidelines:

- Check blood glucose every 4 hours.
- Check urine for ketones, and report moderate or large amounts to the healthcare provider.
- If the blood glucose is less than 200 mg/dL, stay hydrated with Gatorade or a sugar-containing soda.
- If the blood glucose is over 200 mg/dL, drink plenty of sugar-free liquids. In patients who can tolerate a salt load, we recommend broth or soup in a cup (ramen noodle soup).
- Uncontrolled hyperglycemia, nausea and vomiting, or high ketones are indications to alert the provider as soon as possible.

### Low Carb or Carbohydrate-free Meals

The popularity of paleo or keto diets confronts healthcare providers with the issue of insulin management with low carbohydrate intake. In most cases, premeal insulin can be reduced and occasionally eliminated based on postprandial blood sugar. We have occasionally observed insulin-using T2DM patients totally eliminate insulin use and return to near-normal glycemia with carefully monitored, hypocaloric ketotic diets.

### Types of Insulin

Insulin preparations are categorized by their duration of action. This is referred to as the *pharmacodynamics* (PD) of insulin (duration of action) as opposed to the *pharmacokinetics* (PK) of insulin (circulating half-lives). The distinction between PK and PD is simply because insulin acts on membrane-bound receptors, and subsequent downstream action with most insulins is much longer than the circulating half-lives (PK). All insulins sold in the United States are synthetic, derived from genetically altered yeast or bacteria. All insulins are dosed using “units,” a historically interesting measure of bioactivity that was originally derived from the amount of insulin needed to reduce glucose by about 50 mg/dL in a standard laboratory rabbit. The unit now is primarily based on weight (0.0347 mg). Because the molecular weight of some synthetic insulins differs from that of human insulin, the unit is used to ensure that there is equal potency among preparations. That is, 1 unit of any given insulin preparation will be expected to have the same impact on glucose lowering. See [Table 4](#).

The combination insulins generally have high interpatient and inpatient variability. Despite this, some studies show that twice- or thrice-daily use of these combinations produces acceptable control of glucose with slightly more hypoglycemia than basal insulin plus short premeal insulin.

- **Rapid-acting insulins.** These typically have a duration of action between 3 and 6 hours and are given right before or immediately after meals or used in insulin pumps. Fiasp, an ultra-short-acting aspart insulin, peaks a bit sooner than the short-acting analogues. Some evidence shows a modest decrease in postprandial hypoglycemia and decrease in postprandial glycemia compared with other short-acting analogues.
- **Short-acting insulin (human).** These are the least expensive forms of premeal insulin and are often available without prescription. The reduced cost is offset in part by inconvenience in that they should be taken 30 to 45 minutes before eating (except with premeal hypoglycemia), and they produce slightly more hypoglycemia. We consider them a good option for patients facing high drug costs.
- **Intermediate-acting insulin.** NPH is the only form of this insulin and, like regular human insulin, is much less expensive than the analogue insulins. It is amorphous and thus cloudy. Before use, it should be mixed by rolling the vial or pen rather than vigorously shaking the preparation. Although it can be an adequate lower-cost alternative to analogue insulin, it has relatively high variability in its peak and duration of action. It is associated with slightly more frequent hypoglycemia than the newer basal and

**TABLE 4** Comparison of Various Types of Insulin

TRADE NAME	GENERIC NAME	ONSET	PEAK	DURATION	COST
<b>Rapid-Acting</b>					
Admelog	Lispro	15–30 min	30–90 min	3–5h	\$\$
Apidra	Glulisine	10–20 min	90–120 min	2–4 h	\$\$

Novolog Mix 70/30	NPH 70%/aspart 30%	15–30 min	50 min–2 h and 6–10 h	18–24 h	\$\$
Humalog Mix 75/25	NPH 75%/lispro 25%	15–30 min	50 min–2 h and 6–10 h	12–24 h	\$\$
Humalog Mix 50/50	NPH 50%/lispro 50%	15–30 min	2–4 h and 6–10 h	12–24 h	\$\$

\*The fixed combination insulins generally have high inter- and inpatient variability because of their reliance on NPH as a background or late-peaking insulin. With their use, the practitioner is trading convenience in exchange for flexible dosing. Despite these concerns, some studies have found using these combinations in T2DM produces acceptable control of glucose with slightly more hypoglycemia than multiple daily injections (separate dosing) of basal insulin plus short-acting premeal insulin. NPH, Neutral protamine Hagedorn.

ultra-long-acting forms of insulin. Although it theoretically can be given once a day, it is usually given before breakfast and a second dose before the evening meal or bedtime. It can be used in a basal-bolus fashion with one dose at bedtime and regular insulin before each meal. The tendency of an injection of NPH to peak in the afternoon/evening makes it a logical choice in the treatment of glucocorticoid-induced hyperglycemia.

- **Basal, or ultra-long-acting, insulin.** These insulin preparations have a duration of action of nearly 24 hours or longer and are often the first insulin used in a treatment regimen. When cost is no object, they are usually the preferred basal preparations, with a few caveats.
  - Detemir (Levemir) has the shortest duration in the class and may not always fill the role as a once-a-day insulin. When used, we prefer to give it at night and sometimes will give it approximately every 12 hours to provide a constant background of insulin.
  - Glargine (Lantus, Basaglar, Toujeo, Semglee) is an acidic insulin that cannot be mixed in the same syringe with other insulins. As such, it sometimes causes minor irritation at the injection site. The primary differences between Basaglar and Lantus, on one hand, and Toujeo on the other, is the concentration of glargine. Toujeo is highly concentrated (300 U/mL), and this increases the duration of action by slowing its

absorption from the injection site. Toujeo, then, has a more linear pharmacodynamic profile than its chemical twins and is a bit more forgiving in not requiring a precise dosing time. A new biosimilar insulin approved in the United States for the treatment of diabetes is Semglee (insulin glargine-yfgn). It is considered a generic drug and a more affordable long-acting insulin that is interchangeable with insulin glargine. These insulins do not provide a postmeal peak in insulin. Thus they may be best suited for patients who have some capacity to produce endogenous insulin to act on mealtime calories. Glargine insulin is advertised as a “flat insulin,” but it develops peaks if the injected units exceed 0.3 U/kg. Thus it is our practice to split Lantus or Basaglar into two daily shots when the required amount of insulin exceeds approximately 50 U/day. Glargine insulin is usually given at bedtime or with the evening meal, but morning dosing is successful in some patients as well.

- Degludec (Tresiba) has the longest duration of action of the marketed insulins and has a slight benefit in that its use is associated with a bit less hypoglycemia and more flexible dosing schedules.
- **Pumps.** These devices are infrequently used in general practice, but it is appropriate to be comfortable with suggesting their use to the suitable patients. Pumps are rarely helpful in patients who

struggle with compliance and are in poor control. Broadly speaking, pumps fall into two classes: open-loop and semiautonomous pumps. Open-loop pumps must be programmed by the patient or provider to deliver basal doses of insulin as near-constant injections of small amounts of insulin and premeal insulin based on the calculation of the amount of insulin needed to treat premeal hyperglycemia and calorie/carbohydrate content of the meal. Closed-loop pumps (semi-autonomous) are paired through Bluetooth with a continuous subcutaneous glucose monitor and are programmed to vary the amount of basal insulin to maintain a tight range of near-normal glycemia between meals. The patient is still obliged to alert the pump that it is mealtime, and the patient must input the amount of anticipated carbohydrate in the meal. In practice, the pumps are fairly successful at achieving near-normal glycemia with reduced variance.

## Hypoglycemia

Hypoglycemia is defined as a glucose concentration of less than 70 mg/dL and is further classified into three levels. Level 1 is a glucose value less than 70 mg/dL but greater than or equal to 54 mg/dL. Level 2 is a glucose value less than 54 mg/dL. Level 3 is any event with severe symptoms that require medical assistance for treatment. Hypoglycemia can present with both neurogenic (autonomic) and neuroglycopenic symptoms. Neurogenic symptoms include adrenergic responses such as tremor, palpitations, and/or anxiety as well as cholinergic responses such as diaphoresis, hunger, and paresthesias. Conversely, neuroglycopenic symptoms are those that cause an altered sensorium such as confusion, dizziness, weakness, and drowsiness but can ultimately progress to seizures or coma with severe hypoglycemia. Neuroglycopenic symptoms typically occur with glucose values less than 54 mg/dL.

Studies have suggested significant long-term risks from frequent severe hypoglycemia, including significant cognitive impairment, falls and fractures, and increased mortality. Risk factors for hypoglycemia include advanced age, African American race, longer duration of diabetes, use of sulfonylureas and/or insulin, renal impairment, dementia, alcohol ingestion, and erratic meal timing.

Hypoglycemia is also graded as mild, moderate, or severe. *Mild* is an event in which the patient feels the symptoms and treats the low level on his or her own. *Moderate* events require assistance but do not involve unconsciousness or the need for glucagon. *Severe* hypoglycemia is defined as a seizure, obtundation, need for emergency department visit, or need to call emergency medical technicians (EMTs). Many patients with well-controlled insulin-treated diabetes experience occasional mild hypoglycemia, and these episodes can be acceptable provided that they are not too frequent or reach moderate-to-severe levels. Moderate and severe events should be addressed with changes in the regimen and a thorough investigation as to why the event occurred, such as skipping a meal or insulin dose error.

Clinicians should be aware that patients with poorly controlled diabetes with frequent episodes of hypoglycemia can often lose their counterregulatory responses to low blood glucose and develop hypoglycemia unawareness in which blood glucose can drop significantly. Thus it is important to ask patients at which glucose threshold they begin to feel symptoms of hypoglycemia. Patients can, occasionally, regain some sensitivity to hypoglycemia by relaxing blood glucose control for several weeks.

Hypoglycemia should be treated with glucose administration if the patient is alert and able to take in food by mouth. The authors educate their patients on the “Rule of 15” for treating hypoglycemia. Patients should ingest 15 g of rapid-acting carbohydrates (such as 4 oz orange juice, 4 oz regular soda, 8 oz skim milk, 3 to 4 glucose tablets, or 15 jellybeans or hard candies) every 15 minutes until fingerstick blood glucose is greater than 70 mg/dL. For prolonged hypoglycemia,

we suggest a snack with complex carbohydrates, fats, and protein. It is important to always evaluate the underlying cause of hypoglycemia and adjust the treatment regimen accordingly.

For severe hypoglycemia in which the patient needs the assistance of another person or medical professional, glucagon can be administered. Glucagon is now available in intramuscular (GlucaGen), subcutaneous (GlucaGen, Gvoke), or intranasal (Baqsimi) formulations. The authors always educate patients that use of an emergency glucagon kit warrants evaluation in the emergency department after they have taken it.

## DIABETIC KETOACIDOSIS

Method of

Aidar R. Gosmanov, MD, PhD, DMSc

### CURRENT DIAGNOSIS

- Initial evaluation includes physical examination and comprehensive metabolic panel, serum osmolality, serum ketones and  $\beta$ -hydroxybutyrate, complete blood count, urinalysis, urine ketones, and arterial blood gases.
- Search for precipitating causes. Omission of insulin, underlying medical illness, cardiovascular events, gastrointestinal disorders, recent surgery, stress, medications, eating disorders, psychological stress, insulin pump malfunction, and infection are potential causes; white blood cell count greater than 25,000 suggests presence of infection.
- $\beta$ -Hydroxybutyrate of 3.8 mmol/L or greater in adults indicates presence of diabetic ketoacidosis (DKA), even if serum ketones are negative.
- Patients with severe chronic kidney disease (CKD) require careful evaluation of acid-base status.

## CURRENT THERAPY

- Start intravenous fluids early before insulin therapy.
- Potassium level should be more than 3.3 mEq/L before insulin therapy is initiated. Supplement potassium intravenously if needed.
- Initiate continuous insulin infusion at 0.14 U/kg/h and measure bedside glucose every 1 h to adjust the insulin infusion rate.
- Avoid hypoglycemia during the insulin infusion by initiating dextrose-containing fluids and/or reducing the insulin infusion rate until DKA is resolved.
- Transition to subcutaneous insulin only when DKA resolution is established.

### Epidemiology

There were 188,965 hospital discharges for diabetic ketoacidosis (DKA) in 2014 in the United States, compared to 140,000 in 2009 and 80,000 in 1988. The in-hospital fatality rates declined consistently from 2009 to 2014 from 1.1% to 0.4%, although mortality remains high in developing countries. In 2014, the direct and indirect annual cost of DKA hospitalization was \$5.1 billion.

### Risk Factors

Omission of insulin is the most common precipitant of DKA. Infections, acute medical illnesses involving the cardiovascular system (myocardial infarction, stroke) and gastrointestinal tract (bleeding, pancreatitis), diseases of the endocrine axis (acromegaly and Cushing syndrome), and stress from recent surgical procedures can contribute to the development of DKA by causing dehydration, increase in insulin counterregulatory hormones, and worsening of peripheral insulin resistance. Medications such as diuretics,  $\beta$ -blockers, corticosteroids, second-generation antipsychotics, and anticonvulsants can affect carbohydrate metabolism and volume status and can, therefore, precipitate DKA. Other factors that can contribute to DKA include psychological problems, eating disorders, insulin pump malfunction, lower socioeconomic status, and drug abuse. It is now recognized that new-onset type 2 diabetes mellitus can manifest with DKA. These patients are obese, mostly African American or Hispanic, and extremely insulin resistant on presentation. The use of sodium-glucose cotransporter 2 (SGLT-2) inhibitors has been implicated in the development of DKA in patients with both type 1 and type 2 diabetes. Most recently, the immune checkpoint inhibitors (ICI) used in patients with advanced malignancy can cause DKA de novo in patients without a prior history of diabetes. The DKA risk is significantly more common with use of programmed cell death protein 1 inhibitors such as nivolumab (Opdivo) compared to cytotoxic T-lymphocyte associated antigen 4 inhibitors such as ipilimumab (Yervoy). Early evidence suggests that coronavirus disease 2019 (COVID-19) infection can trigger DKA in subjects without or with prior diabetes history.

### Pathophysiology

Insulin deficiency, increased insulin counterregulatory hormones (cortisol, glucagon, growth hormone, and catecholamines), and peripheral insulin resistance lead to hyperglycemia, dehydration, ketosis, and electrolyte imbalance, which underlie the pathophysiology of DKA. The hyperglycemia of DKA evolves through accelerated gluconeogenesis, glycogenolysis, and decreased glucose utilization, all due to absolute insulin deficiency. Owing to increased lipolysis and decreased lipogenesis, abundant free fatty acids are converted to ketone bodies: acetoacetate and  $\beta$ -hydroxybutyrate ( $\beta$ -OHB). Hyperglycemia-induced osmotic diuresis, if not accompanied by sufficient oral fluid intake, leads to dehydration, hyperosmolarity, electrolyte loss, and subsequent decrease in glomerular filtration.

With a decline in a renal function, glycosuria diminishes, and hyperglycemia worsens. With impaired insulin action and hyperosmolar hyperglycemia, potassium uptake by skeletal muscle is markedly diminished, which, along with hyperosmolarity-mediated efflux of potassium from cells, results in intracellular potassium depletion. Potassium is lost via osmotic diuresis, causing profound total body potassium deficiency. Therefore DKA patients can present with a broad range of serum potassium concentrations. A “normal” plasma potassium concentration still indicates that potassium stores in the body are severely diminished and the institution of insulin therapy and correction of hyperglycemia will result in hypokalemia.

On average, patients with DKA have the following deficit of water and key electrolytes: water 100 mL/kg, sodium 7 to 10 mEq/kg, potassium 3 to 5 mEq/kg, and phosphorus 1 mmol/kg.

### Clinical Manifestations

Polyuria, polydipsia, weight loss, vomiting, and abdominal pain usually are present in patients with DKA. Abdominal pain can be closely associated with acidosis and resolves with treatment. Physical examination findings such as hypotension, tachycardia, poor skin turgor, and weakness support the clinical diagnosis of dehydration in DKA. Mental status changes can occur in DKA and are likely related to the degree of acidosis and hyperosmolarity. A search for symptoms of precipitating causes such as infection, vascular events, or existing drug abuse should be initiated in the emergency department. Patients with hyperglycemic crises can be hypothermic because of peripheral vasodilation and decreased utilization of metabolic substrates.

### Diagnosis

Diagnostic criteria for DKA include blood glucose higher than 250 mg/dL, arterial pH 7.30 or less, bicarbonate level 18 mEq/L or less, and adjusted for albumin anion gap greater than 10 to 12. Therefore initial laboratory evaluation should include a comprehensive metabolic panel and arterial blood gases. Positive serum and urine ketones can further support the diagnosis of DKA but are not required. In early DKA, acetoacetate concentration is low, but it is a major substrate for ketone measurement by many laboratories; therefore ketone measurement in serum by usual laboratory techniques has a high specificity but low sensitivity for the diagnosis of DKA. Conversely,  $\beta$ -OHB is an early and abundant ketoacid that can first signal development of DKA, but its measurement requires the use of a specific assay that is different from ketone measurement.  $\beta$ -OHB of 3.8 mmol/L or higher was shown to be highly sensitive and specific for DKA diagnosis.

In patients with chronic kidney disease stage 4 or 5, the diagnosis of DKA is challenging because of the presence of chronic metabolic acidosis and the possibility of mixed acid-base disorders on presentation with DKA. An anion gap greater than 20 supports the diagnosis of DKA in such patients.

### Differential Diagnosis

Hyperglycemic hyperosmolar state is usually not associated with ketosis, but mixed hyperglycemic hyperosmolar state and DKA can occur. Clinical scenarios that may be accompanied by acidosis are described in [Table 1](#). Pregnancy, starvation, and alcoholic ketoacidosis are not characterized by hyperglycemia greater than 250 mg/dL. With hypotension or a history of metformin (Glucophage) use, lactic acidosis should be suspected. Ingestion of methanol, isopropyl alcohol, and paraldehyde<sup>2</sup> can also alter the anion gap and/or osmolality but are not associated with hyperglycemia.

### Treatment

The therapeutic goals of management include optimization of volume status, hyperglycemia and ketoacidosis, electrolyte

abnormalities, and potential precipitating factors. DKA management workflow is presented in Figure 1. The efficiency of early DKA therapy can be improved by clustering key diagnostic and therapeutic steps in one protocol that is easy to understand by both nursing staff and physicians. Table 2 provides one example of such a DKA care bundle. Given the complexity of the condition management, provision of a single care bundle/order set allows the fundamentals of DKA treatment to be delivered safely and efficiently while giving the providers guidance on tackling unanticipated issues during DKA care. Special considerations should be given to patients with congestive heart failure and chronic kidney disease (CKD). These patients tend to retain fluids; therefore caution should be exercised during volume resuscitation in these patient groups.

Bicarbonate therapy is not indicated in mild and moderate forms of DKA because metabolic acidosis should correct with insulin therapy. The use of bicarbonate in severe DKA is controversial owing to a lack of prospective randomized studies. It is thought that the administration of bicarbonate actually results in peripheral hypoxemia, worsened hypokalemia, paradoxical central nervous system acidosis, cerebral edema in children and young adults, and an increase in intracellular acidosis. Because severe acidosis is associated with worse clinical outcomes and can lead to an impairment in sensorium and a deterioration of myocardial contractility, bicarbonate therapy may be indicated if the pH is 6.9 or less. Therefore the infusion of 100 mmol (2 ampoules) of bicarbonate in 400 mL of sterile water mixed with 20 mEq potassium chloride over 2 hours and repeating the infusion until the pH is greater than 7.0 can be recommended pending the results of prospective trials.

A whole-body phosphate deficit in DKA can average 1 mmol/kg. Insulin therapy during DKA will further lower serum phosphate concentration. Prospective randomized studies have failed to show any beneficial effect of phosphate replacement on the clinical outcome in DKA. However, a careful phosphate replacement is sometimes indicated in patients with serum phosphate concentration less than 1.0 mg/dL and in those with cardiac dysfunction, anemia, or respiratory depression who have a serum phosphate level between 1.0 and 2.0 mg/dL. An initial replacement strategy may include infusion of potassium phosphate at the rate of 0.1 to 0.2 mmol/kg over 6 hours, depending on the degree of phosphate deficit (1 mL potassium phosphate solution for intravenous use contains 3 mmol phosphorous and 4.4 mEq potassium). Overzealous phosphate replacement can result in hypocalcemia; therefore close monitoring of phosphorous and calcium levels is recommended. Patients who have renal insufficiency or hypocalcemia might need less-aggressive phosphate replacement.

When DKA is resolved, and independent of the patient’s ability to tolerate oral intake, transition to subcutaneous insulin must be initiated. Patients are given intermediate neutral protamine Hagedorn (NPH) or long-acting insulin (detemir [Levemir], glargine [Lantus]) 2 hours before termination of intravenous insulin to allow sufficient time for the injected insulin to start working (Table 3). Once the patient can eat, we recommend the addition of short- or rapid-acting insulin for prandial glycemic coverage (see Table 3). This is the basal-bolus insulin regimen and provides physiologic replacement of insulin. It is common to see transition from intravenous to subcutaneous insulin using sliding-scale insulin only. This strategy as a sole approach should be discouraged because it cannot provide the necessary insulin requirement in patients recovering from hyperglycemic crisis and beta-cell failure.

If the patient used insulin prior to admission, the same dosage can be restarted in the hospital. Insulin-naïve patients require insulin at a total dose of 0.5 to 0.8 U/kg/day divided as 50% basal insulin and 50% as prandial insulin before each meal. Initially, after DKA resolution and given the possibility of fluctuating oral intake, the use of once-daily long-acting insulin such as glargine or detemir to provide basal insulin coverage is encouraged. Long-acting insulin glargine U300 (Toujeo) and insulin degludec (Tresiba), which were approved by the FDA in 2015, as well as biosimilar insulin glargine (Basaglar), which was approved in 2016, have not been studied in hospitalized patients treated for DKA and, therefore, cannot be recommended for subcutaneous administration immediately following DKA resolution. For patients who are not able to adhere to or afford multiple daily insulin injections, conversion of inpatient basal-bolus insulin regimen before discharge to split-mix insulin preparation (Humulin 70/30, Novolin 70/30, Humalog mix 75/25, Novolog mix 70/30) twice a day that contains a mixture of intermediate-acting insulin NPH and short-acting insulin formulations such as regular (Humulin R, Novolin R), aspart (Novolog), or lispro (Humalog) can be considered. Finger-stick glucose measurements before each meal and at night should be taken after discontinuation of intravenous insulin to correct for possible fluctuations in insulin needs while in the hospital.

### Monitoring

Serial measurements—every 2 to 4 hours—of metabolic parameters are required to monitor therapy and then confirm the resolution of DKA. DKA is considered resolved when plasma glucose is less than 200 to 250 mg/dL, serum bicarbonate concentration is 15 mEq/L or higher, venous blood pH is greater than 7.3, and anion gap 12 or less. In general, resolution of hyperglycemia,

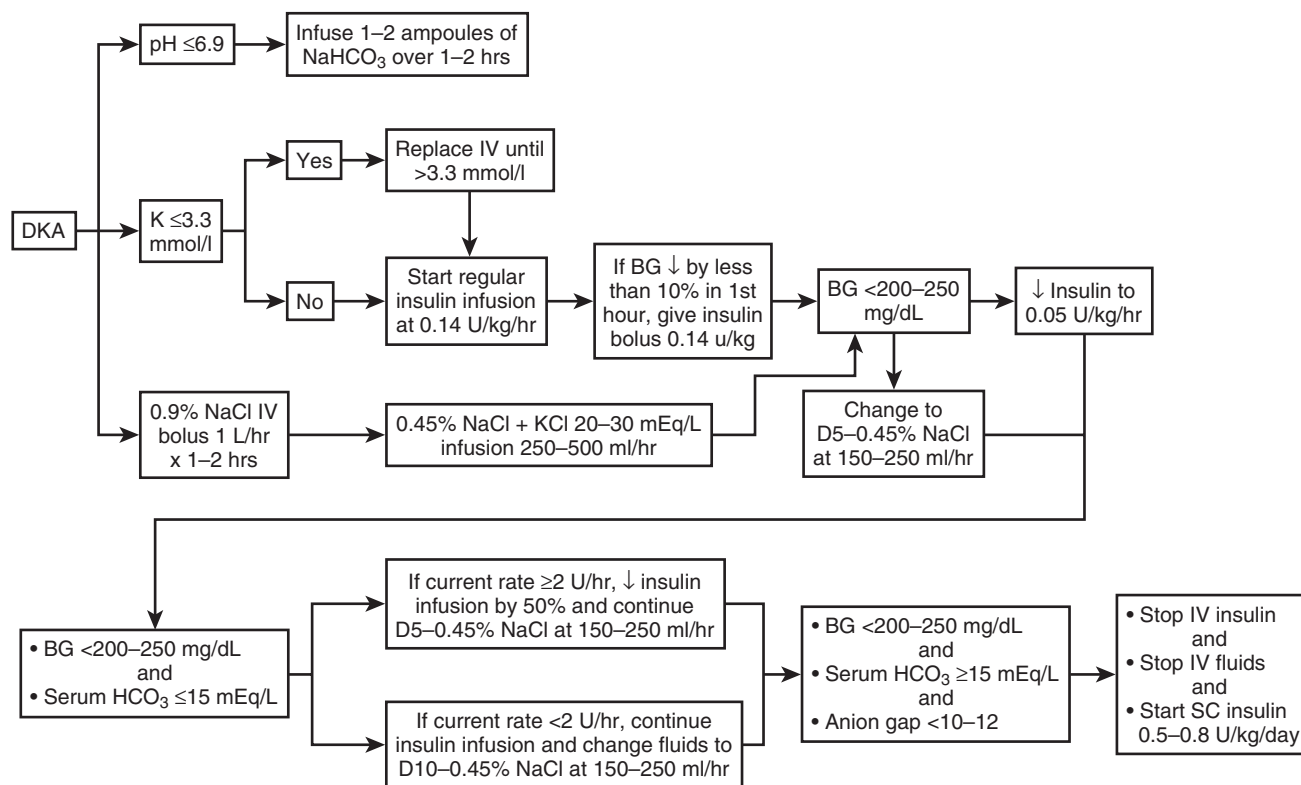

Figure 1 Diabetic ketoacidosis management protocol. BG, Blood glucose.

normalization of bicarbonate level, and closure of the anion gap is sufficient to stop insulin infusion. The anion gap is calculated by subtracting the sum of  $\text{Cl}^-$  and  $\text{HCO}_3^-$  from measured (not corrected)  $\text{Na}^+$  concentration and can improve even before the restoration of serum bicarbonate owing to hyperchloremia from normal saline infusion. Venous pH is adequate for assessing the degree of acidosis, with consideration that it is 0.02 to 0.03 lower than arterial blood. If plasma glucose is less than 200 mg/dL but bicarbonate and pH are not normalized, insulin infusion must be continued, and dextrose-containing intravenous fluids started. The latter approach will continue to suppress ketogenesis and prevent hypoglycemia.

### Complications

Hypoglycemia is the most common complication and can be prevented by the timely adjustment of insulin dosage and frequent monitoring of blood glucose levels. Hypoglycemia is defined as any blood glucose level below 70 mg/dL. If DKA is not resolved and blood glucose level is below 200 to 250 mg/dL, decreases in insulin infusion rate and/or addition of 5% or 10% dextrose to current intravenous fluids may be implemented (see Figure 1). For patients in whom DKA is resolved, strategies to manage hypoglycemia depend on whether the patient is able to eat or not. For patients who are able to drink or eat, ingestion of 15 to 20 g of carbohydrates—for example, four glucose tablets or 6 oz orange or apple juice or “regular” soft drink—is advised. In patients who are allowed nothing by mouth, are unable to swallow, or have an altered level of consciousness, administer 25 mL 50% dextrose IV or give 1 mg glucagon IM if no IV access is present. Blood glucose should be rechecked in 15 minutes; only if the glucose level is less than 80 mg/dL should these steps be repeated.

Non-anion-gap hyperchloremic acidosis occurs from urinary loss of ketoanions, which are needed for bicarbonate regeneration, and preferential reabsorption of chloride in proximal renal tubules secondary to intensive administration of chloride-containing fluids and low plasma bicarbonate. The acidosis usually resolves and should not affect the treatment course. Cerebral edema has been reported in young adult patients. This condition is manifested by the appearance of headache, lethargy, papillary changes, or seizures. Mortality is up to 70%. Mannitol (Osmirol) infusion and mechanical ventilation should be used to treat this condition. Rhabdomyolysis is another possible complication resulting from hyperosmolality and hypoperfusion. Pulmonary edema can develop from excessive fluid replacement in patients with CKD or congestive heart failure.

### Prevention

Discharge planning should include diabetes education, selection of an appropriate insulin regimen that the patient can understand and afford, and preparation of set of supplies for the initial insulin administration at home. Many cases of DKA can be prevented by better access to medical care, proper education, and effective communication with a healthcare provider during an intercurrent illness.

Sick-day management should be reviewed periodically with all patients. It should include specific information on when to contact the healthcare provider, blood glucose goals and the use of supplemental short- or rapid-acting insulin during illness, insulin use during fever and infection, and initiation of an easily digestible liquid diet containing carbohydrates and salt. Most importantly, the patient should be advised to never discontinue insulin and to seek professional advice early in the course of the illness. The patient or family member must be

able to accurately measure and record insulin administered, blood glucose, and blood  $\beta$ -hydroxybutyrate with a point-of-care device when blood glucose is higher than 300 mg/dL. Recent studies demonstrated that  $\beta$ -OHB testing in outpatient setting is more effective than urine acetoacetate testing in preventing DKA, which may reduce the costs of care of patients

with insulin-dependent diabetes. COVID-19-positive patients with diabetes outside of a hospital environment should be particularly vigilant in monitoring home blood glucose and/or  $\beta$ -OHB until the resolution of infection. Most recent studies have convincingly demonstrated that the implementation of intermittently scanned continuous glucose monitoring as part of

Degludec (Tresiba)	1 h	No peak	42 h	Once a day

global care of a type 1 diabetes patient can significantly reduce risk of new or recurrent DKA episodes.

Because of the significant cost of repeated admissions for DKA, resources should be directed toward educating primary care providers and school personnel so that they can identify signs and symptoms of uncontrolled diabetes earlier.

## GENDER AFFIRMING CARE

Method of

Molly McClain, MD, MPH, MS

### CURRENT DIAGNOSIS

- The diagnosis of gender dysphoria can be made by any clinician trained and licensed to manage behavioral health diagnoses. A team approach to care of gender expansive people, particularly youth, is optimal. Linking the expertise of primary care, endocrinology, nursing, and behavioral health is preferred though not always possible.
- Primary care is becoming the most appropriate and accessible venue to receive gender care, similar to endocrinologic diagnoses that are routinely addressed in the primary care setting, such as diabetes or thyroid anomalies.
- The diagnostic terminology has changed over time as the understanding of gender has evolved. Gender identity and expression is most accurately represented as a continuum. Diversity in gender is not a pathology. To reflect this, terms such as “transsexualism” or “gender identity disorder of children” are no longer used.
- The current diagnosis “gender dysphoria” is categorized in the Diagnostic and Statistical Manual of Mental Disorders (DSM-V). When the 11th revision of the International Statistical Classification of Diseases and Related Health Problems (ICD-11) is initiated, the diagnosis will become “gender incongruence,” which will be categorized as a sexual health diagnosis. The significance of this shift is that there will no longer be a diagnostic requirement for significant distress or impairment related to one’s gender.
- That gender diversity should require a diagnosis is up for debate. However, the World Health Organization included gender incongruence in the ICD-11 to ensure trans and nonbinary people’s access to gender affirming care, as well as adequate health insurance coverage for these services.
- There are no current recommendations to screen for gender diversity in childhood or adolescence by primary care physicians or healthcare professionals. This may change given the increasing proportion of youth who identify as gender expansive, the long-term benefits of access to affirming care if desired, and the reticence that youth have in discussing gender identity with their families and providers.
- **Box 1** defines commonly used terminology.

## CURRENT THERAPY

- There is a paucity of data related to general health and long-term effects of hormone therapy or pubertal blockade for gender diverse people. The most commonly utilized guidelines from the World Professional Association of Transgender Health (WPATH), the Endocrine Society and the University of San Francisco (UCSF) Transgender Center of Excellence are based on available empirical evidence and clinician consensus.
- In addition to the above guidelines, general principles support the creation of an affirming environment for patients. Principles such as informed consent recognize that the medical provider is not a gatekeeper to desired therapies but is an advisor to the patient for their own decision making in the setting of limited empirical data.
- Trauma-informed care, or a healing-centered approach, is based on facilitating a safe environment where patient empowerment and dignity is supported, recognizing people's inherent strengths and capacities.
- Patient-centered care recognizes that everyone's gender journey is different, and there is no "full transition" that has a shared meaning. This requires the provider to follow the lead of the patient in terms of their personal gender goals, which may not include medications or surgery.
- As avoiding harm is an important ethical stance of medical professionals and use of accurate names and pronouns has been shown to dramatically reduce suicidal behavior, using correct names and pronouns are part of the care plan.
- Withholding of gender affirming treatments, or access to a physician who can, is not a neutral option given the well-documented evidence of depression, anxiety, substance use, and suicidality in the setting of lack of access to gender affirming medical therapies.

### Epidemiology

The estimates of the number or percentage of those who are gender diverse are based on limited and incomplete data. The most frequently referenced estimate, using population-based probability samples, is 0.4% to 0.6% of any population. In the United States this would equate to 1 to 1.4 million adults. The dearth of data is largely related to the lack of options to select a gender other than male and female on most surveys, census data collection tools, and health system electronic medical records. In addition, the discrimination faced by gender expansive people results in reduced disclosure of gender in settings when the option to select something other than male or female is available.

### Structural Determinants of Health Outcomes

The key determinant of health for gender expansive people is gender affirmation. The depth and breadth of discrimination against gender expansive people in families, education, healthcare, housing, and employment creates severe social and economic exclusion. It is this exclusion, not any biologic determinant, that leads to poorer health outcomes compared with cisgender counterparts. An observational study with nearly 28,000 trans and nonbinary respondents found that nearly 60% reported significant rejection from family because of their gender identity or harassment so severe that almost one-sixth reported leaving school in K-12 or higher education settings. Additionally, 19% were refused medical care because of their gender, and 41% reported attempting suicide (compared with 1.6% of the general population).

On the other hand, data demonstrates that gender affirmation and social/economic inclusion dramatically improves health outcomes. Use of appropriate name and pronouns have been shown

to decrease suicide attempts by 56% in one study. Access to medications that suspend puberty or initiate appropriate puberty has been shown to confer lifetime protection against suicide. Even in the face of extensive institutional discrimination, family acceptance has been shown to have the most significant protective effect against homelessness, incarceration, tobacco smoking, drug and alcohol use, anxiety, depression, and suicidal behaviors.

Experts in the neurobiology of trauma describe a lack of gender affirmation as "not being seen or heard." This involves a significantly broader conceptualization of trauma than the diagnostic criteria for posttraumatic stress disorder. Many physical and behavioral health issues that gender expansive people experience stem from chronically not being seen or heard in regard to their gender. The effects of chronic trauma, or stress, on health have been well-documented. The concept of allostatic load might explain the physiologic link between discrimination and ill-health. Short bursts of stress that cause release of cortisol, adrenaline, and other hormones responsible for the "fight or flight" response is adaptive. However chronic, repeated exposures to stress and the chronic release of cortisol is similar to long-term administration of corticosteroids; no system in the human body is left unaffected. As a result, it is common for gender expansive people and anyone who has been exposed to chronic stress to experience depression, anxiety, self-harm, suicidal ideation and attempt, and substance use in addition to autoimmune issues (including mast cell activation), autonomic nervous system dysregulation (such as postural orthostatic tachycardia syndrome), chronic pain, increased rates of metabolic disorders, and increased risk of cardiovascular concerns. Recognizing the wide-ranging effects of trauma (in addition to recognition of people's resilience) can support creation of care plans that validate people's medical concerns while also attending to the likely root cause of trauma. Behavioral health providers who are skilled in the trauma-informed model, and in the many evidence-based modalities of trauma processing, can be very helpful in the care of all people with an extensive history of discrimination and social exclusion.

### Evaluation

It is important to create a clinical environment that is affirming, including intake forms with gender neutral language and inclusive options for patient gender selection. All clinic staff should be trained on the importance of correct name and pronoun use and for all clinic employees to use their own pronouns during introductions.

At the initial visit, healthcare professionals might elicit the individual's history including the patient's gender as described by the patient, their gender journey, social support, past medical/surgical/behavioral health history, family history, whether the patient is currently engaged in behavioral health counseling, and the goals of care. Goals of care might include primary care, medical therapy for pubertal suppression or hormone therapy, and/or gender confirmation surgeries. There is no single or "correct" way that people engage in their gender journey, and it is the clinician's role to follow each individual's lead and to provide support and assistance in reaching the stated goals. It is important to use the patient's name, gender (as stated by the patient), and pronouns throughout the visit and consistently in documentation. The identification statement might read "25-year-old male (designated female at birth or DFAB, he/him) here to discuss hypertension."

The diagnosis of gender dysphoria is based on Diagnostic and Statistical Manual of Mental Disorders (DSM)-5 criteria and can be made by any clinician who has been trained and licensed to diagnose and manage behavioral health diagnoses.

The diagnosis supports the consistency (lasting 6 months or greater), and insistence and persistence of one's gender being incongruous with that designated at birth. Commonly, the description of someone's gender journey elicits elements that support the diagnosis. These elements include incongruence of one's experienced gender, their primary and/or secondary sex characteristics, desire to have their primary and secondary sex characteristics be more aligned with their experienced gender, and desire to be treated by others as their experienced gender.

**Sex:** An assignment or designation made at birth (e.g., male, female, or intersex) typically on the basis of external genital anatomy. The appearance of external genital anatomy is the most common method of assigning sex at birth. Other attributes that contribute to sex include sex chromosomes, H-Y antigen, gonadal anatomy, sex hormone levels, and internal and external genitalia. Gender is not based on the appearance of external genitalia. Use of the term “assigned or designated male, female, or intersex at birth” is preferred to “female to male,” “male to female,” or “transgender man or woman” as these terms are limited to binary gender identities and are less precise. Use of “transgender man or woman” does not clearly indicate true gender nor the gender the individual was assigned at birth.

**Gender identity:** A person’s concept of self as male, female, a blend of both, or neither. One’s gender identity can be the same or different from sex assigned at birth. Gender identity results from a complex interaction of biologic traits, environmental factors, self-understanding, and cultural expectations.

**Gender expression:** The external presentation of one’s gender, as expressed through one’s name, clothing, behavior, social roles, hairstyle, or voice. This may or may not conform to socially defined behaviors and characteristics typically associated with being masculine or feminine.

**Gender diverse/expansive:** A term that is used to describe people with gender behaviors, appearances, or identities that do not align with the culturally expected norms assigned to their gender designated at birth. It can be considered an umbrella term for people who identify as transgender, genderqueer, gender fluid, gender creative, gender independent, or agender, as examples.

**Transgender:** A subset of gender diverse people whose gender identity does not align with their designated gender or sex at birth and is persistent, consistent, and insistent over time.

**Cisgender:** A term used to describe a person whose gender is congruent with the gender or sex they were assigned at birth.

**Agender:** A term that people may use when their identity does not align with gender at all.

**Nonbinary/gender fluid:** A term one might use to describe themselves if their gender does not align exclusively with male or female or if their gender identity is dynamic over time.

**Gender affirmation or confirmation surgery:** This term is used for both top and bottom surgeries for those interested in surgery as part of their gender journey.

**Sexual orientation:** This term describes an individual’s attraction to other people or lack thereof. Sexual orientation and gender identity develop separately and they are not linked to each other. There are many terms that people of all genders use to describe their sexual orientation including asexual, pansexual, demisexual, bisexual, gay, straight, and aromantic, to name a few.

It is optimal for gender care to occur in the setting of team-based care consisting of primary care, endocrinology, nursing, behavioral health, and case management. However, expert consensus is consistent with the reality that this type of care is not always accessible. The Endocrine Society recommends that clinicians who diagnose and manage therapies for gender dysphoria be trained in use of the DSM and International Statistical Classification of Diseases and Related Health Problems (ICD), have the ability to determine capacity for consent, be knowledgeable in prescribing and monitoring hormone therapies, and stay abreast of the most current recommendations. Similar to other endocrinologic issues seen in primary care, referral to specialists may be warranted in specific cases but can in large part be addressed by primary care healthcare professionals.

Given the extensive discrimination experienced by gender diverse people, it is helpful for clinicians to have a healing-centered approach in all aspects of care. Healing-centered care orients the care process beyond the effects of trauma that people may have faced and brings focus toward their inherent strength and healing capacity. Creating a therapeutic alliance of safety and respect between the patient and healthcare professional is another foundation of healing-centered care. This concept can be helpful when considering physical examinations.

Many gender expansive people have experienced negative interactions with medical professionals, including inappropriate physical examinations that are incongruent with the presenting issue. To help people feel more comfortable, clinicians can consider making clear that the patient has the right to refuse anything that makes them uncomfortable and that the examination will be based only on the current needs for the visit. It is helpful to ask the patient “Is it ok with you if I listen to your heart and lungs?” and only proceed when consent has been given for each examination. There is little indication for genital examination at the initial visit unless the patient has a stated concern that would warrant it.

## Treatment

### Preventive Health

While there are very few studies that have addressed preventive health in gender expansive populations, there are general principles that can help the clinician advise the patient in their choices regarding health maintenance and preventive care. If an organ is present, follow the same guidelines as for cisgender patients and use gender affirming or gender-neutral language as much as possible.

Bone health is an important consideration for people who may be status post gonadectomy and who may have had subphysiologic levels of sex hormones secondary to pubertal suppression or initiation of hormone therapy. The recommendation for all trans and nonbinary people is to start bone density screening at age 65, and for people between 50 and 64 to be considered for bone density screening if other risk factors are present.

There are mixed data on whether people on hormone therapy are at higher risk for cardiovascular disease. Therefore screening for cardiovascular disease is the same as current recommendations for all people. When calculating the atherosclerotic cardiovascular disease (ASCVD) risk score, it may be more accurate to use the patient’s predominant hormonal milieu when selecting gender on the risk calculator.

There are no data that people on hormone therapy have higher rates of any type of cancer. For cancer screenings, if an individual has a particular body part or organ and meets criteria for screening based on risk factors or symptoms, the patient should be advised on risks and benefits of that screening regardless of hormone use. For breast cancer screening, if tissue is present, the patient should be advised to follow the same guidelines used for ciswomen. Cervical cancer screening is recommended for anyone with a cervix and guidelines used for ciswomen are appropriate regardless of hormone use. Cervical anatomy changes with testosterone use lead to a 10-fold higher incidence of nonsatisfactory cytology results; therefore it is advised to always perform HPV cotesting. Self-swab for HPV alone is an alternative option that can be used by people who find cotesting unacceptable.

Sexually transmitted infection screening is the same for all people as supported by the Centers for Disease Control and Prevention and the U.S. Preventive Services Task Force. Discussion of pre- and post-exposure HIV prophylaxis should be considered for all who meet the criteria. Questions around sexual activity should be limited to the patient’s concerns. It is helpful to ask, “What words do you use to describe your genitals?” before discussing anatomy or sexual practices. Attending to sexual health and satisfaction is an important part of whole person care. There is evidence that many people of all genders are reticent to discuss sexual health with clinicians. Inclusion of a question regarding sexual health in one’s review of systems for all patients during all visits may facilitate comfort in discussing sexual health. For example, “Are you currently sexually active and do you have any questions or concerns?”

## Hormone Therapy

Gender goals may include initiation of hormone therapy. The intent of hormone therapy is to express secondary sex characteristics and to feel more internally aligned with one's affirmed gender. Because gender is a spectrum and goals for hormone therapy might include masculinization, feminization, or nonbinary/gender-fluid goals, it is necessary to ask what an individual's gender and goals for therapy include. Although there is mixed evidence about the safety profile of exogenous hormones compared with endogenous hormones, it can be helpful to consider hormone therapy as initiation of an individual's true puberty and then a lifelong continuation of the hormonal milieu of their accurate gender.

Prior to initiation of hormone therapy, DSM criteria for gender dysphoria must be met and decisional capacity must be established. Any untreated psychiatric issues that affect someone's ability to make safe and informed decisions for themselves is a contraindication to initiation of hormone therapy. The provider should verify absence of hormone-sensitive malignancies and whether the patient has past or current medical issues that may increase the likelihood of side effects from the hormones. It is also imperative that the patient is informed that hormone therapy could irreversibly affect fertility yet does not protect against pregnancy or sexually transmitted illness.

Feminizing regimens consist of an antiandrogen (most commonly spironolactone [Aldactone]<sup>1</sup> in the United States or GnRH agonist for suppression of all sex hormones) and bioidentical estradiol (Estrace, generic).<sup>1</sup> Prior to initiation, the medication's effects and possible side effects must be discussed. In addition to the likely effect on fertility, venous thromboembolic events (VTE) can occur while on estradiol, and the patient should have detailed information on signs and symptoms of both deep vein thrombosis and pulmonary embolism. Tobacco use increases this risk, and clinicians can work with their patients on tobacco cessation if indicated. Effects individuals might look forward to are softening of skin, thinning of body hair growth, fat redistribution, decreased muscle mass, decreased sperm production, decreased spontaneous erections, and breast development. Voice timbre is not typically affected by feminizing therapies. The most commonly used formulations are oral tablets (taken daily), patches (switched once or twice weekly), or injectables (once a week). Subcutaneous and intramuscular injections are equally effective. There is no evidence that any formulation has the capacity to cause more feminization than another as they are all the same medication. The effectiveness stems from the consistency of dosing and level of estradiol and testosterone in the serum. Prior to initiation of hormone therapy, baseline labs should be obtained to evaluate for preexisting issues (chemistry panel, hemoglobin A1c, liver function tests, lipid panel, vitamin D, complete blood count (CBC), and differential, and estradiol and testosterone levels). It is advised to start with a lower dose of antiandrogen and estradiol (50 mg spironolactone daily, and 2 mg PO, injectable at 2.5 mg once a week, or 0.05 mg/day once weekly or twice weekly transdermal patch). Per the Endocrine Society, follow-up should occur every 3 months during the first year of hormone therapy, with previsit labs (estradiol and testosterone levels and chemistry panel if on spironolactone). At each visit, doses of both medications can be adjusted based on patient preference and laboratory values. The final goal for estradiol serum level is between 100 to 200 pg per mL, and the goal for serum testosterone, if full suppression is desired, is below 50 ng per dL. Some patients may be interested in progesterone. There have not been high-quality studies performed on the effects of progesterone. Many people who advocate its use feel that it leads to mood stabilization and more rounded, though not larger, breasts. Bioidentical progesterone (Prometrium)<sup>1</sup> at 100 mg daily is a reasonable starting dose. People should be warned

that it can decrease estradiol serum levels, so a 3-month follow-up with sex hormone levels may be helpful.

Masculinizing therapy consists of some formulation of testosterone only. The most commonly used formulations are injectable (subcutaneous is equally effective as intramuscular), topical gel (or compounded topicals), and patches. The possible side effects of testosterone must be discussed prior to initiation and include erythrocytosis and possible VTE secondary to chronic untreated erythrocytosis. Large population analyses have not shown increased risk of cardiovascular outcomes compared with cismales. Concern for metabolic effects should be considered but have not been consistently demonstrated in studies. The effects of masculinizing hormones include acne, increased body hair growth, male-pattern baldness, increased libido, clitoromegaly, vaginal atrophy, and more readily achievable fat loss and muscle gain. As with feminizing hormones, it is advised to start with a lower dose and increase based on laboratory values and patient preference. For optimized masculinization, the goal serum testosterone is between 400 and 1000 ng per dL. Prior to initiation of hormone therapy, baseline labs should be obtained to evaluate for preexisting medical problems (chemistry panel, hemoglobin A1c, liver function tests, lipid panel, vitamin D, CBC and differential, and estradiol and testosterone levels). A reasonable starting dose is 30 mg injectable testosterone cypionate (Depo-Testosterone)<sup>1</sup> once weekly. Follow-up during the first year is every 3 months with previsit testosterone, estradiol, and hematocrit/hemoglobin levels. Dose change at these visits can be guided by patient preference and serum levels. An increase or decrease by 10 mg may be a reasonable increment at each quarterly visit.

Gender expansive goals can be achieved by lower doses of hormone therapy or "microdosing." If someone is interested in nonbinary outcomes, whether subtle feminizing or masculinizing changes are desired, all of the above instructions can be applied. However, the goal serum levels differ. For nonbinary masculinization the serum level of testosterone should be as close to 400 ng/dL as possible. This is easier to achieve with either daily topical testosterone at lower doses or low doses of injectable testosterone administered twice weekly to achieve a decreased range of peak and trough levels. If people on feminizing hormones are interested in nonbinary outcomes and/or maintenance of sexual function, the serum goal for estradiol is still between 100 and 200 pg/mL, and people can choose to use an antiandrogen to achieve the desired effect. Lower doses of spironolactone may lead to decreased feminizing effect, and the patient can balance what is most affirming to them in terms of feminization and maintenance of sexual function. As long as either estradiol or testosterone is within physiologic range, bone health is maintained.

## Gender Affirming/Confirmation Surgery

As with hormone therapy, not all gender expansive people are interested in gender affirming/confirmation surgeries. The term "sex reassignment surgery" is no longer favored. For those who are interested, access to procedures improves mental health outcomes. Most guidelines suggest that people who undergo gender confirmation surgery be 18 years or older and have been on affirming hormones for at least 12 months. If patients have severe dysphoria and do not meet these criteria, clinicians can still consider supporting the medical necessity of a procedure if they feel it is indicated. "Top surgery" includes chest reduction or breast augmentation. Top surgery requires a letter from a behavioral health provider to verify the diagnosis. The patient need not be engaged in therapy long term to acquire letters for surgery. "Bottom surgery" includes hysterectomy with or without oophorectomy, orchiectomy, vaginoplasty, phalloplasty, and metoidioplasty. For any procedure that may affect fertility, two letters from behavioral health providers should be completed. The choice to undergo hysterectomy is based on patient preference. There is no evidence that hysterectomy is indicated in the

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

setting of long-term masculinizing regimens, nor is there evidence of harms specific to people on testosterone. Those who choose to undergo hysterectomy or orchiectomy should be counseled on the need for lifelong exogenous hormones. Other procedures may include facial feminization, tracheal shave, and gluteal lift.

Insurance coverage differs by insurance carrier and state. There are some states in which the medical and surgical coverage for gender dysphoria must be supplied by insurance carriers; it is helpful for healthcare professionals to have some understanding of the legal context of the state and city they practice in for patient pursuit of surgery. It is also helpful to know what (if any) procedures are available locally and the experience that patients have with local surgeons.

## Youth

Affirming care for youth includes provision of developmentally appropriate care focused on recognizing the individual's gender experience, creation of a nonjudgmental partnership with the whole family, and facilitation of discussions regarding risks and benefits of medical treatments if desired. The prevalence of youth who identify as gender diverse may be higher than that of adults. And similar to data for adults, gender expansive youth have dramatically elevated levels of depression, anxiety, disordered eating, self-harm, substance use, suicidal ideation, and attempts compared with cisgender counterparts. Gender affirmation is the key determinant of health for gender expansive youth, as it is for adults. Data has shown that while family rejection does little to change the gender identity of youth, family acceptance has the most powerful impact on decreasing the above health outcomes. The second most impactful intervention is access to medical therapy if desired. The American Academy of Pediatrics encourages families to seek gender-informed therapy and explore legitimate fears, concerns, and confusion regarding how best to support their gender diverse or gender questioning youth. The care of youth is best provided within the context of multidisciplinary care. However, this is not always available.

Providing affirming primary care and gender care during prepubertal stages of childhood is identical to care of all children with regular well-child visits and acute care visits as needed. When youth begin to experience pubertal changes, they may experience worsening dysphoria. If desired, pubertal suppression using GnRH agonist starting at Tanner stage II or III is indicated. Pubertal suppression allows for cessation of pubertal development, which can decrease dysphoria and allow for continued clarification of gender identity. While pubertal suppression is described as reversible, the long-term effects on bone health and fertility are currently unknown and families should be informed of this. The Endocrine Society guidelines and the World Professional Association for Transgender Health (WPATH) delineate adolescent eligibility for GnRH agonist treatment that can be helpful for providers to use during evaluation of patients who desire pubertal suppression. GnRH agonists can be started if the youth has demonstrated consistent gender incongruence, has decisional capacity, and has been informed of effects and side effects and options to preserve fertility. In addition, the patient and guardians must have given consent, a pediatric endocrinologist or other clinician experienced in pubertal assessment must agree with initiation of pubertal suppression, the patient must be in Tanner stage G2/B2, and there must be no medical contraindications. It is encouraged, but not necessary, for the youth to be engaged in behavioral health support. The dosing, monitoring, and laboratory schedules for safe administration of GnRH agonists can be found in the Endocrine Society Guidelines of 2017.

The timing of pubertal induction with hormone therapy while on GnRH analogs should be based on patient and family-centered circumstances. There is no empirical evidence to support a particular age of hormone therapy initiation. The recommendation of initiation at age 16 was based on the age cut-off of certain countries regarding medical decision making and is not consistent with average age of endogenous puberty. This can make the decision of when to initiate hormone therapy more complex.

## Other Considerations

### Voice Training

Gender diverse individuals may want speech therapy to support their gender affirmation. Masculinizing hormones affect voice tenor permanently, but feminizing regimens do little in this regard. Some speech and language pathologists are specialized in voice feminization or masculinization practices, and for those who find this prohibitively expensive (or if this service is not available locally), there are many smartphone applications that can assist people in voice training.

### Fertility Counseling, Gamete Preservation, and Contraception

While pubertal suppression and hormone therapy affect fertility, there is no data regarding the specifics with which to counsel patients and families. In terms of informed consent, it is most appropriate for people to recognize that the likelihood of having biologic children is drastically reduced, if not impossible. Patients should be counseled to seek gamete preservation if desired. If biologic children are desired, it is safest to postpone initiation of all medications until gamete preservation has been completed. At the same time, none of the medications protect against pregnancy or sexually transmitted infections. Condom use is safe and effective for everyone, and for people on masculinizing hormones more acceptable forms of contraception include progesterone-only birth control pills, Nexplanon, and Mirena IUD.

### Hair Removal

Hair removal from face and body may be pursued for aesthetic purposes or in preparation for surgery. It is best to suggest a hair removal specialist who provides affirming care and can offer electrolysis and laser hair removal for a tailored approach. The patient should first query their insurance carrier for possible coverage of hair removal. It is more common that insurance will cover hair removal in the setting of preoperative preparation for vaginoplasty as this is a requirement for that procedure.

### Legal Considerations

Legal considerations include legal name change, change of gender and/or name on legal documents, providing letters of medical necessity for procedures, and addressing possible insurance denials of medical and/or surgical coverage. The process for legal name change, change of name and gender on birth certificates, and other state-based documents such as driver's licenses differs by state. Many states require that a medical provider write a letter demonstrating that someone meet criteria for gender dysphoria to change any legal documents, but some do not require this form of gatekeeping. Typically, if the state does require provider documentation or signatures, the format for any letter should be readily accessible and easy to create. To change federal documents, such as passports, there is a form letter that is easy to find online (<https://transequality.org/know-your-rights/passports>) that should be adjusted per patient and clinician as indicated, printed on letterhead, and signed in blue ink.

## GOUT AND HYPERURICEMIA

Method of  
Saima Chohan, MD

### CURRENT DIAGNOSIS

- Gout is the most common inflammatory arthritis in men and is increasing in prevalence.
- A definitive diagnosis of gout requires the demonstration of monosodium urate crystals in synovial fluid or tophi.
- Gouty arthritis often begins in the joints of the lower extremity.
- Septic arthritis, rheumatoid arthritis, and calcium pyrophosphate disease (pseudogout) can mimic gout and should be ruled out.

### CURRENT THERAPY

- The goals of successful gout treatment include terminating the acute attack, preventing intermittent attacks, and undertaking long-term therapy to avoid chronic arthritis.
- Indications for the chronic treatment of gout include frequent attacks, recurrent arthritis, and kidney disease.
- A serum urate level of less than 6.0 mg/dL is the goal when urate-lowering therapy is being used.
- Nonpharmacologic treatment includes lifestyle modification and dietary changes.
- The mainstay of urate-lowering therapies remains xanthine oxidase inhibition.

### Epidemiology

Gout, or monosodium urate crystal deposition disease, is the most common inflammatory arthritis of men and is an increasingly common problem among postmenopausal women. It is a chronic disorder, affecting more than 5 million people in the United States and increasing in both prevalence and incidence, especially in persons older than 65 years. Gout is often accompanied by serious comorbid disorders (hypertension, cardiovascular disease, chronic kidney disease, and all of the component features of the metabolic syndrome) and is managed in primary care practice in about 90% of affected persons. Therefore identifying risk factors, optimizing diagnosis, and choosing the appropriate treatment for gout are important skills for a wide array of caregivers.

### Pathophysiology and Risk Factors

Uric acid is the end product of purine metabolism in humans. Hyperuricemia, a serum urate concentration exceeding urate solubility (6.8 mg/dL), is an invariable accompaniment of gout, although serum uric acid levels might not be elevated during an acute attack. Hyperuricemia predisposes affected persons to urate crystal formation and deposition, leading to the inflammatory responses underlying the symptoms of gout. Thus treatment of gout is aimed at reducing and maintaining serum urate concentration at subsaturating levels, usually set at less than 6.0 mg/dL.

### Hyperuricemia

Risk factors for hyperuricemia include obesity, hypertension, hyperlipidemia, insulin resistance, renal insufficiency, and the use of diuretics. Diets rich in certain foods are also associated with increased risk for gout. Many studies with large patient cohorts have demonstrated a relationship between hyperuricemia and hypertension, cardiovascular and peripheral vascular disease, chronic kidney disease, and diabetes mellitus. The association of hyperuricemia and metabolic syndrome has also been shown in

children and adolescents. Interventional trials of asymptomatic patients with hyperuricemia and high cardiovascular risk must be performed before such treatment can be advocated.

### Diagnosis

Acute gout is characterized by an abrupt onset of joint pain, erythema, and swelling, usually of one joint but less commonly of more than one. The arthritis most often occurs first in the joint of a lower extremity, especially the first metatarsophalangeal (MTP) joint at the base of the great toe. The predilection for this site is thought to be secondary to cooler acral temperature or repeated trauma and pressure on this joint.

The gold standard for the diagnosis of gout is the demonstration of monosodium urate crystals by polarized light microscopy either in joint fluid aspirated during an acute attack or between attacks or from material aspirated from suspected tophi. To aspirate the first MTP joint, the joint is first identified by palpating the space at the base of the metacarpal on the dorsal aspect while flexing and extending the toe. The needle is then inserted perpendicularly into the joint space to avoid the extensor hallucis tendon. Synovial fluid from affected joints should immediately be examined under polarized microscopy to confirm the diagnosis of needle-shaped crystals with negative birefringence. If polarized microscopy is unavailable, then fluid should be promptly sent in a sterile tube to an appropriate laboratory for crystal confirmation.

Unfortunately the equipment and analytical expertise necessary to make this diagnosis are not widely available to primary care physicians. As a result, the diagnosis of acute gout is commonly made on clinical grounds, using the 2015 classification criteria of the American College of Rheumatology and the European League Against Rheumatism. These diagnostic guidelines use a point system and emphasize the presence of signs of inflammation (redness, tenderness, and loss of joint function), abrupt onset, monoarticular involvement, occurrence in the first MTP joint, presence of tophi, and radiographic findings.

The initial symptoms and signs of gout often arise after many years of asymptomatic hyperuricemia. In untreated or inadequately treated patients, the course of the disease often involves acute attacks at increasing frequency, with shortening of asymptomatic periods (called intercritical gout) and, ultimately, the development of chronic joint disease (gouty arthropathy) and tophi (masses of urate crystals in a chronic inflammatory matrix) in bone, joints, skin, and even solid organs (Figure 1).

### Indications for Treatment

Early in gout, patients might have attacks that are separated by years and are manageable over the course of a few days with anti-inflammatory medications and adjuncts such as joint rest and the application of ice. Over time, the attacks usually become more frequent, prolonged, and disabling, eventually requiring long-term urate-lowering treatment aimed at preventing the deposition of urate crystals and eventually abolishing acute flares and resolving tophi. Indications for urate-lowering (antihyperuricemic) therapy are listed in Box 1.

### Treatment

#### Acute Gout

Gouty arthritis occurs suddenly, and attacks are often very painful and disabling. Patients describe an acute onset of exquisite pain, swelling, erythema, and inability to bear weight on the afflicted joint. Occasionally patients have constitutional symptoms including fever and chills, with an elevated sedimentation rate and white blood cell count. To terminate an attack, nonsteroidal anti-inflammatory drugs (NSAIDs), colchicine (Colcrys), or corticosteroids can be offered. If given at full anti-inflammatory dosage, NSAIDs have a rapid onset and are quite efficacious in relieving pain and shortening the duration of an attack. The utility of this class of drugs may be limited by renal insufficiency, cardiovascular risk factors, and gastrointestinal bleeding. Although indomethacin (Indocin), sulindac (Clinoril), and naproxen (Naprosyn) are all approved by the US Food and Drug Administration (FDA) for

**Figure 1** Intradermal urate deposit (tophus). (Reprinted with permission from Mandell BF: Gout and crystal deposition disease. In Weisman MH, Weinblatt ME, Louie JS, Van Vollenhoven R, editors: *Targeted Treatment of the Rheumatic Diseases*, Philadelphia, 2010, Saunders, pp 293–302.)

treating acute attacks of gout, nearly every drug in this class and the selective cyclooxygenase (COX) 2 inhibitors also have considerable efficacy. High-dose salicylate therapy lowers serum uric acid by interfering in renal urate transport; low-dose aspirin<sup>1</sup> has the opposite effect, but it is often continued in gout patients because of its overriding importance in managing coronary artery disease.

Oral colchicine has been used to treat gout for many years as an unproven drug with no FDA dosage recommendations or prescribing information. In July 2009, however, the FDA approved Colcrys, a single-ingredient colchicine product, for the first day of treatment of acute gout attacks at a low-dose regimen of 1.2 mg followed by 0.6 mg in 1 hour (total 1.8 mg). With this regimen, colchicine can be used to abort an attack if it is taken immediately after the development of the first symptom of gout flare. Higher colchicine doses (0.6 mg every hour until symptoms improve or until gastrointestinal symptoms of diarrhea, nausea, or vomiting develop for a total of 4.8 mg over 6 hours)<sup>3</sup> have traditionally been recommended. A randomized placebo-controlled trial comparing the low- and high-dose regimens showed both approaches to have equivalent efficacy in pain relief at 24 hours (compared with placebo). However, adverse gastrointestinal events were significantly less common with the low-dose regimen. In subjects warranting additional flare treatment, continued use of colchicine 0.6 mg twice daily (reducing to once daily as the flare subsides) is appropriate in persons with normal renal and hepatic function. Oral colchicine is now available in generic form and in two branded versions (Colcrys, Mitigare).

Gastrointestinal symptoms are generally the first clinical signs of colchicine toxicity in patients with normal renal and hepatic function. More serious toxicities do occur and include neuromyopathy, aplastic anemia, and worsening renal and hepatic function. Patients with

#### BOX 1 Indications for Urate-Lowering Therapy

- Frequent and disabling gouty attacks are often defined as two or three flares annually, although this is not evidence based; the decision to treat is based on both number of flares and the disability resulting from flares.
- Chronic gouty disease: clinically or radiographically evident joint erosions.
- Tophaceous deposits: subcutaneous or intraosseous.
- Gout with renal insufficiency.
- Recurrent kidney stones.
- Urate nephropathy.
- Urinary uric acid excretion exceeding 1100 mg/day (6.5 mmol), when determined in men younger than 25 years or in premenopausal women.

renal or hepatic impairment should be treated with caution; because of potentially serious drug-drug interactions, colchicine should be avoided in patients receiving cyclosporine (Neoral), clarithromycin (Biaxin), verapamil (Calan), or amlodipine (Norvasc). Intravenous colchicine is not available in Europe. The FDA has stopped the marketing of unapproved injectable colchicine products in the United States and discourages the compounding of intravenous colchicine because of reports of preparation errors causing deaths.

Corticosteroids provide a safe alternative for patients with contraindications to NSAIDs or colchicine. For isolated monoarticular attacks, especially of medium or large joints, aspiration of joint fluid and intra-articular injection with triamcinolone acetonide (Kenalog) 20 to 40 mg can quickly terminate an attack. For polyarticular attacks or attacks in smaller joints, systemic corticosteroids (oral or intramuscular) may be used. Oral prednisone starting at 20 mg twice daily with a taper over 10 to 14 days is very effective. Patients can have rebound attacks if oral steroids are terminated too quickly; thus methylprednisolone (Medrol) dose packs should be avoided. If intramuscular injection is required, a single dose of triamcinolone 40 mg may be used.

There is interest in agents blocking the action of interleukin 1 (IL-1), a cytokine thought to play a major role in initiating and sustaining acute gouty inflammation. Anakinra (Kineret)<sup>1</sup> and canakinumab (Ilaris)<sup>1</sup> are potent injectable IL-1 inhibitors; studies are ongoing to assess the utility of these agents to mitigate acute attacks. In 2013 canakinumab became the first biologic agent approved for acute gout in Europe. It was approved by the European Medicines Agency for symptomatic treatment of adult patients with frequent gouty arthritis attacks in whom NSAIDs and colchicine are contraindicated, are not tolerated, or do not provide an adequate response and in whom repeated courses of corticosteroids are not appropriate. Riloncept (Arcalyst),<sup>1</sup> which is also in this class, was declined approval for gout by the FDA in 2012 because of concerns about its long-term safety.

#### Intercritical Gout

After an attack subsides, management is directed at preventing recurrent attacks. During acute attacks of gout, normal serum urate concentration is reported in up to 40% of affected patients, and thus it is not an accurate reflection of the true urate pool. Confirmation of hyperuricemia is best achieved either before the resolution of an attack or 2 to 4 weeks after it to achieve an accurate serum urate concentration. There is a generalizable correlation between the serum urate level and the risk for a recurrent attack.

Prophylaxis of future attacks during early urate-lowering therapy can consist of colchicine at doses of 0.6 mg once or twice a day (based on renal function) or NSAIDs. If chronic NSAIDs are used, acid-reducing medications such as proton pump inhibitors or histamine-2 blockers may be used for patients at risk for gastrointestinal bleeding.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>1</sup>Not FDA approved for this indication.

### Long-Term Urate-Lowering (Antihyperuricemic) Therapy

The aim of urate-lowering therapy is to reduce and maintain serum urate at concentrations below those at which extracellular fluids are saturated with monosodium urate. In general an ultimate serum urate concentration of less than 6.0 mg/dL is advised. Urate lowering can be achieved either by increasing urinary excretion or decreasing production of urate.

Nonpharmacologic urate-lowering treatment begins with lifestyle changes. Diet and weight loss must be addressed. Obesity and weight gain are risk factors for gout, and weight loss has been shown to decrease the risk of gout. A purine-restricted diet has often been recommended to patients but is often unpalatable and impractical. Reduction in alcohol intake, namely beer and liquor, can effectively reduce urate levels. Similarly, a reduced intake of red meat and shellfish also lowers the risk of recurrent gouty attacks. Studies have shown an increased frequency of attacks in patients who consume fruit juices and soft drinks containing high-fructose corn syrup, an ingredient not found in diet drinks.

Once the decision is made to institute serum urate-lowering therapy, the duration of treatment is indefinite and must be long-term to be effective. The majority of patients with gout and tophaceous disease will continue to have attacks if therapy is discontinued; thus education is a key part of the treatment plan. Patients should be instructed that, with initiation of any urate-lowering therapy, they will be at increased risk for a flareup and thus must continue regular use of prophylactic agents as outlined earlier. At least 80% to 95% of cases of hyperuricemia and gout are attributable to impaired urate excretion, which is reflected in diminished urate clearance or fractional excretion of uric acid but not usually in low daily urine uric acid excretion. In practice, 24-hour urine collections are rarely performed. Patients are preferentially treated with xanthine oxidase inhibitors because of the easier dosing schedule and many patients have contraindications to uricosurics such as renal insufficiency and kidney stones.

### Uricosurics

Relative to medications aimed at urate synthesis, uricosurics are relegated to second-line treatment of patients with elevated urate burden or tophaceous disease. The most commonly used uricosuric agent in the United States is probenecid. This is a very effective drug that concentrates and promotes urinary excretion of urate. Its utility is limited in patients with renal insufficiency, and probenecid is not recommended as first-line therapy in patients with nephrolithiasis or uric acid overexcretion. The maintenance dose of probenecid required to achieve and maintain serum urate concentration at less than 6.0 mg/dL is 0.5 to 3 g/day<sup>3</sup> administered in 2 or 3 daily doses. Once goal serum urate concentration has been achieved with a uricosuric agent, the risk of uric acid calculi is diminished because urinary uric acid excretion becomes normal.

Lesinurad (Zurampic) is another uricosuric agent; it is an inhibitor of renal transport proteins and was approved by the FDA in 2016. It is used at a dose of 200 mg/day in combination with a xanthine oxidase inhibitor, including allopurinol (Zyloprim) or febuxostat (Uloric). In 2017, the FDA approved a combination product of lesinurad 200 mg and allopurinol 300 mg (Duzallo), one tablet in the morning for hyperuricemia. This product is also available as a tablet containing lesinurad 200 mg and allopurinol 200 mg for patients with renal impairment. The drug has a boxed warning regarding the risk of acute renal failure.

Other drugs found to have uricosuric effects include fenofibrate (Tricor),<sup>1</sup> a fibric acid derivative used to treat hyperlipidemia, and the antihypertensives losartan (Cozaar)<sup>1</sup> and amlodipine (Norvasc).<sup>1</sup> These agents have mild uricosuric properties and may be useful adjuncts to urate-lowering therapy. The ingestion of skim milk has been shown to lower serum urate levels through uricosuric effects. Lower urate levels have also been seen in patients who consume coffee, but the mechanism of action is unknown.

### Xanthine Oxidase Inhibitors

Allopurinol (Zyloprim) and febuxostat (Uloric) are the only FDA-approved xanthine oxidase inhibitors for the treatment of gout. Allopurinol, introduced in 1966, is approved in doses of 100 to 800 mg/day. More than 90% of patients with gout treated with urate-lowering medication in the United States are given allopurinol, but dosages of more than 300 mg/day are rarely employed and often patients do not achieve serum urate concentrations of 6.0 mg/dL or less. Appropriate use of allopurinol is limited for several reasons. There are genuine concerns about allopurinol drug interactions, gastrointestinal intolerance, rashes (ranging from mild to life threatening), and the rare but sometimes fatal hypersensitivity syndrome. Allopurinol should be avoided with the immunosuppressives azathioprine (Imuran) and 6-mercaptopurine (Purinethol) because it can increase the risk of bone marrow toxicity. That can occur because these medications are partially metabolized by xanthine oxidase. Allopurinol should not be taken with ampicillin owing to an increased risk of rash.

Effective dosing of allopurinol is often not achieved because of compliance with published but disputed recommendations for allopurinol dose reduction in states of renal impairment. Allopurinol should be initiated at 100 mg/day in patients with creatinine clearance of 40 mL/min or greater, and it should be titrated in 100-mg increments every 2 to 4 weeks, with the endpoint of dosing determined by achievement of serum urate concentration of 6.0 mg/dL or less.

The FDA approved febuxostat (Uloric) in 2009. Unlike allopurinol, this is a nonpurine analog and selective xanthine oxidase inhibitor that is not incorporated into purine nucleotides and does not appear to affect pyrimidine metabolism. Febuxostat is primarily metabolized by oxidation and glucuronidation in the liver, with little renal excretion; this contrasts with the renal elimination of oxypurinol, the main allopurinol metabolite. The recommended starting dose of febuxostat is 40 mg/day, with an increase to 80 mg/day if serum urate concentrations do not reach goal urate levels in 2 weeks in patients with normal renal function. In Europe, higher dosages (80–120 mg/day)<sup>3</sup> have received approval, and studies have affirmed the efficacy and safety of dosing in this range. In the FOCUS trial, a 5-year study of efficacy and safety, febuxostat was shown to have durable maintenance of serum urate concentration at 6.0 mg/dL or less, nearly complete elimination of gouty flares, and resolution of baseline tophi in subjects. In 2019, a boxed warning was added by the FDA as studies showed that febuxostat was associated with an increased risk of cardiovascular and all-cause mortality compared with allopurinol. Although an advantage of febuxostat over allopurinol is that it can safely be taken by patients with creatinine clearance greater than 30 mL/min, we recommend allopurinol in patients with elevated cardiovascular risk.

### Pegloticase

Pegloticase (pegylated porcine recombinant uricase [Krystelxa]) was granted FDA approval in 2010 for the treatment of refractory gout. Humans lack the enzyme uricase, which converts uric acid to allantoin, a more soluble purine degradation product. Replacement of this missing enzyme allows direct conversion of urate to allantoin with eventual depletion of increased body urate pools and control of disease, including resolution of tophi. Recombinant uricase therapy profoundly lowers serum urate concentration, as was demonstrated in two large trials. Pegloticase is approved at a dosage of 8 mg IV every 2 weeks.

### Potential New Therapies

A number of other novel agents with new therapeutic targets for the treatment of acute and chronic gout are under investigation.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

## HYPERALDOSTERONISM

Method of

Ruchi Gaba, MD; and Lawrence Chan, MD

## CURRENT DIAGNOSIS

- Hyperaldosteronism may be suspected in patients with severe, resistant, or early-onset hypertension and hypertensive patients with family history, hypokalemia, adrenal mass, and obstructive sleep apnea. Evaluation begins with measurement of morning plasma aldosterone concentration (PAC in ng/dL) and plasma renin activity (PRA in ng/mL/h) in a sodium- and potassium-repleted state and off of significantly interfering medications (spironolactone [Aldactone], eplerenone [Inspra], amiloride [Midamor], triamterene [Dyrenium], potassium-wasting diuretics, and licorice-derived products<sup>7</sup>) for at least 4 weeks.
- Elevated PRA and PAC suggest secondary hyperaldosteronism; suppressed PRA and PAC suggest conditions mimicking hyperaldosteronism; suppressed PRA but elevated PAC suggests primary hyperaldosteronism (screening positive if PAC/PRA ratio >20 to 40 and PAC >5 to 10 ng/dL).
- Positive screening of primary hyperaldosteronism should be confirmed with one of the following tests: IV saline suppression, oral salt loading, fludrocortisone (Florinef)<sup>1</sup> suppression, or captopril (Capoten)<sup>1</sup> challenge test (may skip if spontaneous hypokalemia, renin below the detection limit, and PAC >20 ng/dL).
- Once primary hyperaldosteronism is biochemically confirmed, computed tomography (CT) of the adrenal glands is recommended to exclude adrenocortical carcinoma and help subtype primary hyperaldosteronism.
- If surgical treatment is considered, adrenal vein sampling is indicated to differentiate unilateral versus bilateral lesions (may skip if the patient is <35 years with spontaneous hypokalemia, PAC >30 ng/dL, and unilateral adenoma). A cortisol-corrected aldosterone ratio from the high to the low side greater than 4:1 with cosyntropin (Cortrosyn) stimulation confirms unilateral aldosterone excess.

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as a dietary supplement.

## CURRENT THERAPY

- Laparoscopic adrenalectomy is recommended for unilateral disease. Otherwise, medical treatment with a mineralocorticoid receptor antagonist (MRA; spironolactone [Aldactone] as the primary agent and eplerenone [Inspra] as an alternative) is recommended.
- Spironolactone: 12.5 to 25 mg/day titrated to a maximum dose of 400 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased serum creatinine, hyperkalemia, gynecomastia, and menstrual irregularities.
- Eplerenone: 25 mg once or twice daily titrated to a maximum dose of 100 mg/day to achieve normal blood pressure and normokalemia. Side effects include increased creatinine, hyperkalemia, hypertriglyceridemia, increased liver enzymes, headache, and fatigue.
- Amiloride (Midamor)<sup>1</sup> or triamterene (Dyrenium)<sup>1</sup> (epithelial sodium channel antagonists) can be used in those who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Other antihypertensive agents are also added if necessary to control hypertension.

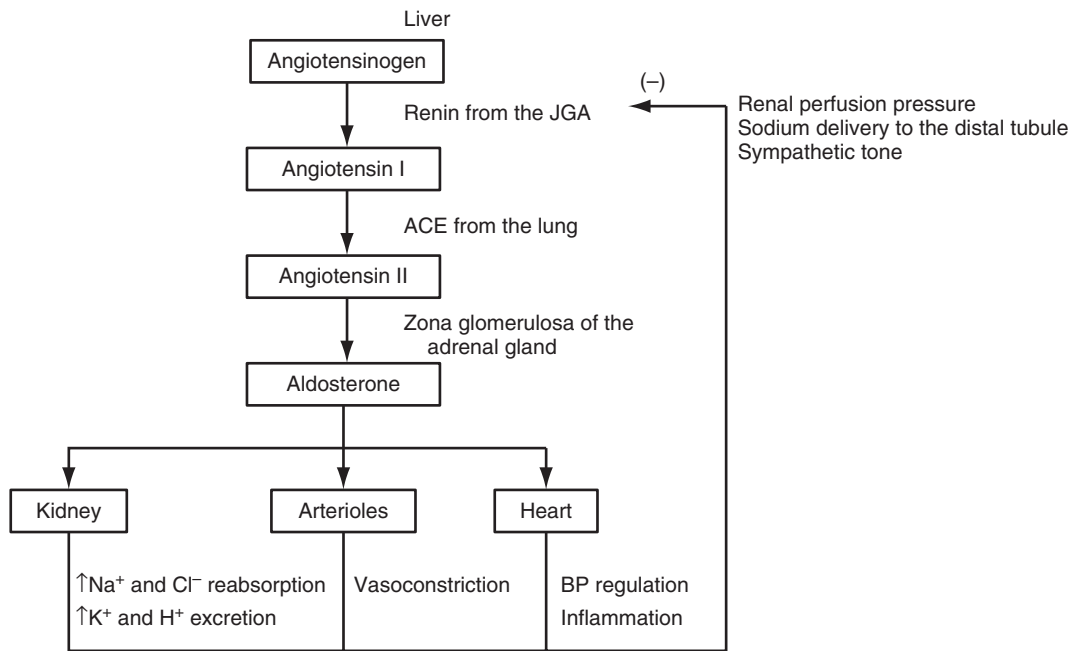

<sup>1</sup>Not FDA approved for this indication.

## Introduction

Hyperaldosteronism is a state of excessive aldosterone secretion. Primary hyperaldosteronism occurs due to autonomous hypersecretion of aldosterone relative to suppressed plasma renin, whereas secondary hyperaldosteronism occurs due to activation of the renin-angiotensin-aldosterone system (RAAS). Primary hyperaldosteronism is the most common cause of secondary hypertension, and recent reports suggest that 5% to 20% of hypertensive patients have primary hyperaldosteronism (as opposed to less than 1%, as previously reported). Secondary hyperaldosteronism includes two different categories; one is compensatory activation of the RAAS due to decreased effective circulating volume, as in congestive heart failure and liver cirrhosis; the other is overactivity of the RAAS accompanied by hypertension, as in renovascular hypertension. There are also several conditions that mimic aldosterone excess through various mechanisms that present with hypertension and other metabolic perturbations. Except for the compensatory activation of the RAAS, these conditions cause secondary hypertension with or without other metabolic consequences, such as hypokalemia and metabolic alkalosis, which bring them to medical attention. This chapter covers the current approaches to hyperaldosteronism for patients suspected of having hypertension secondary to excess aldosterone production.

## Pathophysiology

Aldosterone is a steroid hormone produced by the zona glomerulosa in the adrenal gland and contributes to volume and potassium homeostasis via its action primarily on the principal cells in the collecting tubule of the kidney. The main stimuli of aldosterone secretion are angiotensin II and hyperkalemia, which increase synthesis and activity of aldosterone synthase mediated by calcium signaling. Angiotensin II releases calcium from the endoplasmic reticulum, whereas both angiotensin II and hyperkalemia depolarize membrane potential and open voltage gated calcium channels. Therefore changes in genes regulating ionic homeostasis and membrane potential can affect aldosterone secretion. Aldosterone and angiotensin II are part of the RAAS; plasma renin from the juxtaglomerular apparatus converts angiotensinogen to angiotensin I, and angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II. Subsequently, angiotensin II stimulates secretion of aldosterone. Renin secretion is controlled by renal artery pressure, sodium delivery to the distal nephron, and sympathetic activation (via  $\beta_1$ ). Increased effective arterial circulating

**Figure 1** The renin-angiotensin-aldosterone system (RAAS). ACE, Angiotensin-converting enzyme; BP, blood pressure; JGA, juxtaglomerular apparatus.

volume from the action of aldosterone decreases renin secretion by negative feedback (Figure 1). Other minor factors involved in aldosterone secretion are adrenocorticotropic hormone and hyponatremia (which increase aldosterone secretion) and atrial natriuretic peptide (which decreases aldosterone secretion).

Aldosterone binds to the nuclear mineralocorticoid receptors. Activation of the mineralocorticoid receptors upregulates the basolateral  $\text{Na}^+/\text{K}^+$  pumps and the epithelial sodium channels (ENaC), leading to increased reabsorption of  $\text{Na}^+$  and  $\text{Cl}^-$  and secretion of  $\text{K}^+$  and  $\text{H}^+$ . The mineralocorticoid receptors can also be activated by other hormones with mineralocorticoid activity. Cortisol is able to bind to the mineralocorticoid receptors with similar affinity as aldosterone but normally is converted to inactive cortisone by  $11\beta$  hydroxysteroid dehydrogenase 2 ( $11\beta$  HSD2). Mutations/inhibition of  $11\beta$  HSD2 or very high cortisol levels above the capacity of  $11\beta$  HSD2, as in Cushing syndrome (particularly ectopic Cushing syndrome), and glucocorticoid resistance can cause activation of the mineralocorticoid receptors. Aldosterone precursors such as deoxycorticosterone have a weak mineralocorticoid effect but can cause features of hyperaldosteronism when they are present at very high levels as in some forms of congenital adrenal hyperplasias ( $11\beta$  hydroxylase deficiency or  $17\alpha$  hydroxylase deficiency) or deoxycorticosteroid-secreting tumors. In addition, activating mutations of the ENaCs also cause increased sodium absorption and hypertension mimicking hyperaldosteronism (Liddle syndrome).

### Clinical Manifestations

Primary hyperaldosteronism usually presents with normokalemic hypertension. Hypokalemia is present only in 9% to 37% of cases and may indicate more severe cases. Patients with primary hyperaldosteronism usually do not develop severe volume overload or edema because of aldosterone escape possibly related to atrial natriuretic peptide, pressure natriuresis, or decreased sodium absorption at other nephron segments. Metabolic alkalosis, mild hypernatremia (due to reset osmostat from volume expansion), and hypomagnesemia may be observed. Glomerular filtration rate and urinary albumin excretion can be elevated independent of systemic hypertension. Target organ (heart and kidney) damage and cardiovascular-related morbidity and mortality are higher in primary hyperaldosteronism than in essential hypertension with similar degrees of blood pressure (BP) elevation. Secondary hyperaldosteronism

(when it is not from hypovolemia) and other conditions mimicking hyperaldosteronism can present with similar features as primary hyperaldosteronism plus specific manifestations for each disease entity. Depending on the mechanism of disease, more severe volume overload and pulmonary edema may be found (e.g., renovascular hypertension) because aldosterone escape may not work.

### Evaluation

#### Screening

Hyperaldosteronism may be suspected based on severe (BP >150/100 on three separate occasions) or resistant hypertension (uncontrolled BP despite use of three conventional antihypertensive agents including a diuretic, or well-controlled BP in the presence of four or more antihypertensive agents), early-onset hypertension without known risk factors, and hypertension with other features such as family history of hyperaldosteronism, early-onset hypertension, cerebrovascular accident at a young age, hypokalemia, adrenal mass, and obstructive sleep apnea. Currently there is no evidence-guided screening strategy. Some experts believe that routine screening for primary hyperaldosteronism is warranted in newly diagnosed hypertension considering its high prevalence, whereas others recommend that targeted screening is more appropriate, such as the Endocrine Society guidelines for primary hyperaldosteronism in 2016 (Box 1).

When a decision is made to screen for excessive mineralocorticoid effect, one should first examine the plasma renin and aldosterone levels; that is, plasma renin activity (PRA, ng/mL/h) and plasma aldosterone concentration (PAC, ng/dL). It is important to note that several factors can affect PRA and PAC, such as age, medications, time of day, diet (salt intake), posture, method of blood collection, level of potassium, and level of creatinine (Table 1). Diuretics (both potassium sparing and wasting) and mineralocorticoid antagonists can have a significant effect on PRA and PAC. Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers (ACEI/ARB) and dihydropyridine calcium channel blockers can affect PRA and PAC modestly. Ideally, all medications and other factors that may affect PRA and PAC should be removed; unfortunately, it is not always practical and safe to do this because of the possibility of uncontrolled hypertension. If necessary, antihypertensive agents that affect PRA and PAC only minimally such as slow-release verapamil (Calan SR), hydralazine

(Apresoline), prazosin (Minipress), doxazosin (Cardura), or terazosin (Hytrin) can be used. The Endocrine Society 2016 guidelines recommend certain caveats that optimize the chance for obtaining more easily interpretable PRA and PAC results (Box 2).

Patterns of PRA and PAC help differentiate among primary hyperaldosteronism, secondary hyperaldosteronism, and conditions mimicking hyperaldosteronism. Differential diagnoses

according to different patterns of PRA and PAC are listed in Box 3. If both PRA and PAC are high, further investigation for causes of secondary hyperaldosteronism should follow. If both PRA and PAC are suppressed, further investigation for conditions that mimic hyperaldosteronism is indicated. Suppressed PRA and elevated PAC suggest primary hyperaldosteronism, and aldosterone renin ratio (ARR) should be calculated; ARR above 20 to 40 is considered screening positive for primary hyperaldosteronism. PAC greater than 15 ng/dL was recommended by some investigators to avoid false-positive ARR from very low renin level, but in many cases PAC can be less than 15 ng/dL, though this occurs more commonly in bilateral adrenal hyperplasia (BAH) than in aldosterone-producing adenoma. PAC should at least be above the level considered positive for confirmatory tests (5 to 10 ng/dL). Confirmatory tests should follow to avoid false positives. Diagnostic flow and subsequent management of hyperaldosteronism are summarized in Figure 2. Of note, there is no consensus on cutoff values for PRA, PAC, or ARR. In addition, PRA and PAC are often obtained in a less-than-optimal condition. Therefore it is important to understand how PRA and PAC can be affected by various factors. For example, if ARR is positive while on medications that decrease PAC or increase PRA (thus decreasing ARR), ARR off this medication will be clearly positive. Screening tests should be repeated if results are inconclusive or if PA is strongly suspected but the initial screening tests are negative.

**BOX 1** Groups Indicated for Case Detection With Relatively High Prevalence of Primary Hyperaldosteronism

- Sustained blood pressure >150/100 mm Hg on three different occasions
- Drug-resistant hypertension (>140/90 mm Hg despite three medications including a diuretic)
- Hypertension and hypokalemia (spontaneous or diuretic-induced)
- Hypertension and family history of early-onset hypertension or cerebrovascular accident at a young age (<40 years)
- Hypertension with adrenal incidentaloma
- Hypertensive first-degree relatives of primary hyperaldosteronism patients
- Hypertension with obstructive sleep apnea

NSAIDs, Nonsteroidal antiinflammatory drugs.

\*Premenopausal women have higher aldosterone level during the luteal phase and lower renin level throughout the cycle than men. False positive ARR during the luteal phase was reported when direct renin concentration was used.

**BOX 2** Approach to Measure Plasma Renin Activity and Plasma Aldosterone Concentration

- Correct hypokalemia to 4 mmol/L.
- Liberalize sodium intake.
- Withdraw the following agents that markedly affect PRA and PAC for at least 4 weeks: spironolactone (Aldactone), eplerenone (Inspra), amiloride (Midamor), triamterene (Dyrenium), potassium-wasting diuretic, and products from licorice.<sup>7</sup>
- If not diagnostic and hypertension can be controlled with relatively noninterfering medications, withdraw the following agents for at least 2 weeks:  $\beta$ -blockers, central  $\alpha_2$  agonists (clonidine [Catapres], methyldopa [Aldomet]), NSAIDs, ACEIs/ARBs, renin inhibitors, and dihydropyridine calcium channel antagonists.
- If necessary, start other antihypertensive agents that have fewer effects on ARR: slow-release verapamil (Calan-SR), hydralazine (Apresoline) (with verapamil to prevent reflex tachycardia), prazosin (Minipress), doxazosin (Cardura), and terazosin (Hytrin).
- Obtain blood for PRA and PAC mid-morning after the patient has been up for at least 2 h and seated for 5–15 min.
- Establish use of estrogen products and menstrual cycles. Premenopausal females have higher ARR than men, especially during the luteal phase. False-positive ARR was reported during the luteal phase and from the use of estrogen products when direct renin concentration was used.

<sup>7</sup>Available as dietary supplement.

ARB, Angiotensin receptor blockers; ARR, aldosterone renin ratio; NSAIDs, nonsteroidal antiinflammatory drugs; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

**Confirmatory Tests of Primary Hyperaldosteronism**

The positive screening test should be followed by one or more confirmatory tests to avoid false positives. The confirmatory tests are designed to physiologically suppress aldosterone levels that would normally occur in the absence of primary hyperaldosteronism. However, some experts believe that some aldosterone-producing lesions are not completely independent of the RAAS, and confirmatory suppression tests can give false-negative results. Other experts think that confirmatory tests are not necessary for those with obvious clinical/biochemical features. Those with spontaneous hypokalemia, renin level below the detection level plus PAC greater than 20 ng/dL may not need further confirmatory tests. Furthermore, there is no gold-standard confirmatory. Therefore factors such as cost, accessibility, feasibility, patient compliance, local expertise, and accuracy of assay should be taken into consideration in selecting confirmatory tests. The Endocrine Society guidelines in 2016 state that any of the following four confirmatory tests can be used: oral salt loading test, saline suppression test, fludrocortisone (Florinef)<sup>1</sup> suppression test, and captopril (Capoten)<sup>1</sup> challenge test (Table 2).

**Subtype Classification of Primary Hyperaldosteronism**

Once primary hyperaldosteronism is biochemically confirmed, subtype classification follows to guide treatment. Lateralization of the source of excessive aldosterone production is crucial as the next step, as unilateral lesions such as aldosterone-producing adenomas (APAs) can be treated surgically; in contrast, bilateral lesions such as BAHs are treated medically. Aldosterone-producing carcinoma is rare but should be ruled out. In this regard, CT of the adrenal

<sup>1</sup>Not FDA approved for this indication.**BOX 3** Differential Diagnoses According to Plasma Renin Activity and Plasma Aldosterone Concentration**Causes of Primary Hyperaldosteronism:  $\downarrow$  PRA and  $\uparrow$  PAC ( $>5\text{--}10$  ng/dL); ARR  $>20\text{--}40$** 

- Most Common
  - Aldosterone-producing adenoma
  - Bilateral adrenal hyperplasia or idiopathic hyperaldosteronism
- Less common
  - Unilateral hyperplasia or primary adrenal hyperplasia
  - Familial hyperaldosteronism type 1 or glucocorticoid remediable aldosteronism
  - Familial hyperaldosteronism type 2
  - Aldosterone-producing adrenocortical carcinoma
  - Ectopic aldosterone-secreting tumor (ovary, kidney)
  - Multiple endocrine neoplasia type 1

**Causes of Secondary Hyperaldosteronism:  $\uparrow$  PRA and  $\uparrow$  PAC; ARR  $\approx 10$** 

- Renovascular hypertension
- Diuretic use
- Renin-secreting tumor
- Malignant hypertension
- Coarctation of the aorta

**Causes of Conditions That Mimic Mineralocorticoid Excess:  $\downarrow$  PRA and  $\downarrow$  PAC**

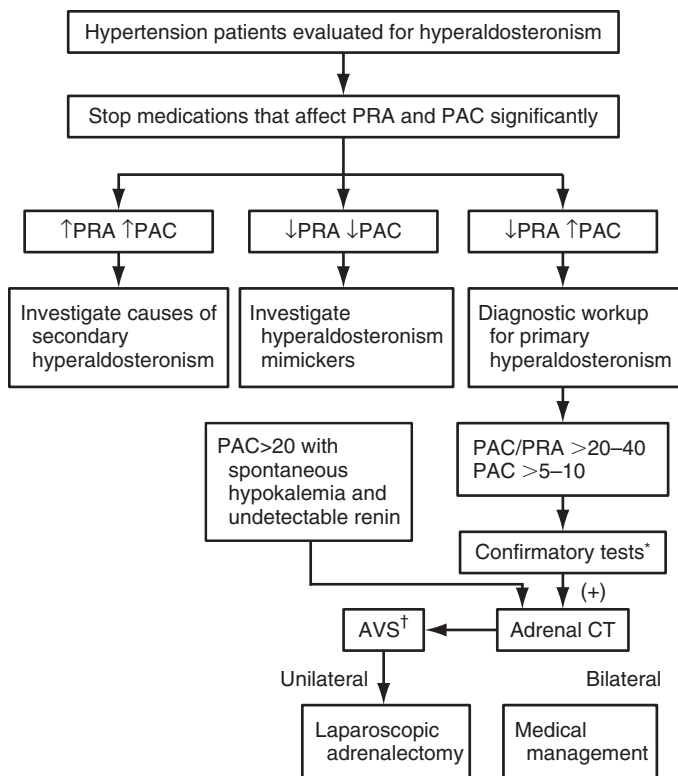

- Congenital adrenal hyperplasia
- Exogenous mineralocorticoid
- Deoxycorticosterone-producing tumor
- Cushing syndrome
- $11\beta$  HSD2 deficiency
- Altered aldosterone metabolism
- Liddle syndrome
- Glucocorticoid resistance

ARR, Aldosterone-renin ratio; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

glands should be done first to rule out aldosterone-producing carcinoma and obtain anatomic information. However, imaging studies are usually not reliable enough to lateralize lesions. If surgical treatment is considered, adrenal vein sampling (AVS) should be performed. Most cases of primary hyperaldosteronism are sporadic; about 5% are familial, mostly via autosomal dominant inheritance. Young patients ( $<20$  years of age) and those with family history of primary hyperaldosteronism or strokes at young age (less than 40 years) should have genetic testing for glucocorticoid remediable aldosteronism (GRA) or familial hyperaldosteronism type 1 (FH-1), which is caused by the hybrid gene of  $11\beta$  hydroxylase and aldosterone synthase (increased aldosterone synthesis by adrenocorticotrophic hormone). In very young patients, *KCNJ5* germline mutations, causing familial hyperaldosteronism type III, should be tested. Familial hyperaldosteronism type II is clinically indistinguishable from nonfamilial hyperaldosteronism, and can be caused by gain-of-function mutations in the *CLCN2* (chloride voltage-gated channel 2) gene. Type IV familial hyperaldosteronism generally involves patients with early onset hypertension and primary hyperaldosteronism before the age of 10. Germline mutations in the *CACNA1H* (calcium voltage-gated channel subunit  $\alpha 1H$ ) gene occur in type IV patients who also exhibit mental retardation and developmental disorders, as well as seizures and neurological abnormalities in some patients.

**Imaging**

CT/MRI scans of the adrenal glands provide one of five conclusions: normal adrenal glands, unilateral macroadenomas ( $>1$  cm), minimal unilateral adrenal limb thickening, unilateral microadenomas ( $\leq 1$  cm), and bilateral macroadenomas and/or microadenomas.

**Figure 2** Evaluation of hyperaldosteronism. AVS, Adrenal vein sampling; CT, computed tomography; PAC, plasma aldosterone concentration in ng/dL; PRA, plasma renin activity in ng/mL/h. \*May skip if spontaneous hypokalemia, renin level below the detection limit, and PAC >20 ng/dL. †If surgical treatment is pursued. May skip if <35 years old, spontaneous hypokalemia, PAC >30 ng/dL, and unilateral adenoma.

APAs are typically smaller than 2 cm, and BAHs exhibit either normal or nodular changes. Aldosterone-producing adrenal carcinomas are almost always larger than 4 cm in diameter and have imaging characteristics suspicious for malignancy. However, there are limitations; small APAs may be missed, hyperplasia may be misread as adenomas, and nonfunctional tumors are radiologically indistinguishable from APAs. Although several studies suggested imaging criteria for different subtypes, no study has conclusively established specific criteria that differentiate among different subtypes of primary hyperaldosteronism. In fact, CT accurately lateralizes in only about 50% to 70% of cases, and there is no evidence that MRI is superior to CT for subtype classification. Therefore AVS is required to differentiate unilateral from bilateral lesions if surgical resection is being pursued. Patients younger than 35 years with marked hyperaldosteronism with spontaneous hypokalemia and PAC greater than 30 ng/dL and solitary unilateral adenoma may not need AVS, because nonfunctioning tumors are uncommon in this young age group.

### Adrenal Vein Sampling

Aldosterone levels are measured from adrenal venous blood samples (Box 4) obtained through adrenal vein cannulation to distinguish between unilateral and bilateral lesions. Unilateral lesions are associated with a marked increase in PAC on the side of the tumor (and suppressed PAC on the other side), whereas bilateral lesions have little difference between the two sides. AVS should be performed only by experienced physicians in part because recognition and successful cannulation of the right adrenal vein especially can be challenging. Complications of AVS include adrenal hemorrhage, adrenal infarction, adrenal vein perforation, and adrenal vein thrombosis, which occur only rarely (<2.5%) in the hands of a physician skilled in the procedure.

The use of cosyntropin (Cortrosyn) stimulation to minimize stress-induced fluctuation in aldosterone level is controversial,

and some believe that it has no effect on AVS accuracy. If cosyntropin is not used, then AVS should be done in the morning after overnight recumbency to avoid postural aldosterone changes and reflect circadian aldosterone secretion.

In reality, different centers use different techniques, protocols, and interpretation criteria. The Endocrine Society guidelines in 2016 provide interpretation criteria with and without cosyntropin use. The first step for interpretation is to determine whether the procedure was done correctly. The adrenal vein-to-IVC cortisol ratio should be greater than 5:1 with cosyntropin given and greater than 3:1 without cosyntropin. If the ratio is significantly lower than these values, improper cannulation is implied. Next, divide the PAC values for the right and left adrenal veins by their respective cortisol values to correct the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; this is termed the *cortisol-corrected aldosterone (A/C)*. If cosyntropin is used, an A/C ratio of the high to the low side of greater than 4:1 indicates unilateral aldosterone hypersecretion, whereas an A/C ratio of less than 3:1 suggests bilateral aldosterone hypersecretion. These cutoffs were reported to have sensitivity of 95% and specificity of 100% for unilateral lesions. If the A/C ratio is between 3:1 and 4:1, the results of AVS should be interpreted in the context of CT, clinical findings, and other tests. Without cosyntropin, an A/C ratio of the high to the low side of greater than 2 or an A/C ratio of the high side to the periphery greater than 2.5 plus an A/C ratio of the low side to the periphery of less than 1 (suppressed contralateral aldosterone secretion) is consistent with unilateral aldosterone excess.

### Ancillary Tests

Clinical findings and other ancillary tests may help differentiate unilateral APAs from BAHs. BAHs will respond with increase in plasma aldosterone to postural stimulation, whereas APAs will not. Plasma 18-hydroxycorticosterone level tends to be higher in APAs as compared with BAHs. Iodocholesterol scintigraphy may be able to show functional correlation of anatomic abnormalities (but is not available at most centers). APA-specific tracers such as (11)C-Metomidate for positron emission tomography may be useful. Interpretation criteria of these tests are listed in Table 3. Patients with APAs tend to be younger (<40 years), predominantly female, very hypertensive with marked hypokalemia (<3 mmol/L), and tend to have a very high PAC (>25 mg/dL) compared with those with BAHs.

### Treatment

Treatment of secondary hyperaldosteronism and conditions mimicking hyperaldosteronism depends on their etiology. Treatment of primary hyperaldosteronism is discussed here. The goals of treatment of primary hyperaldosteronism are (1) normalization of the serum potassium in hypokalemic patients, (2) normalization of the BP, and (3) reversal of the effects of hyperaldosteronism on the cardiovascular system. When a small group of patients were followed after treatment with adrenalectomy or mineralocorticoid receptor antagonists (MRAs), left ventricular mass was reduced (faster with adrenalectomy than MRAs), increase in carotid intima-media thickness and arterial stiffness was reversed, glomerular filtration rate and urinary albumin secretion decreased and became similar to that in essential hypertension, and excessive cardiovascular risk compared to essential hypertension disappeared. Cardiovascular complications were rather related to age, duration of hypertension, and smoking. In addition, there was an improvement in the quality of life at 3 months, which was sustained at 6 months. Therefore timely diagnosis and treatment is essential. For unilateral lesions, surgical resection of the affected adrenal gland is recommended mainly to obviate the need for prolonged medical treatment and side effects. For bilateral lesions, medical treatment is recommended because surgical risk outweighs benefits. BP control per se does not reduce risk of cardiovascular complications unless renin activity is restored to normal (>1 ng/mL/h), which can be accomplished by salt restriction or increasing the dose of the MRA. MRAs are a key component of medical treatment

**TABLE 2** Protocols and Interpretation of Recommended Confirmatory Tests

	PROTOCOL	INTERPRETATION	REMARKS
Oral sodium loading test	<ol style="list-style-type: none"> <li>Place the patient on a high-sodium diet (&gt; 200 mmol/day) for 3 days.</li> <li>Replace potassium to compensate for the kaliuresis induced by the high-sodium diet.</li> <li>Collect a 24-h urine on the third day for determination of aldosterone, sodium, and creatinine; adequate if the urine sodium &gt;200 mmol/24 h</li> </ol>	Confirmed if the 24-h urine aldosterone is > 12 mcg (33.3 nmol) to 14 mcg (38.8 nmol). Ruled out if the 24-h urine aldosterone is <10 mcg (27.7 nmol). The test is equivocal if the value falls in between	Do not perform this test in patients with severe uncontrolled hypertension, renal failure, cardiac failure/arrhythmias, or severe hypokalemia
IV saline infusion test*	<ol style="list-style-type: none"> <li>Place the patient supine 1 h before drawing blood for morning baseline fasting levels of renin, aldosterone, cortisol, and potassium</li> <li>Infuse 2 L of 0.9% NaCl over 4 h, keeping the patient supine. Monitor blood pressure and heart rate</li> <li>After 4 h, draw blood for measurement of renin, aldosterone, cortisol, and potassium</li> </ol>	Confirmed if the PAC is >10 ng/dL (277 pmol/L). Ruled out if the PAC is <5 ng/dL (139 pmol/L). If the PAC falls between these values, the test is equivocal	Do not perform this test in patients with severe uncontrolled hypertension, renal failure, cardiac failure/arrhythmias, or severe hypokalemia
Fludrocortisone <sup>1</sup> suppression test	<ol style="list-style-type: none"> <li>Give 0.1 mg fludrocortisone every 6 h for 4 days, with the potassium level checked every 6 h to be sure that it is greater than 4 mmol/L</li> <li>Encourage a liberal sodium diet to keep urinary sodium excretion greater than 3 mmol/kg/day</li> <li>On day 4, draw blood for an upright 7 a.m. plasma cortisol level and 10 a.m. plasma aldosterone, renin, and cortisol levels</li> </ol>	Confirmed if the 10 a.m. PAC is >6 ng/dL, as long as PRA is <1 ng/mL/h and the plasma cortisol at 10 a.m. is less than at 7 a.m. (to exclude the ACTH effect)	The test may require hospitalization. Risks include severe hypokalemia, QT changes, worsening of left ventricular function, hypertension, and frequent phlebotomy
Captopril <sup>1</sup> challenge test	<ol style="list-style-type: none"> <li>Give 25–50 mg captopril after the patient has been sitting or standing for 1 h. The patient remains seated throughout the test.</li> <li>Draw blood for measurement of plasma renin, aldosterone, and cortisol at time 0, at 1 h, and at 2 h</li> </ol>	Normally, captopril suppresses PAC by more than 30% from baseline. Confirmed if there is no suppression of PAC and PRA remains suppressed. The false-negative rate for this test is high because suppression occurs in more than 30% of cases. A slight decrease in aldosterone can suggest bilateral adrenal hyperplasia	

\*The patient may be seated for 30 minutes before and during the infusion to improve sensitivity and PAC greater than 6 ng/dL (170 pmol/L) confirms primary hyperaldosteronism.

<sup>1</sup>Not FDA approved for this indication.

ACTH, Adrenocorticotropic hormone; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

#### BOX 4 Adrenal Vein Sampling

- After both adrenal veins have been cannulated, draw baseline samples for PRA, PAC, ACTH, and cortisol from the peripheral such as cubital or iliac, right adrenal vein, and left adrenal vein.
- Inject 250 mcg of cosyntropin (Cortrosyn) after cannulation, or infuse 50 mcg cosyntropin per hour beginning 30 min before adrenal vein cannulation. This reduces stress-related fluctuations in aldosterone and cortisol values and augments the biochemical gradients. (This step is controversial.)
- Draw blood for aldosterone and cortisol levels at 5, 15, and 30 min from the peripheral site and from each adrenal vein.

ACTH, Adrenocorticotropic hormone; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

and used as a preoperative measure or maintenance treatment (GRA should be treated with the lowest dose of glucocorticoid that can normalize BP and potassium levels rather than MRAs). A low-sodium diet (sodium <100 mEq/day = 2.3 g/day or salt 6 g/day) is also important, because left ventricular hypertrophy is associated with urine sodium excretion in primary hyperaldosteronism but not in essential hypertension. Other lifestyle changes include aerobic exercise, smoking cessation, and weight loss.

#### Unilateral Hypersecretion

Adrenalectomy, usually laparoscopic, is recommended. After adrenalectomy, BP improves in all patients (maximal improvement in 1 to 6 months, sometime continues to fall up to 1 year), but 30% to 60% of patients have persistent hypertension. BP and potassium level should be controlled before surgery. MRAs such as spironolactone (Aldactone) and eplerenone (Inspra)<sup>1</sup> can be used to control BP in patients awaiting adrenalectomy and also to prevent postoperative hypoaldosteronism. Postoperatively, normal saline is given to maintain volume status, MRAs and potassium supplements are discontinued, and antihypertensive medications may be reduced. To confirm biochemical cure, PAC and PRA should be checked shortly after the operation though renin levels might not change immediately. Risk factors for persistent hypertension after adrenalectomy include older age, duration of hypertension (>5 years), use of two or more antihypertensive agents preoperatively, BP higher than 165/100 mm Hg, low ARR preoperatively, low urine aldosterone, poor response to spironolactone preoperatively, family history of more than one first-degree relative with hypertension, and elevated serum creatinine level.

#### Bilateral Hypersecretion

MRAs and/or ENaC antagonists combined with other antihypertensives are used. One study showed that spironolactone

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Interpretation of Dynamic Testing

TEST	FINDINGS
<b>Screening Test</b>	
PAC/PRA ratio	Positive if >20–40 with PAC >5–10 ng/dL
<b>Confirmatory Tests</b>	
Oral sodium loading test	Positive if 24-h urine aldosterone excretion is >12–14 mcg
Saline infusion test	Positive if PAC after infusion is >10 ng/dL
Fludrocortisone <sup>1</sup> suppression test	Positive if upright PAC is >6 ng/dL on day 4 at 10 a.m.
Captopril <sup>1</sup> challenge test	Positive if PAC does not decrease by 30% and PRA remains suppressed
<b>AVS</b>	
With cosyntropin stimulation	A/C ratio (the high to the low side) >4:1 → unilateral aldosterone excess A/C ratio 3:1–4:1 → unclear A/C ratio <3:1 → bilateral aldosterone excess
Without cosyntropin stimulation	A/C ratio from the high to the low side >2:1 → unilateral aldosterone excess A/C ratio from the high side to the periphery >2.5 and A/C ratio from the contralateral side to the periphery <1 → unilateral aldosterone excess
<b>If Equivocal AVS</b>	
Postural stimulation test	PAC falls or fails to rise by 30%: consistent with APAs PAC increases by at least 33%: consistent with BAHs
Recumbent 18-hydroxycorticosterone	>100 ng/dL is consistent with APAs
NP-59 iodocholesterol scintigraphy	Unilateral early uptake (<5 days): consistent with unilateral aldosterone excess Bilateral early uptake (<5 days): consistent with bilateral aldosterone excess Negative scan does not rule out either etiology
(11)C-Metomidate positron emission tomography	Preliminary data showed (11)C-Metomidate uptake in APA

<sup>1</sup>Not FDA approved for this indication.

A/C ratio, Cortisol-corrected aldosterone ratio; APA, aldosterone-producing adenomas; AVS, adrenal vein sampling; BAH, bilateral adrenal hyperplasia; PAC, plasma aldosterone concentration; PRA, plasma renin activity.

had stronger antihypertensive effect than eplerenone, but there is insufficient evidence to choose one medication over another. Subtotal adrenalectomy has been tried, but only a minority of patients have responded with significant BP improvement. Unilateral adrenalectomy, however, may help selected patients by debulking aldosterone-producing tissues.

Spironolactone is the most widely used MRA. It is very effective in decreasing BP. The medication is initiated at 12.5 to 25 mg/day and can be titrated to 400 mg/day, with most patients requiring at least 200 mg/day. Potassium should be maintained at normal levels without use of potassium supplements. Use of spironolactone can be limited by side effects; antiandrogenic effects can cause gynecomastia in men and progesterone effect can cause menstrual irregularities

in women. There are drug interactions to consider; spironolactone increases the half-life of digoxin (Lanoxin) and salicylates, and other NSAIDs may decrease the effectiveness of spironolactone. Serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks, in particular for those with renal insufficiency or diabetes. Spironolactone is not recommended if creatinine clearance is less than 30 mL/min.

Eplerenone<sup>1</sup> is a competitive and selective antagonist of the aldosterone receptors. It has a lower binding affinity to androgen and progesterone receptors than spironolactone. This leads to fewer side effects. Eplerenone is 25% to 50% less potent in antagonizing the aldosterone receptors than spironolactone. Eplerenone has a short half-life and should be taken twice daily. Dosing is started at 25 mg twice daily, with a maximum dose of 100 mg/day. Again, serum potassium and creatinine should be closely monitored for the first 4 to 6 weeks in particular for those with renal insufficiency or diabetes. Other adverse effects include hypertriglyceridemia, increased liver enzymes, headache, and fatigue. Eplerenone is contraindicated if serum potassium is greater than 5.5 mEq/L at initiation, if creatinine clearance is less than 30 mL/min, or if there is concomitant use of strong CYP3A4 inhibitors such as ketoconazole (Nizoral) and itraconazole (Sporanox).

ENaC antagonists, amiloride (Midamor)<sup>1</sup> and triamterene (Dyrenium)<sup>1</sup>, can be used in patients who cannot tolerate MRAs or are still hypertensive/hypokalemic while on MRAs. Amiloride is prescribed at 10 to 20 mg/day in divided doses. Side effects include dizziness, fatigue, and impotence. Triamterene is dosed at 100 to 300 mg/day in divided doses, and its side effects are mainly dizziness and nausea. Addition of thiazide diuretics can help control BP by relieving volume overload. If BP remains uncontrolled, other antihypertensive agents such as ACEIs/ARBs or calcium channel blockers may be used.

<sup>1</sup>Not FDA approved for this indication.

## HYPERLIPIDEMIA

Method of

Xiaoming Jia, MD; Mandeep Bajaj, MD; and Lawrence Chan, MD

### CURRENT DIAGNOSIS

- Hyperlipidemia is diagnosed based on the fasting lipid profile in the context of global cardiovascular risk. The exception is when the triglyceride level is greater than 500 mg/dL because of substantial risk of pancreatitis.
- Secondary causes of hyperlipidemia, such as hypothyroidism, alcoholism, uncontrolled diabetes mellitus, kidney disorders, pregnancy, and medications, should be thoroughly investigated and treated if diagnosed.
- Possibility of familial hyperlipidemia based on the lipid profile, family history, and physical examination should be considered because cardiovascular risk can be underestimated and treatment can be challenging.

### CURRENT THERAPY

- Therapy should be guided by goals of treatment based on estimated cardiovascular risk unless triglyceride level >500 mg/L, in which case lowering triglycerides to prevent acute pancreatitis is a priority.
- Low-density lipoprotein (LDL) cholesterol is a primary goal followed by non-high-density lipoprotein (HDL) cholesterol as a secondary goal. Triglycerides have also emerged as a target to further reduce residual cardiovascular risk in select patients with high cardiovascular risk.
- Therapeutic lifestyle changes should be initiated in everyone with lipid parameters above their target. Therapeutic lifestyle changes are also recommended for those with very high, high, or moderately high cardiovascular risk.
- Pharmacologic agents should be added if therapeutic lifestyle changes are not successful. Pharmacologic agents can be considered from the beginning for those with very high, high, or moderately high cardiovascular risk.
- Statin therapy is preferred if tolerated, and the intensity of therapy to use should be dictated by the degree of cardiovascular risk.
- Statins are the treatment of choice for their proven effects on cardiovascular outcomes. Other agents can be added based on response to statins and other targets such as high triglycerides.
- All other cardiovascular risk factors should be treated aggressively at the same time.

Hyperlipidemia is a condition of elevated serum lipids and lipoproteins. Hyperlipidemia is associated with an increased risk of atherosclerotic cardiovascular disease (ASCVD) and, if the triglyceride level is greater than 500 mg/dL, pancreatitis. Unless the triglyceride level is greater than 500 mg/dL, the primary goal of management of hyperlipidemia is to decrease the risk of ASCVD. ASCVD as defined by the *2018 Multisociety Guideline on the Management of Blood Cholesterol* encompasses acute coronary syndrome, history of myocardial infarction, stable or unstable angina or coronary or other arterial revascularization, stroke, transient ischemic attack, or peripheral arterial disease including aortic aneurysm, all of atherosclerotic origin. In this regard, appropriate treatment of hyperlipidemia is essential in patients with established cardiovascular disease (secondary prevention), whereas detection and treatment of hyperlipidemia are guided by the risk of ASCVD in patients without known clinical ASCVD (primary prevention).

The prevalence of hyperlipidemia varies with the definition of hyperlipidemia and the population studied. The percentage of US adults with a total cholesterol level of 240 mg/dL or higher declined from 19% to 14% in men and from 21% to 15% in women from 1988 to 2008. This may be in part due to increased use of lipid-lowering medications, from 3.4% to 15.5%. However, major risk factors for cardiovascular disease actually have become more common: the prevalence of obesity (BMI  $\geq$  30 kg/m<sup>2</sup>) increased from 19.9% to 31.6% in men and from 25.2% to 34.1% in women, and the prevalence of diabetes increased from 5.5% to 11.1% in men and from 4.6% to 6.3% in women over this period. Therefore optimal treatment of hyperlipidemia to reduce cardiovascular risk is of paramount importance.

Various societies and professional organizations have published clinical guidelines for hyperlipidemia. The approach used in this chapter is mostly based on the *2013 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines* and the *2018 Multisociety Guideline on the Management of Blood Cholesterol*. The 2013 American College of Cardiology/American Heart Association guideline represents a substantial departure from previous guidelines in that it emphasizes the use of statins of appropriate strength according to the estimated cardiovascular risk without specific low-density lipoprotein (LDL) cholesterol targets. The 2016 European Society of Cardiology and European Atherosclerosis Society (ESC/EAS) Guidelines for the Management of Dyslipidaemias will also be integrated in the sections on Evaluation and Treatment.

### Pathophysiology

Lipids have two main points of entry into the circulation: the gut (exogenous pathway) and the liver (endogenous pathway). The exogenous and endogenous pathways are interconnected by intermediate pathways (reverse cholesterol transport pathway and others). These pathways are outlined in [Figure 1](#).

### Exogenous Pathway

Lipids in food are emulsified by bile acids and then hydrolyzed into fatty acids and cholesterol by pancreatic lipases in the intestinal lumen. Inside the intestinal cells, fatty acids and cholesterol are re-esterified and then packaged with apolipoprotein (Apo) B48 into chylomicrons. Chylomicrons are secreted into the intestinal lymph and delivered to the systemic circulation. At peripheral tissues, triglycerides are hydrolyzed by lipoprotein lipase with Apo CII acting as a cofactor. Released free fatty acids are then taken up for further metabolism or storage. Chylomicron remnants are taken up by the liver via the chylomicron remnant receptors.

### Endogenous Pathway

The endogenous pathway begins in the liver with the synthesis of triglyceride-rich very-low-density lipoproteins (VLDLs). Microsomal triglyceride transfer protein facilitates the transfer of lipids onto Apo B100 and stabilizes the protein for secretion as

**Figure 1** Overview of exogenous and endogenous pathways of lipid metabolism. CM, chylomicrons; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; VLDL, very-low-density lipoproteins.

VLDLs. VLDLs, as chylomicrons, undergo lipolysis by lipoprotein lipase, releasing free fatty acids, generating smaller particles called intermediate-density lipoproteins (IDLs, also known as VLDL remnants). IDLs are either removed by the liver or further processed into cholesterol-rich LDLs. LDLs are taken up into the liver or other cells via LDL receptors, a process regulated by cellular cholesterol requirement. Macrophages in the arterial wall can also take up LDLs via the scavenger receptors and become foam cells. Foamy macrophages play a key role in the development of atherosclerosis. Recent research has further suggested that the precursors of macrophages, monocytes, can also uptake lipoprotein particles in circulation and transform into foamy monocytes, which may also play a role in atherogenesis.

#### Reverse Cholesterol Transport

High-density lipoproteins (HDLs) are the major lipoproteins involved in the transport of cholesterol from peripheral tissues back to the liver. HDLs are synthesized by both the hepatocytes and the enterocytes in the form of small discoidal particles containing Apo AI and phospholipids. HDLs acquire additional lipids and apolipoproteins from triglyceride-depleted chylomicrons and VLDL remnants. HDLs remove free cholesterol from tissues with the help of Apo AI and esterify it with lecithin cholesterol acyltransferase. Cholesteryl esters are then transferred to Apo B 100-containing lipoproteins (VLDLs, IDLs, and LDLs) by cholesteryl ester transfer protein (CETP). HDLs can also be taken up directly by the liver class B type I scavenger receptors (SR-BI).

#### Plasma Lipids and Atherosclerosis

Multiple studies have shown that total cholesterol and LDL cholesterol levels contribute to cardiovascular disease risk and that lowering of total cholesterol and LDL cholesterol levels reduces the risk. Non-HDL cholesterol (i.e., total cholesterol - HDL cholesterol = VLDL + IDL + LDL cholesterol) reflects total atherogenic lipoprotein burden and may be a better risk indicator than LDL cholesterol, especially in people with combined hyperlipidemia, diabetes, metabolic syndrome, and chronic kidney disease. [Table 1](#) shows the classification of lipid profile.

Recent Mendelian randomization studies have suggested that triglyceride-rich lipoproteins (TRLs), including chylomicrons, VLDLs, and their remnants, also have a causal relationship with ASCVD. Therefore not only does hypertriglyceridemia represent an independent cardiovascular risk marker, it is also a significant risk factor and a target for therapy. Not surprisingly, the development of treatments targeting triglyceride pathways is an area of immense interest in the last few years. It is significant that Mendelian randomization studies suggest that HDL cholesterol does not have a causal relationship with ASCVD. Moreover, medications that increase HDL cholesterol (i.e., niacin and CETP inhibitors) have largely failed to show efficacy in ASCVD risk reduction in randomized clinical trials. Therefore, although HDL cholesterol was shown to be inversely associated with cardiovascular risk, the mechanism of the relationship between HDL cholesterol and ASCVD is not fully understood. Importantly, ASCVD cannot be viewed as a disease caused solely by a lipid disorder; rather, it is the result of a complex interplay between dyslipidemia, metabolic derangements, inflammation, and endothelial dysfunction. For instance, even

**TABLE 1** Classification of LDL, Total, and HDL Cholesterol and Triglycerides (mg/dL)

<b>LDL Cholesterol (mg/dL)</b>	
<100	Optimal
100–129	Near optimal/above optimal
130–159	Borderline high

mildly elevated triglycerides (>150 mg/dL) can suggest metabolic syndrome, an important risk factor for cardiovascular disease. Meanwhile, chronic systemic inflammation was shown to accelerate atherogenesis, and therapies that target inflammation have been demonstrated in clinical trials to reduce the risk for ASCVD.

#### Evaluation

##### Global Cardiovascular Risk Assessment

Risk assessment is an integral part in the evaluation of patients with hyperlipidemia. Contemporary guidelines from the United States provide detailed algorithms for risk stratification. The 2013 and 2018 cholesterol guidelines identified four subgroups of patients for whom the benefits of statin therapy outweigh the risk. Secondary prevention patients are automatically considered to be at high risk for recurrent ASCVD events and, thus, would necessitate initiation of lipid lowering therapy. In the 2018 Multisociety guideline, secondary prevention patients may be further stratified into those at very high risk, and those at not very high risk, for ASCVD, based on the presence or absence of high-risk features. The value of further delineating risk among secondary prevention patients was in part to facilitate the evidence-based use of newer nonstatin therapies (i.e., ezetimibe [Zetia]<sup>1</sup> and PCSK9 inhibitors).

Among primary prevention patients, a history of diabetes mellitus, or significantly elevated LDL cholesterol (≥190 mg/dL or 4.9 mmol/L) signifying a likely genetic cause of hypercholesterolemia (i.e., familial hypercholesterolemia), automatically warrants initiation of lipid lowering therapy. In primary prevention patients with hyperlipidemia but without these two high-risk features, a global cardiovascular risk score can be used to further stratify a patient. Global risk scores estimate 10-year cardiovascular risk, which combines the effects of well-known risk factors, using one of several risk-calculation tools. Individual tools have been developed based on large epidemiology

<sup>1</sup>Not FDA approved for this indication

studies examining a limited number of available risk factors. Traditional risk factors such as age, sex, cigarette smoking, cholesterol, diabetes, and blood pressure are able to predict 80% to 90% of the cardiovascular events in people 40 years or older. However, these tools may not accurately estimate cardiovascular risk in individuals with unaccounted risk factors or those with demographics distinct from the populations used to derive the risk scores. The risk score most commonly used (and endorsed by guidelines) in the United States is the Pooled Cohort Equation (PCE). The PCE is used to estimate a 10-year risk for ASCVD for men and women aged 40 to 79 years, who are white or black race, incorporating age, sex, race, HDL and total cholesterol, diabetes, hypertension, and smoking status (<http://tools.cardiosource.org/ASCVD-Risk-Estimator>). The 2018 Multisociety guidelines recommend the initiation of statin therapy in patients with intermediate ( $\geq 7.5\%$  to  $< 20\%$ ) and high ( $\geq 20\%$ ) 10-year ASCVD risk, with consideration of statins even in select patients with borderline 10-year risk ( $5\%$  to  $< 7.5\%$ ). Of note, the risk stratification used by the European guideline is similar to that used by the American guideline. Although patients with a history of clinical ASCVD and those with high-risk comorbidities (i.e., diabetes mellitus, significant chronic kidney disease) are also classified as higher risk, the risk assessment score used is different. The Systematic Coronary Risk Evaluation (SCORE), used in the ESC/EAS Guidelines for the Management of Dyslipidemias, incorporates similar risk factors and predicts fatal cardiovascular events ([www.heartscore.org](http://www.heartscore.org)).

Finally, further risk assessment for subclinical coronary atherosclerosis via the measurement of coronary calcium by computer tomography (calcium score) has also been incorporated into the most current guidelines. With the rapid advancement of cardiovascular imaging technologies, further refinement of risk assessment that incorporates calcium score or other imaging modalities will likely play a significant role in future clinical practice.

### Measurement of Lipid Profiles

Lipid profiles should be measured as a part of global risk assessment, and the frequency of checkup is determined by age, sex, and risk factors for cardiovascular disease. In patients on lipid lowering therapy, a lipid panel should be performed after the initiation or dose change in therapy; it should also be performed periodically in patients on stable therapy to assess treatment efficacy and medication adherence.

A fasting lipid profile (fasting for 9 to 12 hours) is recommended to ensure the most precise lipid assessment, specifically triglycerides (subsequently LDL cholesterol if calculated using the Friedewald equation). Nonfasting lipid profile provides an accurate measurement of other lipids, including total cholesterol, HDL cholesterol, Apo B, and Apo AI. Recent studies showed that differences in triglyceride levels according to fasting time were small. Therefore lipid values from nonfasting samples should not be ignored.

LDL cholesterol can either be calculated or measured directly. The standard method used to derive LDL cholesterol from other components of the lipid panel is the Friedewald equation ( $\text{LDL cholesterol} = \text{total cholesterol} - \text{HDL cholesterol} - \text{triglycerides}/5$ ). This equation should be used with appropriate caution: fasting state samples should be used; it becomes less accurate if triglycerides  $> 200$  mg/dL; it becomes invalid with triglycerides  $> 400$  mg/dL; LDL cholesterol can be underestimated at levels  $< 70$  mg/dL.

Apolipoproteins, including Apo B and Apo AI, may also be measured. The Apo B level (Apo B100) reflects the number of atherogenic lipoprotein particles. Apo B level and Apo B/Apo AI ratio are as good as traditional lipid profiles and are especially useful in certain situations such as combined hyperlipidemia, metabolic syndrome, diabetes, and chronic kidney disease. In patients with history of premature ASCVD, recurrent ASCVD events despite optimal therapy, and those with a strong family history of premature ASCVD, a measurement of lipoprotein (a) [Lp(a)] may be considered.

Other medical conditions may also affect lipid profiles. Secondary causes include hypothyroidism, nephrotic syndrome, dysgammaglobulinemia, use of progestin (especially those with androgenic activity), cholestasis, use of protease inhibitors, chronic kidney disease, uncontrolled diabetes, obesity, excessive

alcohol intake, use of thiazide or  $\beta$ -blockers, use of corticosteroids, use of oral estrogen (not transdermal), and pregnancy. These conditions should be detected and treated, if appropriate, to improve control of hyperlipidemia.

Family history of premature cardiovascular disease and hyperlipidemia and physical findings such as xanthomas, xanthelasmas, and premature arcus cornealis may suggest familial hypercholesterolemia. As the risk for ASCVD associated with very elevated levels of atherogenic lipoproteins begins to accumulate very early in life, patients with familial hypercholesterolemia should be treated aggressively.

## Treatment

### Overview

Treatment is primarily aimed at lowering LDL cholesterol level, which has been shown to decrease the risk of cardiovascular disease in numerous randomized clinical trials. In clinical scenarios where the triglyceride level is  $> 500$  mg/dL, triglycerides should be lowered immediately to prevent acute pancreatitis. Every reduction of LDL cholesterol of 1 mmol/L ( $\sim 40$  mg/dL) is associated with  $\sim 20\%$  reduction in cardiovascular risk. The absolute risk reduction by lowering LDL cholesterol is proportional to the global cardiovascular risk.

It should be noted that the American guidelines have shifted away from hard LDL cholesterol targets. The treatment goals and approaches according to the 2018 cholesterol guidelines are summarized in Table 2. Briefly, high-risk patients are recommended to be started on a high-intensity statin with a goal LDL cholesterol reduction of  $\geq 50\%$ . In high-risk patients who cannot tolerate high-intensity statins and in intermediate risk patients, a moderate-intensity statin is recommended with a goal of LDL-C reduction of 30% to 49%. In secondary prevention patients who are determined to be at very high risk, additional validated nonstatin medications (ezetimibe and PCSK9 inhibitors) may be considered if LDL cholesterol remains  $\geq 70$  mg/dL on maximally tolerated therapy. At the time of the writing of this chapter, the Europeans, as reflected by the 2016 ESC/EAS guidelines, have maintained hard LDL cholesterol targets based on patient risk, as presented in Table 3.

As a first line, therapeutic lifestyle changes should be initiated when LDL cholesterol is above the target range. People with very high, high, or moderately high risk should also start making therapeutic lifestyle changes regardless of their LDL cholesterol level. Medications may be added at the same time as therapeutic lifestyle changes for these patients. If medications are indicated, statin is preferred because of proven efficacy that has been consistently shown in multiple clinical trials. The intensity of treatment is dictated by the patient's risk profile, ability to tolerate therapy as well as patient preference. Generally, response to treatment by a lipid panel and appropriate safety laboratory measures should be assessed 4 to 12 weeks after treatment initiation or change. Once under control, lipid panels and clinical laboratory safety profiles can be monitored every 3 to 12 months.

### Therapeutic Lifestyle Changes

All patients with hyperlipidemia should be counseled on lifestyle modifications. Dietary modification to limit intake of lipids is an essential component, given that the main source of lipids is exogenous dietary fat. Saturated fatty acids and trans-unsaturated fatty acids increase LDL cholesterol, whereas dietary fibers decrease LDL cholesterol. Carbohydrates do not affect LDL cholesterol but increase triglycerides and decrease HDL cholesterol, particularly if they have a high glycemic index. Intake of fructose, a component of sucrose, increases triglycerides and decreases HDL cholesterol. Body weight reduction, increasing physical activity, and avoidance of a sedentary lifestyle have a small effect on LDL cholesterol, but they reduce triglycerides, increase HDL cholesterol, and are associated with improved cardiovascular outcome. Alcohol intake has an adverse effect on triglycerides and should be avoided.

**TABLE 2** Risk Groups and Treatment Goals (2018 Multisociety Blood Cholesterol Guideline)

	RISK CATEGORY	RECOMMENDED STATIN THERAPY TO INITIATE	NONSTATIN THERAPY
Secondary Prevention	Very high risk*	High-intensity statin (Goal LDL cholesterol reduction of ≥50%).	If LDL cholesterol ≥70 mg/dL on maximally tolerated statin then adding ezetimibe or a PCSK9 inhibitor should be considered. Ezetimibe should be tried first, given cost effectiveness.
	Not very high risk	High-intensity statin (Goal LDL cholesterol reduction of ≥50%).	If LDL cholesterol ≥70 mg/dL on maximally tolerated statin then may consider adding ezetimibe.
Primary Prevention	LDL cholesterol ≥190 mg/dL	High-intensity statin (Goal LDL cholesterol reduction of ≥50%).	If LDL cholesterol reduction of ≥50% was not achieved or if an LDL cholesterol level remains above 100 mg/dL on maximally tolerated statin, may consider ezetimibe and then a PCSK9 inhibitor if needed.
	Diabetes mellitus	Moderate-intensity statin (Goal LDL cholesterol reduction of 30% to 49%). In patients with multiple other ASCVD risk factors, high-intensity statin may be considered.	Reasonable to add ezetimibe to maximally tolerated statin therapy to reduce LDL cholesterol by ≥50%.
	High risk (10 years ASCVD risk† ≥20%)	High-intensity statin	Reasonable to add ezetimibe to maximally tolerated statin therapy to reduce LDL cholesterol by ≥50%.
	Intermediate risk (10 year ASCVD risk ≥7.5% to <20%)	If risk enhancers‡ present or if CAC score elevated, should initiate moderate intensity statin.	In patients with multiple additional ASCVD risk factors. Reasonable to add ezetimibe to maximally tolerated statin therapy to reduce LDL cholesterol by ≥50%.
	Borderline risk (10 year ASCVD risk 5% to <7.5%)	If risk enhancers present, then may consider moderate intensity statin.	
	Low risk (10 years ASCVD risk <5%)		

\*Very high risk defined by a history of multiple major ASCVD events or at least 1 major ASCVD event plus multiple high-risk conditions (age ≥65 years, heterozygous familial hypercholesterolemia, history of coronary bypass surgery or percutaneous coronary intervention outside of the major ASCVD events, diabetes mellitus, hypertension, chronic kidney disease, current smoking, persistently elevated LDL cholesterol ≥100 mg/dL despite maximally tolerated statin and ezetimibe, or history of congestive heart failure).

†10 year ASCVD risk as estimated by the Pooled Cohort Equation.

‡Risk enhancers include family history of premature ASCVD, chronic kidney disease, metabolic syndrome, inflammatory disease, conditions specific to women (i.e., pre-eclampsia, premature menopause), ethnicity (i.e., South Asian ancestry), persistently elevated LDL cholesterol ≥160 mg/dL, persistently elevated triglycerides (≥175 mg/dL), high sensitivity C-reactive protein ≥2.0 mg/L, lipoprotein (a) >50 mg/dL or 125 nmol/L, apolipoprotein B ≥130 mg/dL, ankle-brachial index <0.9.

ASCVD, atherosclerotic cardiovascular disease; CAC, calcium; LDL, low density lipoprotein; PCSK9, proprotein convertase subtilisin/kexin type 9.

**TABLE 3** LDL Cholesterol and Apo B Goals in the ESC/EAS Guideline\*

	GOAL	
	LDL CHOLESTEROL (MG/DL)	APO B (MG/DL)
Very high risk: established cardiovascular disease, diabetes plus major cardiovascular risk factor(s), severe CKD (GFR <30 mL/min/1.73 m <sup>2</sup> ), or 10 year fatal CVD risk ≥10%	70 or > 50% reduction if baseline 70–135	80
High risk: markedly uncontrolled risk factor(s), diabetes, moderate CKD (GFR 30–59 mL/min/1.73 m <sup>2</sup> ), or 10 years fatal CVD risk 5%–10%	100 or >50% reduction if baseline 100–200	100

\*10-year risk calculation using Systematic COronary Risk Evaluation (SCORE).

Apo B, apolipoprotein B; CKD, chronic kidney disease; CVD, cardiovascular disease; GFR, glomerular filtration rate; LDL, low density lipoprotein.

Individual patients will need different approaches based on their cardiovascular risk and lipid profiles. Generally, total dietary fat is recommended to constitute 25% to 35% of the total calorie intake mainly as mono- or poly-unsaturated fat, limiting saturated fat <7% and trans fat <1% of the total calorie intake. Therapeutic lifestyle changes include diets with emphasis on vegetables, fruits, whole grains, low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts as well as limited intake of sweets, sugar-sweetened beverages, and red meats; further reduction of saturated fat (<5% to 6% of the total caloric intake) and trans fat; weight reduction; and increased regular physical activity. The amount of cholesterol intake is not well correlated with LDL cholesterol level and there is no recommended

limit for intake. Management of other risk factors such as smoking cessation and controlling blood pressure in hypertensive patients and blood glucose in diabetics is also very important.

**Pharmacologic Agents**

The currently available lipid-lowering agents can be classified based on their mechanism of action. Statins (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors), ezetimibe (Zetia), PCSK9 (proprotein convertase subtilisin/kexin type 9) inhibitors, and bile acid sequestrants are used primarily to reduce LDL cholesterol. Fibrates, niacin, and omega-3 fatty acid prescriptions are used primarily for the treatment of hypertriglyceridemia. These classes of agents differ with regard to degree and type of lipid

lowering, and agents within the same group may differ in efficacy and side effects. Conventional dosing regimens and common adverse effects are summarized in Table 4. Expected changes in lipid profiles are shown in Table 5. The choice of drug depends on the specific lipid abnormalities, patient's tolerability to the medication, and concurrent medical conditions. In general, statins are the most effective drugs to lower cardiovascular risk and are the treatment of choice when medications are indicated based on the global cardiovascular risk. If the treatment goal is not achieved by statins or statins are not tolerated, other validated nonstatin therapies (ezetimibe and PCSK9 inhibitors) may be considered, followed by other agents such as bile acid sequestrants. If the primary goal is to lower triglycerides, fibrates, omega-3 fatty acids, or niacin may be more effective.

### Statins

Statins are usually the first drug of choice in patients with high cholesterol levels to reduce cardiovascular risk and have been validated in multiple randomized controlled trials and their meta-analyses. Furthermore, risk reduction was apparent in a wide range of patients in both primary and secondary prevention, in men, women, smokers, patients with diabetes, as well as those with hypertension. In general, statins result in a high degree of LDL cholesterol reduction. The approximate equipotent dosages of various statins and their cholesterol-lowering effects are listed in Table 6. The 2013 and 2018 cholesterol guideline recommends moderate-or high-intensity statins (see Table 6) based on the global risk. Statins inhibit HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis. By blocking cholesterol biosynthesis, statins upregulate the LDL receptor

on the hepatocytes and increase clearance of IDL and LDL. In addition to their direct effects on lipid metabolism, statins have been reported to have pleiotropic effects (e.g., reduced formation of reactive oxygen species, inhibition of platelet reactivity, and decreased vasoconstriction).

Statins are usually well tolerated. Potential common side effects include myopathy, fatigue, headaches, and nonspecific gastrointestinal symptoms such as dyspepsia. Elevation of liver enzymes occurs in less than 1%. There is also a small but significant association with increase in risk of developing diabetes. Myopathy is one of the most common causes for cessation of statins. Myalgia can occur in about 10% to 20% of patients, which is much more often than reported in the clinical trials. The risk of rhabdomyolysis, however, is very low (0.1 to 0.2 per 1000 person-years). Risk for myopathy is increased in patients with advanced age, female sex, small body habitus, hypothyroidism, alcoholism, medical conditions (particularly liver or kidney disease), major surgery, excessive physical activity, history of myopathy, family history of myopathy, high-dose statins, and interacting medications or food such as grapefruit juice (>1 L/day). Simvastatin (Zocor), lovastatin (Mevacor), and atorvastatin (Lipitor) are primarily metabolized through CYP3A4, which is inhibited by protease inhibitors, cyclosporine (Neoral, Sandimmune), amiodarone (Cordarone, Pacerone), nondihydropyridine calcium channel blockers, fibrates, and other agents. Pravastatin (Pravachol) is metabolized by the kidney, not by the P450 system. Fluvastatin (Lescol) and rosuvastatin (Crestor) are primarily metabolized through CYP2C9. Pitavastatin (Livalo) is marginally metabolized by CYP2C9 and to a lesser extent by CYP2C8. Simvastatin and lovastatin should be avoided in patients receiving

**TABLE 4** Major Drugs for Management of Hyperlipidemia

AGENT	STARTING DAILY DOSAGE	DOSAGE RANGE	MECHANISM	SIDE EFFECTS
<b>Statins</b>				
Lovastatin (Mevacor)	20 mg	10–80 mg	Decreased cholesterol synthesis, increased hepatic LDL receptors, decreased VLDL release	Myalgias, arthralgias, high liver enzymes, dyspepsia
Pravastatin (Pravachol)	40 mg	10–80 mg		
Simvastatin (Zocor)	20–40 mg	5–80 mg		
Fluvastatin (Lescol)	40 mg	20–80 mg		
Atorvastatin (Lipitor)	10–20 mg	10–80 mg		
Rosuvastatin (Crestor)	10 mg	5–40 mg		
Pitavastatin (Livalo)	2 mg	2–4 mg		
<b>Cholesterol Absorption Inhibitors</b>				
Ezetimibe (Zetia)	10 mg	10 mg	Decreased intestinal cholesterol absorption	High liver enzymes
<b>Combination Therapies (single pill)</b>				
Ezetimibe/Simvastatin (Vytorin)	10/20 mg	10/10–10/80 mg		
<b>PCSK9 Inhibiting Monoclonal Antibodies (subcutaneous)</b>				
Alirocumab (Praluent)	75 mg every 2 weeks	75–150 mg every 2 weeks	Increased hepatic LDL receptors	Injection site reactions, nasopharyngitis, upper respiratory tract infection, influenza, back pain
Evolocumab (Repatha)		140 mg every 2 weeks or 420 mg monthly		
<b>Bile Acid Sequestrants</b>				
Cholestyramine (Questran)	8–16 g	4–24 g	Increased bile acid excretion, increased LDL receptors	Bloating, constipation, elevated triglycerides
Colestipol (Colestid)	2 g	2–16 g		
Colesevelam (Welchol)	3.75 g	3.75 g		
<b>Fibrates</b>				

**TABLE 4** Major Drugs for Management of Hyperlipidemia—cont'd

AGENT	STARTING DAILY DOSAGE	DOSAGE RANGE	MECHANISM	SIDE EFFECTS
Fenofibrate (Tricor)	48–145 mg	48–145 mg	Increased LPL activity, decreased VLDL synthesis	Dyspepsia, myalgia, gallstones, high liver enzymes
Gemfibrozil (Lopid)	1200 mg	1200 mg		
Fenofibric acid (Trilipix)	45–135 mg	45–135 mg		
<b>Niacin</b>				
Immediate release	250 mg	250–3000 mg	Decreased VLDL synthesis	Flushing, high glucose, uric acid, high liver enzymes
Extended release (Niaspan)	500 mg	500–2000 mg		
<b>Omega-3 Fatty Acid Prescriptions</b>				
Icosapent ethyl (Vascepa)	4 g	4 g		Arthralgia, atrial fibrillation, lower extremity edema*
Omega-3 fatty acid ethyl esters (Lovaza)	4 g	4 g		Eructation, dyspepsia, and taste perversion

\*The on-label side-effect profile of icosapent ethyl includes arthralgia. Increased rates of atrial fibrillation and lower extremity edema were reported in the REDUCE-IT trial. However, at the time of the writing of this chapter, the use of icosapent ethyl in patients meeting REDUCE-IT entry criteria would be considered off-label use. LDL, low-density lipoprotein; LPL, lipoprotein lipase; TG, triglycerides; VLDL, very-low-density lipoprotein.

**TABLE 5** Metabolic Effects of Each Lipid-Lowering Drug Class

	LDL CHOLESTEROL	HDL CHOLESTEROL	TRIGLYCERIDES
Statins	↓ 21%–55%	↑ 2%–10%	↓ 6%–30%
Fibric acids	↓ 20%–25%	↑ 6%–18%	↓ 20%–35%
Niacin	↓ 10%–25%	↑ 10%–35%	↓ 20%–30%
Bile acid sequestrants	↓ 15%–25%		May ↑
Cholesterol absorption inhibitors	↓ 10%–18%		
PCSK9 inhibitors	↓ 39%–62%	↑ 4%–7%	↓ 12%–17%

Adapted from lipoprotein management in patients with cardiometabolic risk, consensus statement from the American College of Cardiology Foundation and the American Diabetes Association (ACC/ADA) (2008), and American Association of Clinical Endocrinologists' (AACE) guidelines for management of dyslipidemia and prevention of atherosclerosis (2012).

protease inhibitors. Statin dosage should be reduced in patients taking cyclosporine. Because of significant risk of myopathy and rhabdomyolysis related to high-dose simvastatin, the FDA recommends that 80 mg/day should not be used. The FDA further recommends that the dose be limited to 20 mg if the patient is also taking amiodarone, amlodipine (Norvasc), or ranolazine (Ranexa), and to 10 mg/day if taking diltiazem (Cardizem), dronedarone (Multaq), or verapamil (Calan). Addition of fibrates increases the risk of myopathy; in patients on a statin, fenofibrate (Tricor) is preferred, whereas gemfibrozil (Lopid), which has a much higher risk of rhabdomyolysis, is contraindicated. Symptoms of statin myopathy are heaviness, stiffness, cramping associated with weakness during exertion, and tendon-associated pain. Location of symptoms can be at the thighs, at the calves, or generalized. Symptoms can be very nonspecific, and differentiating statin-related myopathy from other causes is not easy. Therefore baseline symptoms, physical examination, and assessment of creatinine kinase level before the initiation of statins can be very helpful. Further decisions regarding stopping, dose reduction, or switching medications can be made based on the severity of symptoms, level of creatinine kinase elevation, and presence of rhabdomyolysis. In patients who develop myopathy while on simvastatin or atorvastatin, if the decision is to continue treatment with a statin, one option is to cautiously switch them to pravastatin, fluvastatin, or rosuvastatin, which are less prone to cause myopathy. Alternatively, lower statin dosing or less frequent dosing may

be considered. For instance, rosuvastatin has a long duration of action and can be taken once every other day or weekly<sup>1</sup> if necessary. Theoretically, coenzyme Q10<sup>7</sup> may help manage statin-induced myopathy, but there is insufficient data to support its use. For patients who cannot tolerate statins, other agents should be used, starting with validated nonstatin agents.

#### Ezetimibe

Ezetimibe (Zetia) is the first in a new class of pharmaceutical agents that primarily targets the cholesterol transport protein Niemann-Pick C1-like 1 protein in the intestine. Ezetimibe is an efficacious and cost-effective add-on agent in people taking a statin, if the LDL cholesterol goal is not achieved or high doses of statin cannot be tolerated. Ezetimibe was shown to modestly decrease LDL cholesterol and cardiovascular events when added to simvastatin in high-risk patients in the Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) study. Moreover, ezetimibe has become a generic prescription in the United States and its safety profile is well characterized. Elevated liver enzymes have been reported but the risk of hepatotoxicity seems to be not different from that of placebo.

<sup>1</sup>Not FDA approved for this indication

<sup>†</sup>Moderate-intensity statins (reduction of low-density lipoprotein (LDL) cholesterol 30%–50%).

<sup>‡</sup>High-intensity statins (reduction of LDL cholesterol >50%).

Modified from Penning-van Beest FJA, Termorshuizen F, Goettsch WG, et al. Adherence to evidence-based statin guidelines reduces the risk of hospitalizations for acute myocardial infarction by 40%: a cohort study. *Eur Heart J*. 2007;28:154–159.

### PCSK9 Inhibitors

The PCSK9 (proprotein convertase subtilisin/kexin type 9) protein plays a major role in regulating the number of LDL receptors at the cell surface, including on hepatocytes. Binding of the LDL receptor by PCSK9 leads to the destruction of the LDL receptor. Therefore interference with the binding capacity of PCSK9 to LDL receptor or silencing the expression of the PCSK9 gene allows more LDL receptors to recycle to the cell surface effecting the removal of more of the circulating plasma LDL. Over a decade ago, individuals with gain-of-function mutations of the PCSK9 gene were found to underlie a rare form of autosomal dominant hypercholesterolemia. Subsequently, individuals with loss-of-function mutations were found to have very low LDL cholesterol levels and were protected from coronary heart disease (CHD). These discoveries led to the development of monoclonal antibodies directed against PCSK9 as a novel cholesterol-lowering agent.

Two human monoclonal antibodies against PCSK9, alirocumab (Praluent) and evolocumab (Repatha), have been approved by the FDA. Both are given by subcutaneous injection. In the Further Cardiovascular Outcomes Research With PCSK9 Inhibition in Subjects With Elevated Risk (FOURIER) trial, evolocumab was found to significantly reduce the risk for ASCVD events in patients with clinical ASCVD and LDL-C  $\geq 70$  mg/dL or a non-HDL-C level  $\geq 100$  mg/dL, who were receiving optimized lipid-lowering using high-intensity statin or at least atorvastatin 20 mg with or without ezetimibe. Similarly, in the Evaluation of Cardiovascular Outcomes After an Acute Coronary Syndrome During Treatment With Alirocumab (ODYSSEY OUTCOMES) trial, alirocumab was shown to significantly reduce the risk for ASCVD events in patients with recent acute coronary syndrome, who had a LDL-C  $\geq 70$  mg/dL, a non-HDL-C  $\geq 100$  mg/dL, or an apolipoprotein B level  $\geq 80$  mg/dL and were receiving statin therapy at a high-intensity dose or at the maximum tolerated dose. Taking into account the results, inclusion criteria, and secondary analyses from these trials, the 2018 Multisociety guidelines recommended the consideration of PCSK9 inhibitors in secondary prevention patients, especially those at very high risk, whose LDL cholesterol remains above 70 mg/dL or non-HDL cholesterol remains above 100 mg/dL on maximally tolerated statin therapy. Both alirocumab and evolocumab are also indicated for heterozygous familial hypercholesterolemia. Evolocumab is also indicated for homozygous familial hypercholesterolemia as an adjunct to other LDL-lowering therapies.

PCSK9 inhibitors are powerful LDL cholesterol lowering agents and enable reduction of LDL cholesterol by up to ~60%

as a single agent or an adjunct therapy. Moreover, the absolute level of LDL cholesterol achieved may be as low as <25 mg/dL. There have been concerns regarding the potential adverse effects that may occur at such low LDL cholesterol levels, such as neurocognitive side effects. However, results from these trials and their sub-analyses have not shown a significant signal, although more long-term follow-up analysis is needed. Common side effects associated with PCSK9 inhibitors include injection site reactions, nasopharyngitis, upper respiratory tract infection, influenza, and back pain.

Currently, a significant hurdle to more widespread use of PCSK9 inhibitors is their high cost. Multiple cost-effective analyses have concluded that PCSK9 inhibitors are not yet cost effective. In 2018, the price of evolocumab was reduced by 60% by its manufacturer. Further studies will be needed to assess whether PCSK9 inhibitors are cost effective with this price reduction.

### Bile Acid Sequestrants

Bile acid sequestrants have been in clinical use for many decades. These agents promote fecal excretion of bile acids. The liver responds with increased integration of cholesterol into bile acid synthesis to maintain a stable bile acid pool. The consequent decrease in cholesterol in the liver leads to upregulation of the LDL receptor and enhanced LDL clearance from the plasma. HMG-CoA synthase activity can increase, so combination therapy with statins would be synergistic, especially in patients with a suboptimal response. Available agents are cholestyramine (Questran), colestipol (Colestid), and colesevelam (Welchol). Most side effects involve the gastrointestinal tract, with constipation and bloating being the most common. These agents may interfere with the absorption of warfarin, phenobarbital, levothyroxine (Synthroid), and digoxin (Lanoxin), among other medications. Patients on multiple medications should be advised to take bile acid sequestrants 1 hour before or 4 hours after taking the other medications. These agents can also cause elevation of triglyceride level. As they are not systemically absorbed, the bile acid sequestrants may be the preferred agents when systemic absorption is to be avoided, such as during pregnancy or lactation.

### Fibrates

The effect of fibrates on cardiovascular outcomes is not as favorable as with statins. However, fibrates can be useful in subsets of patients with high triglycerides and low-HDL cholesterol. Recently, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) lipid trial showed that addition of

fenofibrate to simvastatin in type 2 diabetic patients with cardiovascular risk factors did not improve cardiovascular outcomes, although there was a trend for better outcomes in a subgroup with triglycerides greater than 204 mg/dL and HDL cholesterol less than 34 mg/dL. Fibrates have multiple favorable metabolic effects including activation of peroxisome proliferator-activated receptor- $\alpha$  (contributing to the regulation of both lipid and carbohydrate metabolism), stimulation of lipoprotein lipase (increasing triglyceride hydrolysis), and downregulation of Apo CIII (improving lipoprotein remnant clearance as Apo CIII inhibits lipoprotein lipase). An enhanced VLDL-to-LDL conversion may lead to mild LDL cholesterol elevation in some patients. This effect may decrease over weeks, as the LDL receptors are upregulated. Fibrates are generally well tolerated. The most common side effect is dyspepsia. Other side effects include myopathy and hepatic enzyme elevation, particularly when fibrates are added to statins. The use of gemfibrozil (Lopid) should be avoided in patients on statin therapy due to increased risk for muscle-related adverse events. Fibrates increase the risk of gallstones, and patients on warfarin (Coumadin) may need dose adjustment. Monitoring of liver enzymes is recommended, at baseline and within 3 months and then periodically. Creatinine level can be increased through unclear mechanisms.

### Niacin

Niacin or nicotinic acid effectively decreases the hepatic production of VLDL and thus, LDL cholesterol levels, and raises HDL cholesterol levels by reducing cholesterol transfer from HDL to Apo B-containing lipoproteins and HDL clearance by the liver. Niacin is also the most potent agent currently available to reduce the level of Lp(a); however, this effect on the reduction of cardiovascular events in patients with elevated Lp(a) is not known. Several trials showed the effect of niacin in preventing cardiovascular disease; however, the benefit of adding niacin to statins has not been proved. Niacin did not improve cardiovascular risk when added to simvastatin in patients with high risk for cardiovascular disease in the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes (AIM-HIGH) study and the Heart Protection Study 2—Treatment of HDL to Reduce the Incidence of Vascular Events (HPS2-Thrive) study. There were excess adverse events and trends toward signs of harm among the niacin groups. The FDA has recently withdrawn the approval for the coadministration of niacin extended-release tablets (Niaspan) with statins. The most common side effect of niacin is flushing. This can be avoided or minimized by initiating therapy with a low dose of niacin, taking an aspirin 1 hour before niacin, avoiding hot foods or beverages at the time the niacin is taken, or switching to extended-release forms (Niaspan). Hepatotoxicity can occur at any time. Immediate-release forms are less likely to cause hepatotoxicity than sustained-release forms (Slo-Niacin). Extended-release forms can minimally elevate transaminases but significant hepatotoxicity is rare. They can, however, also cause dose-dependent reversible thrombocytopenia, which can be insidious and severe. When switching to different forms, it is recommended that one should start with low doses and titrate up to achieve desired response. Liver function tests should be monitored regularly, at baseline and every 3 months for the first year and then periodically. Other side effects include pruritus, increased uric acid levels, and hyperglycemia.

### Omega-3 Fatty Acid Prescriptions

Highly purified omega-3 fatty acid preparations containing either a mixture of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Lovaza) or EPA alone (Vascepa) are effective agents used in the treatment of hypertriglyceridemia, the first FDA approved indication for these agents.

Omega-3 fatty acids are polyunsaturated fatty acids (PUFA) and are essential in humans. A significant proportion of omega fatty acids is consumed in the diet. Major dietary sources of omega-3 fatty acids include nuts, vegetable oils, flax seeds, and leafy vegetables as well as fish and fish oil. EPA and DHA are the two major types of marine-derived omega-3 fatty acids. The mechanism by which omega-3 fatty acids lower triglycerides is incompletely understood.

Multiple clinical trials have been examining the efficacy of omega-3 fatty acid in improving cardiovascular outcome. Although trials using lower doses of EPA-DHA mixtures ( $\leq 1$  g total daily) have shown inconsistent results, findings from recent trials assessing higher doses of pure EPA have been more favorable.

Purified EPA was first shown in the Japan Eicosapentaenoic acid (EPA) Lipid Intervention Study (JELIS) trial to significantly reduce risk for major coronary events in patients with hypercholesterolemia. Subsequently, the Reduction of Cardiovascular Events With Icosapent Ethyl—Intervention Trial (REDUCE-IT) study, a large, randomized controlled trial, assessed the efficacy and safety of purified EPA ethyl ester, icosapent ethyl (Vascepa) in secondary prevention and high-risk primary prevention patients with reasonably controlled LDL cholesterol but elevated triglycerides. The REDUCE-IT trial showed that treatment with icosapent ethyl was associated with a significant reduction in ASCVD events. In secondary analyses, icosapent ethyl has also been shown to reduce the risk for total ischemic events (first plus subsequent events). Results from REDUCE-IT suggest that in addition to LDL cholesterol lowering, high-risk patients with elevated triglycerides will likely benefit from icosapent ethyl. It is unknown whether higher doses of EPA-DHA mixtures may have similar efficacy as purified EPA; however, the relevant trial is underway. Lastly, the overall rates of adverse events were not significantly different between the treatment and control arms of REDUCE-IT. However, there were increased rates of atrial fibrillation and peripheral edema associated with patients taking icosapent ethyl observed in the trial.

## HYPERPARATHYROIDISM AND HYPOPARATHYROIDISM

Method of

Claudio Marcocci, MD; and Filomena Cetani, MD

### CURRENT DIAGNOSIS

#### Primary Hyperparathyroidism

- Third most common endocrine disorder and most common cause of hypercalcemia in the general population.
- Diagnosis based on confirmed hypercalcemia (total calcium [albumin corrected] or ionized calcium) associated with elevated or inappropriately normal serum parathyroid hormone level.
- Hypercalcemia on routine blood testing or in postmenopausal women investigated for osteoporosis is typically the first clue to the diagnosis.
- Mainly occurs as a solitary disease (90%) but may be part of hereditary syndromes.
- Genetic causes should be searched for in young patients.

#### Secondary Hyperparathyroidism

- Secondary hyperparathyroidism defines any condition in which the increased PTH secretion occurs as a normal physiologic response, often mediated by a decrease of serum calcium.
- Vitamin D deficiency, as a result of inadequate nutritional intake/sun exposure, malabsorption, liver diseases, or chronic renal failure, is the most common cause.
- At variance with primary hyperparathyroidism, secondary hyperparathyroidism is characterized by low or, more often, low-normal serum calcium and decreased urinary calcium excretion.

#### Hypoparathyroidism

- Rare disorder.
- Inadvertent removal or damage to the parathyroid gland during thyroid surgery and, much less frequently, autoimmune destruction are the most common causes.
- Diagnosis based on low serum calcium along with undetectable or inappropriately low serum parathyroid hormone level.

### CURRENT THERAPY

#### Primary Hyperparathyroidism

- Parathyroidectomy is the only definitive therapy.
- Surgery should be considered in all cases and recommended in symptomatic patients and in those who, albeit asymptomatic, meet the surgical criteria.
- Surveillance without surgery can be considered in asymptomatic patients who do not meet the surgical criteria.
- Patients followed without surgery should be replete with vitamin D and calcium intake should not be restricted.
- Medical treatment can be considered in selected cases: antiresorptive therapy to increase bone mineral density and cinacalcet (Sensipar) to lower serum calcium.

#### Hypoparathyroidism

- Severe hypocalcemia is a medical emergency and treatment with intravenous calcium should be promptly instituted and maintained for 24 to 48 hours; oral therapy with calcium and active vitamin D metabolites should be started as soon as practical.

- The goal of chronic treatment is to maintain serum calcium in the low-normal range, avoiding hypocalcemic symptoms and long-term complications.
- Chronic conventional therapy is based on adequate calcium intake (calcium supplement needed in most cases) and active vitamin D metabolites.
- Recombinant full-length parathyroid hormone 1-84 (Natpara) has been approved by the U.S. Food and Drug Administration and European Medicines Agency for patients not controlled with conventional therapy.
- An individualized approach is necessary to optimize patient care. Lifelong monitoring is needed to decrease the risk of complications.

## Primary Hyperparathyroidism

### Epidemiology

Primary hyperparathyroidism (PHPT) is currently the third most common endocrine disorder and the most frequent cause of hypercalcemia in the general population.

The disease was considered rare until the early 1970s, when its incidence in the United States rose dramatically following the introduction of serum calcium in the multichannel autoanalyzer. The incidence varies according to geographic areas and assessment measures; recent data in the United States indicate an incidence of 79.6 per 100,000 person-years in women and 35.6 per 100,000 person-years in men of all races, with the highest rate among blacks. The incidence peaks in the sixth decade of life. The prevalence ranges between 1 and 7 cases per 1000 adults. Most cases occur in women (with a female-to-male ratio of 3:1), but there is no sex difference before the age of 45 years. PHPT is rare in children and adolescents.

### Pathogenesis

PHPT mainly occurs as a solitary disease (90%) but may be part of hereditary syndromes (e.g., multiple endocrine neoplasia [MEN] types 1, 2A, 4, and 5 hyperparathyroidism–jaw tumor syndrome [HPT-JT], and familial isolated hyperparathyroidism [FIPH]) (Table 1). A single, benign adenoma is found in 80% to 85% of cases, multigland involvement in 15% to 20%, and parathyroid carcinoma in less than 1%. Multigland involvement is more common in hereditary cases, particularly MEN1. In the absence of local infiltration or metastases, the diagnosis of parathyroid carcinoma may be difficult at histology. Genetic studies (*CDC73* gene mutations) and immunohistochemical studies (loss of parafibromin [the protein encoded by the *CDC73* gene] expression) may help in equivocal cases. Predisposing factors are external neck irradiation in childhood and long-term lithium therapy.

PHPT is characterized by excessive parathyroid hormone (PTH) secretion from one or more parathyroid glands, due to the loss of the homeostatic control of PTH synthesis and secretion. Extracellular ionized calcium ( $\text{Ca}^{2+}_o$ ) is the main regulator of PTH secretion.  $\text{Ca}^{2+}_o$  interacts with the  $\text{Ca}^{2+}$ -sensing receptor (CaSR) present on the surface of parathyroid cells; there is an inverse sigmoidal relationship between  $\text{Ca}^{2+}_o$  concentration and PTH release. In adenomas hypercalcemia is due to the loss of normal sensitivity of the parathyroid cell to the inhibitory action of  $\text{Ca}^{2+}_o$ , whereas in parathyroid hyperplasia the increased number of parathyroid cells, which have a normal sensitivity to the inhibitory action of  $\text{Ca}^{2+}_o$ , causes hypercalcemia. Serum phosphate, 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ), and fibroblast growth factor 23 (FGF23) are also involved in the control of PTH secretion.

Although major progress has been made in the last two decades, the molecular basis of PHPT is still unclear in the majority of cases. The clonality of most parathyroid tumors suggests a defect in the pathways that control parathyroid cell proliferation or the expression of PTH. The genes involved are listed in Table 1. Germline mutations are often found in hereditary forms. On the

**TABLE 1** Hereditary Forms of PHPT and Related Involved Gene

DISORDER	GENE	PATTERN OF INHERITANCE
Multiple endocrine neoplasia type 1	<i>MEN1</i>	Autosomal dominant

Neonatal severe hyperparathyroidism	<i>CASR</i>	Autosomal recessive

*Abbreviations:* AP2S1 = Adaptor-related protein complex 2 sigma 1 subunit; CASR = calcium-sensing receptor; CDC73 = cell division cycle 73; CDKN1B = cyclin-dependent kinase inhibitor 1B; GCM2 = glial cells missing transcription factor 2; GNA11 = G protein subunit alpha 11; MAX = myc-associated factor x; MEN1 = multiple endocrine neoplasia type 1; PHPT = primary hyperparathyroidism; RET = rearranged during transfection.

other hand, somatic mutations may occur in sporadic cases, even though germline mutations have also been described in apparently sporadic cases.

### Clinical Presentation

In recent years the clinical presentation of PHPT in Western countries has changed from a symptomatic disease, characterized by hypercalcemia and renal (nephrolithiasis and nephrocalcinosis) and skeletal (osteitis fibrosa cystica, fragility fractures) manifestations, to one with subtle and nonspecific clinical manifestations (asymptomatic PHPT). Nephrolithiasis remains the most common classic clinical manifestation (15%–20%), and silent stones are frequently detected at ultrasound. Bone mineral density (BMD) is reduced particularly at sites rich in cortical bone (one-third distal radius). Studies using peripheral high-resolution quantitative computed tomography (CT) has shown involvement of both cortical and trabecular sites, the latter confirmed by the trabecular bone score (TBS) at the lumbar spine. An increased rate of vertebral and nonvertebral fractures has also been documented. Nonclassical manifestations, including subtle cardiovascular abnormalities and psychological and cognitive symptoms, have also been reported.

A new variant of PHPT (normocalcemic PHPT) has recently been identified, namely patients with increased serum PTH levels in the absence of hypercalcemia (also by measurement of ionized calcium) or other causes of secondary hyperparathyroidism. This condition, called normocalcemic PHPT, has been typically recognized in persons evaluated for low BMD, in whom PTH was measured even in the absence of hypercalcemia. In some cases this new phenotype may represent an early phase of classical hypercalcemic PHPT, when PTH elevation precedes the occurrence of hypercalcemia.

## Evaluation and Diagnosis

The finding of hypercalcemia on routine blood testing or in postmenopausal women investigated for osteoporosis is typically the first clue to the diagnosis of PHPT. Hypercalcemia should be confirmed in repeated testing, preferably evaluating albumin-corrected total calcium (measured total calcium in mg/dL +  $[0.8 \times (4.0 - \text{serum albumin in g/dL})]$ ) or ionized calcium. The next diagnostic step is the measurement of serum PTH. An elevated (or unexpectedly normal) serum PTH in the face of hypercalcemia is virtually diagnostic of PHPT. Serum phosphate is normal or in the low-normal range in mild PHPT and low in severe cases. A low or undetectable PTH level in a hypercalcemic patient rules out the diagnosis of PHPT. The most common cause of PTH-independent hypercalcemia is malignancy, where hypercalcemia is due to the secretion by the tumor of PTH-related peptide, a molecule that shares with PTH the amino-terminal active part but does not cross-react in the PTH assay, or osteolytic lytic bone metastases. Urinary calcium should also be measured. If hypercalciuria is greater than 400 mg per day, a more extended evaluation of the stone risk profile should be performed. Urinary calcium measurement is also useful to exclude familial hypocalciuric hypercalcemia (FHH), which is suggested by the finding of the calcium-to-creatinine clearance ratio of less than 0.01.

A hereditary form of PHPT, accounting for 5% to 10% of cases, should be sought in patients younger than 30 years at diagnosis, with a family history of hypercalcemia and/or neuroendocrine tumors (see Table 1). In this setting serum calcium should be measured in first-degree relatives and genetic tests performed. Parathyroid cancer should be suspected in individuals, especially males, with marked hypercalcemia, a palpable neck mass, and serum PTH concentration 3 to 10 times the upper normal value. Some ultrasound features may raise the suspicion for cancer, such as a large (i.e., >3 cm) lobulated hypochoic/heterogeneous parathyroid gland with irregular borders, thick capsule, suspicious vascularity, and calcifications.

Renal ultrasound should be performed in all patients, even in those with no history of nephrolithiasis, since recent studies have shown that silent kidney stones are common in patients with asymptomatic PHPT. Routine BMD testing by dual-energy x-ray absorptiometry (DXA) at the lumbar spine, hip, and distal forearm is also an essential component of the evaluation. BMD is typically low at the one-third distal radius, a site of enriched cortical bone, but a few patients may show predominant cancellous bone involvement, as documented by vertebral osteopenia or osteoporosis. The involvement of the trabecular compartment is also confirmed by the TBS at the lumbar spine. Vertebral imaging by x-ray or DXA (vertebral fracture assessment, VFA) should also be routinely performed to detect silent vertebral deformities since vertebral fracture risk is increased in asymptomatic patients.

Neck imaging (ultrasound and sestamibi scanning) has no value in the diagnosis of PHPT, but it is a useful tool for localizing the abnormal parathyroid gland in patients selected for parathyroidectomy (PTx). Sestamibi has the advantage of localizing the ectopic parathyroid gland outside the neck. The 4D computerized tomography protocol has emerged as a useful tool. Recently 18F-fluorocholine positron emission tomography (PET) has proven to be useful in the localization of hyperfunctioning parathyroid glands before surgery.

## Treatment

The aim of treatment is to remove all hyperfunctioning parathyroid tissue, resolve biochemical abnormalities, improve BMD, and decrease the risk of nephrolithiasis and fractures.

### Surgical Treatment

Parathyroid surgery represents the only definitive cure of PHPT. Successful PTx normalizes serum calcium and PTH, improves BMD, and decreases the risk of nephrolithiasis and fragility fractures. Patients selected for surgery should be referred to an experienced parathyroid surgeon. A focused, minimally invasive approach, guided by imaging studies associated with

**TABLE 2** Guidelines for Surgery for Patients With Asymptomatic PHPT and Monitoring for Those Followed Without Surgery

*Abbreviations:* BMD = bone mineral density; CT = computed tomography; DXA = dual x-ray absorptiometry; MRI = magnetic resonance imaging; PHPT = primary hyperparathyroidism; VFA = vertebral fracture assessment.

Modified from Bilezikian et al. Guidelines for the management of asymptomatic primary hyperparathyroidism: Summary statement from the fourth international workshop. *J Clin Endocrinol Metab* 99:3561, 2014.

intraoperative monitoring of serum PTH, is the preferred surgical procedure in sporadic PHPT. In experienced hands the rate of surgical cure reaches 95% to 98% with a negligible rate of surgical complications. In hereditary cases the surgical approach (bilateral neck exploration by classical cervicotomy) may differ, since multigland involvement is common. An *en bloc* resection of the parathyroid lesion together with the ipsilateral thyroid lobe with clear gross margins and the adjacent structures is recommended when parathyroid carcinoma is suspected. Particular attention should be paid to avoid seeding of neoplastic parathyroid cells. Surgery should be considered for any patient with a confirmed diagnosis of PHPT and recommended in those with symptomatic disease.

Patients with mild hypercalcemia (serum calcium < 12 mg/dL [3 mmol/L]) can proceed directly to surgery. When serum calcium is higher, preoperative treatment with saline infusion eventually followed by loop diuretics, intravenous bisphosphonates, denosumab (Prolia, Xgeva)<sup>1</sup>, or cinacalcet (Sensipar) may be considered to reduce serum calcium levels and decrease the risk of complications, particularly cardiac arrhythmias, which are associated with more severe hypercalcemia.

Surgery is also a reasonable option for patients with asymptomatic PHPT. International guidelines provide guidance to select patients who should be referred for surgery or followed without surgery. The most recent revised (2013) guidelines for surgery or monitoring are reported in Table 2. These guidelines are largely consistent with the previous ones and recommend PTx for all patients with symptomatic PHPT and asymptomatic patients who meet one or more of the indicated criteria. The new indications for surgery in asymptomatic patients include (1) the presence of silent vertebral fractures detected by x-ray, CT, magnetic resonance imaging (MRI), or vertebral fracture assessment (VFA) by DXA; and (2) a 24-hour urinary calcium excretion greater than 400 mg/dL, increased stone risk (evaluated by urinary stone risk

<sup>1</sup>Not FDA approved for this indication.

profile), and subclinical kidney stone or nephrocalcinosis detected by x-ray, ultrasound, and CT. According to the guidelines, about 60% of patients with asymptomatic PHPT meet the criteria for surgery. As mentioned before, patients with mild PHPT may have subtle cardiovascular abnormalities and complain of psychological and cognitive symptoms. It is unclear whether and to what extent these abnormalities are reversible after successful PTx; for the time being they are not considered indications for surgery. Nonetheless, surgery could be considered in a middle-aged patient in whom asymptomatic PHPT is associated with increased cardiovascular risk (metabolic syndrome, hypertension, ischemic heart disease) if the surgical risk is low.

Randomized clinical trials have also shown that patients with sporadic asymptomatic PHPT who do not meet the surgical criteria may benefit from surgery, not only because it normalizes serum calcium and PTH, but also because it improves BMD and quality of life (QoL). On the other hand, surgery could be postponed in hereditary cases with mild hypercalcemia, because multigland disease, occasionally with asynchronous involvement of the various parathyroid glands, is not uncommon and carries an increased risk of surgical complications and recurrence/persistence of PHPT.

Therefore individual counseling addressing the benefits and risks of PTx is mandatory, and the preference of the patients should be taken into account. It is well known that parathyroid surgery, when performed by skilled neck surgeons, is safe, cost-effective, and associated with low perioperative morbidity. On the other hand, it is important to recognize that PTx, particularly if performed by inexperienced surgeons, may be associated with complications that could be invalidating and not acceptable for a patient with mild disease and a good QoL. In this regard, the choice of surgery may be reconsidered in a patient with asymptomatic PHPT in whom parathyroid surgery was initially advised or selected by the patient when preoperative imaging studies are negative. Indeed, in this setting the patient may feel uncomfortable undergoing a blind neck exploration, a surgical procedure more extensive than the minimally invasive approach and carrying the greatest risk of complications.

### **Nonsurgical Management**

As mentioned before, many patients with PHPT do not meet the criteria for surgery. These patients, as well as those who decline surgery or have contraindications to surgery, need to be monitored.

**Monitoring.** Randomized clinical studies have shown stability over a short period of observation (up to 2 years) in patients with asymptomatic PHPT followed without surgery and benefits in those who underwent PTx even if they did not meet the criteria for surgery. The extension up to 5 years of one of these randomized studies has shown a more frequent occurrence of a vertebral fracture in patients belonging to the observation group than in those cured by PTx. Long-term observational studies indicate that the disease remains stable in the majority for up to 8 to 9 years, but more than one-third of patients show a progression of the disease.

Calcium intake should not be restricted, and an intake appropriate for age and sex as in the general population (preferably with food) should be recommended. Vitamin D–depleted patients should be supplemented with daily doses of 800 to 1000 IU of vitamin D; weekly or monthly doses calculated on this daily dose can also be used. A serum level of 25(OH)D greater than 20 ng/mL should be reached, and the attainment of a higher target (> 30 ng/mL) is suggested by some guidelines.

General principles for monitoring are reported in Table 2. Serum calcium and creatinine (estimated glomerular filtration rate [eGFR]) should be measured annually and BMD at the lumbar spine, total hip, and distal forearm measured every 1 to 2 years. Vertebral morphometry (by x-ray or VFA) should be performed when clinically indicated (back pain, height loss). Finally, 24-hour urinary collection for biochemical stone risk profile and renal imaging (x-ray, ultrasound, or CT) should be performed if there is a suspicion of renal stones.

Parathyroid surgery should be recommended in patients who are followed without surgery in the following instances: (1) serum calcium concentration greater than 1 mg/dL above the upper normal limit; (2) creatinine clearance less than 60 mL/min; (3) detection of nephrocalcinosis or kidney stones; (4) BMD T-score at any site less than  $-2.5$  or the finding of a significant (greater than the least significant change as defined by the International Society for Clinical Densitometry) decrease of BMD, even if the T-score is not less than  $-2.5$ ; and (5) clinical fractures or morphometric vertebral fractures, even if asymptomatic.

**Medical Treatment.** No medical treatment is currently available to cure PHPT. Therefore when PTx is indicated and there are no contraindications for surgery, medical treatment should not be considered a valuable alternative option. Medical treatment may be considered for patients who have contraindications to surgery or are unwilling to undergo PTx, as well as for those who have failed surgery. Treatment should be guided by the aim of therapy.

**Calcimimetics.** If the aim of treatment is to reduce serum calcium, the calcimimetic cinacalcet (Sensipar) can be effective. The serum calcium typically declines over a few weeks and may normalize in most patients with moderate hypercalcemia. In addition, cinacalcet increases serum phosphate and only slightly reduces PTH concentration, but has no effect on BMD. The beneficial effects are sustained over time as long as the drug is used. Adverse events are dose related: modest and transient when low doses of cinacalcet are used (up to 30 mg twice daily), but rather frequent, particularly gastrointestinal, symptoms, occasionally severe enough to require treatment withdrawal, when higher doses are employed. The use of cinacalcet has been approved by the US Food and Drug Administration (FDA) for the treatment of severe hypercalcemia in patients with PHPT who are unable to undergo PTx, and by the European Medical Agency (EMA) for the reduction of hypercalcemia in patients with PHPT, for whom PTx would be indicated on the basis of serum calcium levels (as defined by relevant guidelines), but in whom surgery is not clinically appropriate or contraindicated. As clearly stated, the EMA indications leave more room for the use of cinacalcet.

Cinacalcet should not be used as an initial treatment or in patients who do not meet the approved criteria for its prescription. The long-term safety of cinacalcet has not been established. Moreover, the rather high cost is another important limit for its long-term use.

**Antiresorptive Therapy.** If the aim is to increase BMD, antiresorptive therapy can be considered. Alendronate (Fosamax) is the bisphosphonate that has been more extensively used and shown to be effective in reducing bone turnover markers and increasing BMD. Over a short period of time, its effectiveness in increasing BMD is comparable to that observed after successful PTx. No effect has been shown on serum calcium and PTH levels. BMD also improved in a retrospective study that included 50 elderly women treated with denosumab for 2 years.

**Combined Therapy With Cinacalcet and Antiresorptive Therapy.** As mentioned before, cinacalcet is effective in the control of hypercalcemia but has no effect on BMD. Conversely, bisphosphonates increase BMD, with no effect on serum calcium. Limited data indicate that combination therapy is associated with both the calcium-lowering effect of cinacalcet and the skeletal advantage of bisphosphonates. Therefore if a patient has a low BMD and serum calcium concentration appropriate for the use of cinacalcet, combined therapy could be of benefit. A recent study has shown that denosumab<sup>1</sup> is effective in increasing BMD and lowering bone turnover irrespective of cinacalcet treatment and might be a valid option for patients in which surgery is undesirable.

### **Pregnancy and Lactation**

PHPT may be diagnosed during pregnancy by the finding of hypercalcemia on routine blood testing. There are some distinctive features that should be considered in the evaluation and management: (1) pregnancy is associated with hemodilution and occasionally hypoalbuminemia, and therefore it would be

preferable to measure ionized calcium; (2) the hereditary form should be sought because of the young age of pregnant women; and (3) women with mild elevation of calcium should be managed conservatively, mostly by hydration—in the case of worsening of hypercalcemia PTx in the second trimester and cinacalcet<sup>1</sup> may be considered.

### Secondary Hyperparathyroidism

Secondary hyperparathyroidism (SHPT) defines any condition in which the increased PTH secretion occurs as a normal physiologic response, often mediated by a decrease of serum calcium. Vitamin D deficiency, as a result of inadequate nutritional intake/sun exposure, malabsorption, liver diseases, or chronic renal failure, is the most common cause. Other, less common causes include vitamin D resistance (Fanconi syndrome, vitamin D receptor defects), PTH resistance (pseudohypoparathyroidism, hypomagnesemia), drugs (calcium chelators, inhibitors of bone resorption, and drugs that interfere with vitamin D metabolism [phenytoin and ketoconazole]), acute pancreatitis, and osteoblastic metastases (prostate and breast cancer).

SHPT should always be considered and ruled out before making the diagnosis of normocalcemic PHPT. At variance with PHPT, SHPT is characterized by low or, more often, low-normal serum calcium and decreased urinary calcium excretion. An elevation of serum phosphate levels can be a clue to pseudohypoparathyroidism.

A prolonged stimulation of PTH synthesis and secretion, as may occur in end-stage renal failure and severe gastrointestinal diseases, may lead to the emergence of an autonomous clone of parathyroid cells into a single gland, leading to hypercalcemia (tertiary hyperparathyroidism).

### Hypoparathyroidism

Hypoparathyroidism (HypoPT) is the clinical spectrum caused by insufficient production of PTH by the parathyroid glands. The major distinguishing feature is hypocalcemia, resulting from inadequate mobilization of calcium from bone and reabsorption of calcium at the distal tubule, and decreased activity of renal 1 $\alpha$ -hydroxylase and therefore generation of calcitriol; as a consequence, the intestinal calcium absorption will be reduced.

### Epidemiology

HypoPT is a rare condition designated in both the United States and Europe as an orphan disease. The estimated prevalence is 37 and 24 per 100,000 inhabitants in the United States and Europe, respectively.

### Pathogenesis

HypoPT can be congenital or acquired (Table 3).

Congenital HypoPT is usually hereditary and may be isolated or combined with organ defects. The autoimmune is the most common form and may be either isolated or part of the autoimmune polyglandular syndrome type 1 (APS1). The other forms are much more rare.

Acquired HypoPT is much more common than the congenital counterpart. Bilateral neck surgery for thyroid or parathyroid disorders is the most common cause. Postoperative HypoPT can be transient (caused by reversible parathyroid ischemia and resolving within a few weeks) or chronic/permanent (caused by irreversible parathyroid damage such as ischemia, electric scalpel damage, or, rarely, inadvertent removal of parathyroid glands). Its rate largely depends on the experience of the surgeon and the extent of the neck surgery.

### Clinical Presentation

The clinical manifestations of HypoPT are largely related to the level of serum calcium and the speed of its fall and may range from asymptomatic cases, when hypocalcemia is mild (corrected

**TABLE 3** Classification of Hypoparathyroidism\*

#### Congenital

- Isolated
  - Defective PTH biosynthesis (*PTH*)<sup>^</sup>
  - Abnormal development of parathyroid glands (*GCM2*, *GCM2*, *GATA3*)
  - Autosomal dominant hypocalcemia
    - Type 1 (*CASR*)
    - Type 2 (*GNA11*)
- Associated with additional features or organ defects
  - Autoimmune
    - Isolated
    - Polyglandular syndrome type 1 (*AIRE*)
  - Di George syndrome (*TBX1*)
  - Sanjad-Sakati/Kenny-Caffey type 2 (*TBCE*)
  - Kenny-Caffey type 2 (*FAM111A*)
  - Mitochondrial DNA mutations
- Defective action of PTH
  - Pseudohypoparathyroidism
    - Type 1a (*GNAS*)
    - Type 1b (*STX16*, *GNAS*; in sporadic form paternal UPD)
    - Type 1c (*GNAS*)
    - Type 2 (not yet identified)

#### Acquired

- Destruction or removal of the parathyroid glands
  - Postoperative (neck surgery)
  - Radiation induced
  - Infiltration of the parathyroid glands (metastatic, granulomatous)
  - Deposition of heavy metals (iron, copper)
- Reversible impairment or PTH secretion or action
  - Severe magnesium deficiency
  - Hypermagnesemia (e.g., due to tocolytic therapy)
- CaSR-stimulating antibodies

\*Mutated genes are indicated in parentheses.

**Abbreviations:** *AIRE* = autoimmune regulatory; *CASR* = calcium-sensing receptor; *FAM111A* = family with sequence similarity 111 member A; *GATA3* = GATA-binding protein 3; *GCM2* = glial cell missing homolog 2; *GCM2* = glial cell missing gene; *GNA11* = G protein subunit alpha 11; *GNAS* = GNAS complex locus; *PTH* = parathyroid hormone; *STX16* = syntaxin 16; *TBCE* = tubulin folding cofactor E; *TBX1* = T-Box1; UPD = uniparental disomy.

calcium  $\geq$  7.0 mg/dL [1.75 mmol/L]), to a severe, life-threatening condition that requires hospital admission and intensive treatment. In mild cases signs related to neuromuscular irritability, namely the Chvostek sign (twitching and/or contracture of the facial muscles produced by tapping on the facial nerve just anterior to the ear and just below the zygomatic bone) and Trousseau sign (carpal spasm evoked by inflating a sphygmomanometer cuff above systolic blood pressure for several minutes), may be present at physical examination. Moderate to severe hypocalcemia (corrected calcium  $<$  7.0 mg/dL [1.75 mmol/L]) is usually symptomatic, even though there is no strict relationship between the severity of symptoms and the degree of hypocalcemia. In patients with postoperative HypoPT, symptoms usually appear on the first postoperative day, but in some cases hypocalcemia may become clinically manifest even after 3 to 4 days. Classical manifestations include paresthesias, carpedal spasm, tetany, seizures, positive Chvostek and Trousseau signs, and prolongation of the QT interval on electrocardiography. Papilledema and subcapsular cataract can be present. Pseudohypoparathyroidism is a group of genetic disorders caused by end-organ resistance to the action of PTH. Patients with the type 1a variant have a typical phenotype (Albright hereditary osteodystrophy), characterized by short stature, shortened fourth and fifth metacarpals, rounded face, and mild intellectual deficiency. Other endocrine glands, including the thyroid and the gonads, may be dysfunctional. This clinical and endocrine phenotype is also typical of patients with type 1c. Patients with type 1b have PTH resistance and in some cases partial resistance to thyroid-stimulating hormone (TSH) and mild brachydactyly. Patients with the type 2

<sup>1</sup>Not FDA approved for this indication.

**TABLE 4** Calcium Preparation and Vitamin D Metabolites in the Management of Hypocalcemia

Calcium	AGENT	FORMULATION AND DOSE	COMMENTS	
Calcium gluconate		One ampule of 10% calcium gluconate contains 93 mg; preferably diluted in 5% dextrose	Tissue necrosis may be caused by elemental calcium; preferably diluted in 5% dextrose extravasation in the adjacent subcutaneous space	
Calcium salts				
Calcium carbonate		40% elemental calcium by weight: 1 g calcium carbonate contains 400 mg elemental calcium	Best absorbed with meals in an acidic environment; constipation is a common side effect	
Calcium citrate		21% elemental calcium by weight, 1 g calcium citrate contains 210 mg elemental calcium	Well absorbed independent of meal and acid environment; in patients with atrophic gastritis or taking proton pump inhibitors	
<b>Vitamin D Metabolites</b>				
	MEDICATION	TYPICAL DAILY DOSE	TIME TO ONSET OF ACTION	TIME TO OFFSET OF ACTION
	Calcitriol [1,25(OH) <sub>2</sub> D] <sub>3</sub> (Rocaltrol)	0.25–2.0 µg once or twice	1–2 days	2–3 days
	Alfacalcidol* [1α(OH)D]*	0.5–4 µg once	1–2 days	5–7 days
	Dihydroxycholecalciferol* <sup>†</sup>	0.3–1.0 mg once	4–7 days	7–21 days
	Vitamin D <sub>2</sub> (ergocalciferol) (Drisdol) or vitamin D <sub>3</sub> (cholecalciferol) <sup>‡</sup>	25,000–200,000 IU	10–14 days	14–75 days

\*Not available in the United States.

<sup>†</sup>This compound is rapidly activated in the liver to 25(OH) dihydroxycholecalciferol.

<sup>‡</sup>These compounds could be used in a setting where active vitamin D metabolites are not available and/or are too expensive.

Modified from Shoback D: Clinical practice. Hypoparathyroidism. *N Engl J Med* 2008;359:391–403, 2008.

variant have PTH resistance in the absence of the aforementioned clinical phenotype.

### Evaluation and Diagnosis

The finding of low albumin-corrected serum calcium, high serum phosphate, and inappropriately low or undetectable serum PTH confirms the diagnosis of HypoPT. A recent neck surgery strongly suggests the postoperative form. A family history of hypocalcemia suggests a genetic cause. Coexistence of other autoimmune endocrinopathies (i.e., adrenal insufficiency) or candidiasis prompts consideration of APS1. Immunodeficiency and the presence of other congenital organ defects point to DiGeorge syndrome. Genetic testing may be warranted to confirm the diagnosis of this and other genetic forms. Magnesium should also be measured because magnesium deficiency impairs the secretion of PTH and its action in target tissues. Urinary calcium is usually low because of the low filtered calcium. The 24-hour calcium-to-creatinine clearance ratio is increased in patients with the activating mutation of *CaSR*. A biochemical profile of low serum calcium and high phosphate levels, together with high serum PTH, in the absence of vitamin D deficiency, reflects the PTH-resistant state, and suggests a case of pseudohypoparathyroidism.

### Treatment

The goal is to control symptoms of hypocalcemia and improve QoL while avoiding side effects and complications. The target serum calcium concentration is in the lower part of the normal range. Treatment relies on the administration of calcium (oral [dietary or supplements] or intravenous), active vitamin D metabolites, magnesium, and, where available, recombinant human PTH<sub>1-84</sub> (Natpara). Thiazide diuretics may help reduce hypercalciuria; a low-phosphate diet and phosphate binders may help control hypophosphatemia and lower the calcium–phosphate product.

### Acute Hypoparathyroidism

Acute hypocalcemia typically follows neck surgery and may be favored by a low vitamin D status and magnesium deficiency that,

when present, should be corrected before surgery. In patients with high risk (total thyroidectomy, repeated thyroid surgery), perioperative administration of calcitriol (Rocaltrol) decreases the incidence of postoperative hypocalcemia and shortens the hospital stay.

**Mild Hypocalcemia.** In mild hypocalcemia (corrected calcium  $\geq 7.0$  mg/dL [1.75 mmol/L]), oral calcium supplements (usually calcium carbonate, 1–3 grams daily in divided doses) alone or combined with active vitamin D metabolites should be administered. Calcitriol is typically initiated at an initial dose of 0.5 to 1.0 µg twice daily; equivalent doses of 1α-calcifediol<sup>2</sup> (1.0–2.0 µg) may also be used (see later [Chronic Hypoparathyroidism, Conventional Therapy] for more details on calcium and active vitamin D therapy) (Table 4). Serum calcium is checked weekly until optimal levels are reached.

**Moderate to Severe Hypocalcemia.** Patients with moderate to severe hypocalcemia (corrected calcium  $<7.0$  mg/dL [1.75 mmol/L]) are usually admitted to the hospital and treated with IV calcium until an oral regimen can be started. One to two ampules of 10% calcium gluconate diluted in 50 to 100 mL of 5% dextrose should be infused over a period of 10 to 20 minutes with electrocardiographic and clinical monitoring. The calcium infusion will raise the serum calcium concentration for no more than 2 to 4 hours; thus this initial treatment should be followed by a continuous infusion (50–100 mL/h) of a solution containing 1 mg/mL of elemental calcium (11 ampules of 10% calcium gluconate added to 5% dextrose in a final volume of 1 liter). The rate should be adjusted according to corrected serum calcium level, which should be measured initially every 1 to 2 hours and subsequently every 4 to 6 hours, and maintained at the lower limit of the normal range, while the patient is asymptomatic. This calcium infusion protocol maintained for 8 to 10 hours will raise serum calcium by approximately 2 mg/dL. Oral administration of active vitamin D metabolites and calcium should be started as soon as practical. Calcitriol is typically initiated at a dose of 0.5 to 1.0 µg twice daily; oral calcium (1–3 g daily in divided doses) is also added.

<sup>2</sup>Not available in the United States.

If hypocalcemia is due to magnesium deficiency, the previous protocol should be applied while magnesium is being replaced by administering IV magnesium sulfate (initial dose 2 g as a 10% solution over 10–20 minutes, followed by 1 g/h in 100 mL) until a normal serum level of magnesium is reached. The only administration of magnesium will be unable to correct hypocalcemia because hypomagnesemia inhibits the secretion of PTH, and consequently the renal activation of 25OHD and induces a peripheral resistance to the action of PTH.

The rate of calcium infusion should be increased if symptoms of hypocalcemia recur. The IV infusion should be slowly tapered and discontinued when an effective regimen of oral calcium and active vitamin D is reached (up to 24–48 hours or longer) and stable desired serum calcium levels are obtained.

### Chronic Hypoparathyroidism

The goal of therapy is to maintain serum calcium in the low-normal range, avoid hypocalcemic symptoms and long-term complications, and improve QoL. An individualized approach is necessary to optimize patient care. Guidelines for the management of chronic HypoPT have only recently been developed by the European Society of Endocrinology, the American Association of Clinical Endocrinologists, the American College of Endocrinology, and a panel of international experts.

**Conventional Therapy.** An adequate calcium intake from dietary sources (mainly dairy products) should be recommended, but calcium supplements (1–3 g daily in divided doses) are needed in almost all adult patients. Calcium carbonate is generally preferred because fewer pills per day are needed. Calcium carbonate requires an acidic gastric environment to be absorbed and should be taken with meals. Its bioavailability decreases in patients with atrophic gastritis or taking proton pump inhibitors. In these circumstances, calcium citrate, which is well absorbed independent of meal and acid environments, should be preferred. Calcium citrate might also be a preferred option for patients who complain of gastrointestinal side effects using calcium carbonate or who prefer to take calcium supplements outside mealtimes. Calcium carbonate and calcium citrate interfere with levothyroxine absorption; therefore thyroidectomized patients should be advised to take levothyroxine well apart from calcium supplements.

Prior to the availability of synthetic active vitamin D metabolites, supraphysiologic doses (25,000–200,000 IU daily) of either cholecalciferol (vitamin D<sub>3</sub>) or ergocalciferol (vitamin D<sub>2</sub>) were used (Table 4). Nowadays, active 1 $\alpha$ -hydroxylated vitamin D metabolites are preferred because patients with HypoPT have impaired renal activation of 25-hydroxyvitamin D. Calcitriol (Rocaltrol) and alfacalcidol (One-Alpha)<sup>2</sup> have a similar time of onset, but the latter has a longer time of offset (5–7 vs. 2–3 days). Calcitriol is more potent (about 50%) than alfacalcidol when compared in terms of the calcemic effect. The daily dose of calcitriol in adults ranges between 0.25 and 2.0  $\mu$ g, equal to 0.5 to 4  $\mu$ g of alfacalcidol. Weight-based dosing (0.01–0.04  $\mu$ g per kg per day), eventually associated with calcium supplements (20–40 mg per kg per day) should be used in infants and young children. Adult doses should be used in older children. Another active vitamin D analog, dihydrotachysterol, is also available in some countries. Where active vitamin D metabolites are not available or too expensive, large doses of parent vitamin D can still be used, but attention should be paid to the risk of vitamin D toxicity.

A low vitamin D status is not uncommon in patients with HypoPT, and vitamin D-deficient patients treated with active vitamin D metabolites should be supplemented with vitamin D<sub>2</sub> or D<sub>3</sub>, because active vitamin D metabolites do not correct hypovitaminosis D.

Active vitamin D metabolites stimulate intestinal absorption of phosphate, which may cause hyperphosphatemia and an

increased calcium–phosphate product, with the risk of soft tissue calcification. In this setting the intake of phosphate-rich foods should be reduced and the daily dose of calcium supplements increased, since calcium binds phosphate.

Hypercalciuria ( $\geq 250$  mg [6.25 mmol] in women or  $\geq 300$  mg [7.5 mmol] in men or  $> 4$  mg [0.1 mmol]/kg body weight in both sexes) is a common feature in patients with chronic HypoPT, because of the lack of PTH-dependent renal tubular reabsorption of calcium. In such instances a low-sodium diet should be advised either alone or combined with the administration of a thiazide diuretic that decreases renal calcium excretion. The combination of thiazide with amiloride<sup>1</sup> may further lower urinary calcium excretion and decrease the risk of hypokalemia. Thiazide diuretics are not advised in autosomal dominant hypocalcemia, a condition caused by mutations of the CaSR. Magnesium deficiency, when present, should also be corrected.

Lifelong monitoring is needed in patients with chronic HypoPTH. No study has evaluated how to best monitor these patients. The target serum calcium concentration is within the low-normal range, with no symptoms of hypocalcemia. In some patients a higher serum calcium level is needed to be symptom-free. A baseline renal imaging should be obtained. The recently published guidelines of the European Society of Endocrinology suggest measuring ionized or albumin-corrected total calcium, magnesium, and creatinine (eGFR) and 24-hour urinary calcium excretion every 3 to 6 months and performing renal imaging when patients have symptoms of nephrolithiasis or increasing serum levels of creatinine. Biochemical monitoring should be performed weekly or every other week when changing the daily dose of calcium or active vitamin D metabolites or introducing a new drug. It is important to note that serum calcium may fluctuate once the therapeutic regimen has been stabilized. Several comorbidities (e.g., gastrointestinal disease, diarrhea, immobilization) and drugs (loop and thiazide diuretics, systemic glucocorticoids, proton pump inhibitors, antiresorptive drugs, cardiac glycosides, and chemotherapeutics) may interfere with calcium homeostasis, and therefore patients should be periodically asked about their occurrence or use.

Conventional therapy only partially restores calcium homeostasis, and patients with chronic HypoPT have a reduced QoL and an increased risk of comorbidities, which include nephrocalcinosis, nephrolithiasis, impaired renal function, neuropsychiatric diseases, muscle stiffness and pain, infections, and seizures. An increased rate of intracerebral calcifications and cataracts has been documented in nonsurgical HypoPT. Bone mineral content is increased in patients with chronic HypoPT, but cancellous bone microarchitecture is abnormal.

**Parathyroid Hormone.** Until recently, HypoPT was the only major hormonal insufficiency state not treated with the missing hormone. The development of the recombinant human N-terminal 1–34 fragment (rhPTH<sub>1–34</sub>) and the full-length 1–84 (rhPTH<sub>1–84</sub>) molecule has stimulated several studies on its use as replacement therapy, which led to the approval by the Food and Drug Administration of rhPTH<sub>1–84</sub> (Natpara) for the management of chronic HypoPT.

The official recommendation is to consider rhPTH<sub>1–84</sub> therapy “only in patients who cannot be well-controlled on calcium and active forms of vitamin D and for whom the potential benefits are considered to outweigh the potential risk.” Treatment should be started with subcutaneous administration in the thigh of 50  $\mu$ g once daily, while reducing by 50% the daily dose of active vitamin D if serum calcium is greater than 7.5 mg/dL (1.875 mmol/L). Serum calcium should be monitored every 3 to 7 days and the daily dose of rhPTH<sub>1–84</sub> titrated every 4 weeks, aiming to reduce the daily calcium supplements to 500 mg and discontinue active vitamin D therapy while maintaining the serum calcium in the low-normal range. Afterward, serum calcium should be monitored every 3 to 6 months. Hypercalcemia has been reported in some cases, but a careful adjustment of the daily dose may decrease this

<sup>2</sup>Not available in the United States.

<sup>1</sup>Not FDA approved for this indication.

risk. A “black box” in the official recommendation highlights the potential risk of osteosarcoma (studies in rats have shown that both rhPTH<sub>1-34</sub> and rhPTH<sub>1-84</sub> can cause osteosarcoma). However, there is no evidence that individuals treated with either PTH molecules are at increased risk for osteosarcoma. The safety and efficacy of rhPTH<sub>1-84</sub> in pediatric patients have not been established. The European Medicines Agency has approved the use of rhPTH<sub>1-84</sub> as an adjunctive therapy for adults with chronic hypoparathyroidism who cannot be adequately controlled with standard therapy alone.

The FDA and the European Medicines Agency have approved using rhPTH<sub>1-84</sub> in patient with HypoPT, and that leaves room for decision making in individual cases. The guidelines recently elaborated by a panel of international experts suggest considering the use of rhPTH<sub>1-84</sub> therapy, where available, in any patient with chronic HypoPT of any etiology, except in patients with autosomal dominant hypocalcemia.

### Pregnancy and Lactation

There are limited data to inform treatment strategies in chronic HypoPT in pregnancy and lactation. The guidelines and a recent expert consensus of the European Society of Endocrinology suggest the use of active vitamin D metabolites and oral calcium as in nonpregnant women. Frequent monitoring (every 2–3 weeks) of serum calcium, possibly ionized calcium, is recommended. No studies have addressed the use of rhPTH<sub>1-84</sub> therapy in pregnant women. The FDA suggests that it should be used “only if the potential benefit justifies the potential risk to the fetus.”

## HYPERPROLACTINEMIA

Method of

Ming Li, MD, PhD; and Lawrence Chan, MD

### CURRENT DIAGNOSIS

- Hyperprolactinemia is diagnosed by biochemical tests based on two-site immunoassay, which can be confounded by extreme hyperprolactinemia (hook effect) and biologically inactive macroprolactinemia.
- Hyperprolactinemia can be caused by physiological, pharmacological, or pathological conditions; careful clinical, laboratory, and radiology evaluations are required to identify its underlying cause.
- The most common causes of hyperprolactinemia include medications, prolactinoma, and other pituitary and hypothalamic/pituitary stalk diseases.
- Clinical features of hyperprolactinemia include galactorrhea, menstrual abnormalities (in women), impotence (in men), infertility, and osteoporosis.
- Patients with prolactinoma may also have local compression symptoms including headache, visual disturbance, and hypopituitarism.
- Pituitary magnetic resonance imaging (MRI) is the imaging method of choice for diagnosing prolactinoma and other sellar/parasellar lesions.

### CURRENT THERAPY

- For secondary hyperprolactinemia, treatment should be directed at correcting underlying causes.
- Treatment goals for prolactinoma are relief of symptoms and the long-term effects of hyperprolactinemia, and of tumor mass effects.
- The dopamine agonists cabergoline (Dostinex) and bromocriptine (Parlodel) are effective in normalizing the prolactin level and shrinking the tumor in patients with prolactinoma.
- Surgery and radiotherapy of prolactinoma are reserved for patients resistant to or intolerant of medical therapy.
- Temozolomide (Temodar)<sup>1</sup> monotherapy is the first-line chemotherapy for aggressive or malignant prolactinomas after failing standard treatments.

<sup>1</sup>Not FDA approved for this indication.

## Biochemistry and Physiology of Prolactin

Prolactin is a polypeptide hormone produced by pituitary lactotroph cells. It is also produced locally in a variety of extrapituitary tissues such as mammary glands, decidua, gonads, brain, liver, fat, pancreas, and the immune system, along with its receptors. Prolactin is highly pleiotropic in terms of its functions. Many of its actions collectively support puerperal lactation. Prolactin displays considerable sequence homology to growth hormone (GH) and placental lactogen. The prolactin and GH receptors both belong to the class I cytokine/hematopoietic receptor superfamily. Prolactin is responsible for maturation of the mammary glands during pregnancy, but it plays only a minor role for pubertal mammary development, which requires GH instead. It appears not to be an essential hormone for non-childbearing individuals. Rare patients deficient for either prolactin or its receptor are largely healthy despite difficulty with fertility and lactation.

Prolactin circulates mainly as a 23-kDa 199-aa polypeptide. Several of its cleavage products exist in blood, which may have functions unrelated to lactation; for example, one 16-kDa cleavage product of prolactin displays antiangiogenic and prothrombotic properties, and has been implicated in the development of preeclampsia and peripartum cardiomyopathy. Several forms of prolactin aggregate, known as macroprolactins, also exist in circulation at lower levels. They are formed either by covalent bonding of prolactin monomers or by their nucleating around autoimmune IgG. These macroprolactins are not biologically active *in vivo* and have a prolonged half-life. At times they can build up in the circulation to a level high enough to cause diagnostic difficulties.

Among the major pituitary hormones, prolactin is unique for its predominantly negative mode of regulation by the hypothalamus. It does not have a known hypothalamus-derived releasing hormone. Instead, lactotrophs are under tonic inhibition by dopamine secreted from hypothalamic neurons. Increase in prolactin output is mostly mediated by withdrawing dopaminergic control in response to environmental cues, such as physical activity, stress, and nipple stimuli (Figure 1). Under experimental and pathological conditions, several factors, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide (VIP), oxytocin, and vasopressin, have been shown to increase prolactin secretion, but these peptides appear to play only minor and insignificant roles for the physiological regulation of prolactin.

Estrogen is the main driver of prolactin secretion during pregnancy. Stimulated by persistently elevated estrogen, lactotrophs grow in number and size. By term the pituitary gland can reach 2 to 3 times its normal size, and prolactin levels increase some 20-fold. Along with placental hormones such as estrogen,

progesterone, and placental lactogen, prolactin drives the maturation of the mammary glands. Lactation starts after parturition, when estrogen withdraws from the circulation. Frequent infant suckling maintains physiological hyperprolactinemia, which is important for sustained milk production. In addition, hyperprolactinemia during this critical period provides a natural though unreliable way of contraception. This is achieved by suppression of the hypothalamus–pituitary–gonad axis. Hyperprolactinemic hypogonadism and parathyroid hormone related peptide (PTHrP) secreted from mammary epithelial cells help mobilize skeletal calcium store in support of milk production. Through its receptors in liver, intestine, fat, and pancreas prolactin also adjusts maternal nutrient metabolism for optimal milk output. In the brain, prolactin modifies parental behavior toward closer infant attendance (see Figure 1).

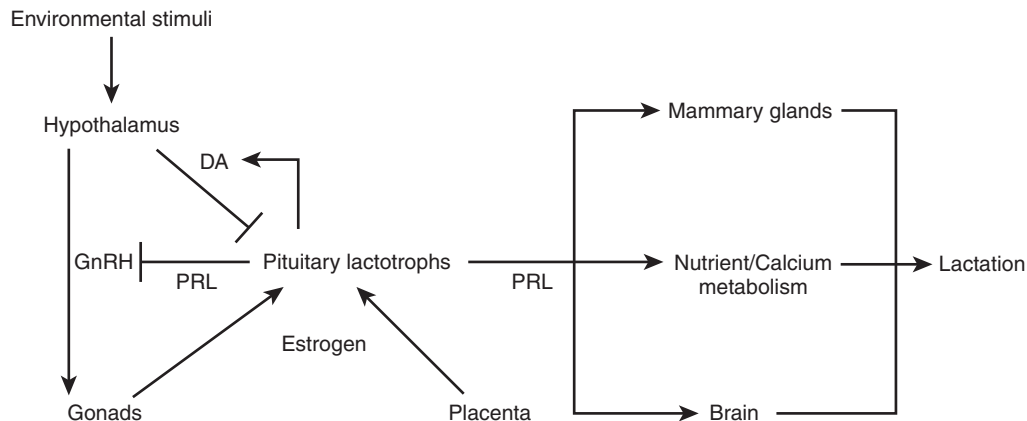

## Pathophysiology of Hyperprolactinemia

Physiological hyperprolactinemia as occurs during pregnancy and nursing is essential for child raising through the actions of prolactin in target organs discussed above. Similar changes in these organs under the influence of persistent pathological hyperprolactinemia in the absence of pregnancy and lactation, however, are inappropriate and could lead to a variety of undesired long-term consequences.

## Mammary Glands

One common symptom of persistent hyperprolactinemia is galactorrhea, that is, milk production not associated with childbirth or breast-feeding. As puerperal lactation normally ends within 6 months after delivery or weaning, any milk production beyond this point is also considered galactorrhea. Since maturation of mammary glands is completed during pregnancy, galactorrhea typically happens in women between 20 to 35 years of age with previous childbirths. It also occurs in nulligravid women, postmenopausal women, and men, although less frequently.

Prolactin is a known mitogen for mammary epithelial cells, and concern has been raised regarding its potential role in the pathogenesis of breast cancer. In a large prospective study by the Women's Health Initiative (WHI), there was evidence of a significant increase in breast cancer incidence in postmenopausal women with high normal prolactin levels, which is within the highest quartile of the normal range compared with those in the lowest quartile. On the other hand, increased breast cancer risk has not been observed in patients with overt hyperprolactinemia. In fact, early parity and lactation history are strong protective factors against breast cancer. Further research is required to resolve these seemingly discrepant observations.

**Figure 1** Physiology of prolactin and its regulation. At baseline, prolactin production and secretion are under tonic inhibition by dopamine released from hypothalamic neurons. The hypothalamus controls prolactin production by altering output of dopamine after integrating environmental stimuli and changes in hormonal homeostasis. Prolactin increases hypothalamic dopamine output, providing a negative feedback regulatory loop. Estrogen stimulates prolactin synthesis and secretion during pregnancy. Prolactin supports puerperal lactation via its action on the mammary glands, nutrient/calcium metabolism, and brain. Unlike most other anterior pituitary hormones, feedback regulation of prolactin secretion does not occur via factors produced by a peripheral endocrine target organ. Prolactin also suppresses hypothalamus–pituitary–gonadal axis by inhibiting GnRH release. *Abbreviations:* DA = dopamine; GnRH = gonadotropin releasing hormone; PRL = prolactin.

### Female Reproductive System

Persistent hyperprolactinemia significantly diminishes the pulsatile release of gonadotropin-releasing hormone (GnRH). As GnRH neurons do not themselves express prolactin receptors, prolactin exerts its effects on their afferent neurons instead by suppression of secretion of kisspeptin, a potent secretagogue for GnRH. Prolactin receptors are also found in the gonads, and prolactin has been reported to inhibit folliculogenesis and estrogen production in the ovary directly. However, this likely has only a limited contribution to infertility and hypogonadism associated with hyperprolactinemia, for the hypothalamus-pituitary-gonad axis can be reactivated by administration of GnRH or kisspeptin, with return of ovulation and fertility in subjects with hyperprolactinemia.

### Male Reproductive System

As in women, hyperprolactinemia causes secondary hypogonadism and infertility in men by suppression of GnRH pulses and a decrease in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels. Patients often have low or low normal testosterone levels, as well as abnormal sperm counts and morphology in semen analysis. Patients usually seek medical attention for diminished libido and impotence. The central nervous system (CNS) actions of prolactin are likely partly responsible for these symptoms, as restoration of testosterone level alone is often inadequate for symptom relief, which occurs only when prolactin levels also return to normal.

### Adrenal Glands

Prolactin stimulates the synthesis of androgen in the zona reticularis of the adrenal cortex. Mild elevations in serum levels of adrenal androgens, for example dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEA-S), are seen in approximately 50% of women with hyperprolactinemia. Symptoms of clinical hyperandrogenism such as hirsutism and acne are rare in these patients. When present, they are almost always associated with a concurrent increase in testosterone level. Elevation of adrenal androgens in hyperprolactinemia may contribute to the suppression of GnRH release in the hypothalamus and secondary hypogonadism.

### Skeletal System

Premenopausal women with hyperprolactinemia have lower bone density and approximately a 4.5 times higher risk for osteoporotic fractures. Hypogonadism associated with hyperprolactinemia is the main cause of bone loss, whereas restoration of sex hormones with either hormonal replacement or correction of hyperprolactinemia improves bone density. Bone density is preserved in women with hyperprolactinemia who continue to have regular menses. Nonetheless, not all studies showed a clear correlation between the degree of bone loss and duration of amenorrhea or levels of sex hormones suggesting involvement of additional processes. For example, the levels of parathyroid hormone-related protein (PTHrP) were found to be significantly higher in patients with hyperprolactinemia, and correlated well with bone density measurements. Correction of hyperprolactinemia by dopamine agonists was shown to normalize PTHrP levels.

### Etiology of Hyperprolactinemia

Any conditions that affect production or clearance of prolactin can lead to hyperprolactinemia (Table 1). Physiological hyperprolactinemia is transient and adaptive, whereas persistent hyperprolactinemia from pharmacological and pathological causes is often symptomatic with undesired long-term consequences. Pituitary adenomas over producing prolactin (prolactinomas) are the most important cause of pathological hyperprolactinemia. In addition to the elevated prolactin levels, prolactinomas also produce pathological local mass effects. Secondary hyperprolactinemia is most commonly related to disruption of dopaminergic control of lactotrophs, secondary to the use of dopamine antagonists or hypothalamic and pituitary stalk lesions.

**TABLE 1** Causes of Hyperprolactinemia

#### PHYSIOLOGICAL

Pregnancy

Lactation and breast stimulation

Neonatal period

Physical activity

Stress

Sexual intercourse

#### PHARMACOLOGICAL

Dopamine antagonists—antipsychotics and antiemetics

Tricyclic antidepressants

Selective serotonin reuptake inhibitors (SSRI)

Antihistamines (H<sub>2</sub>)

Verapamil (Calan)

Protease inhibitors

Dopamine synthesis inhibitors

#### PATHOLOGICAL

##### PITUITARY DISEASES

Prolactinoma

Plurihormonal adenomas

Lymphocytic hypophysitis

Empty sella syndrome

Macroadenoma with or without suprasellar extension

Idiopathic hyperprolactinemia

##### HYPOTHALAMIC/PITUITARY STALK DISEASES

Tumors: meningioma, craniopharyngioma, germinoma, metastasis, etc.

Granulomas

Infiltrative diseases

Irradiation

Trauma

**NEUROGENIC:** chest wall lesions, spinal cord lesions, herpes zoster, and epileptic seizure

### Epidemiology and Natural History of Prolactinoma

Prolactinoma is the most common type of pituitary adenoma, contributing to approximately 40–50% of pituitary tumor cases. Prolactinomas are categorized according to size into microprolactinomas (under 1 cm) and macroprolactinomas (larger than 1 cm). Clinically these two conditions behave very differently and can be considered as separate entities. In general, macroprolactinomas tend to grow progressively and are often locally invasive; they are also generally more resistant to treatment and have a higher risk of recurrence. On the other hand, microprolactinomas rarely progress in size (~ 7% of cases) and have a good chance (~ 15% of cases) of going into remission on their own.

The prevalence of prolactinoma has been estimated to be 500 cases per million and incidence about 27 cases per million per year based on survey of asymptomatic populations. In autopsy series, however, lactotroph neoplasms staining positive for prolactin are much more common, being found in approximately 5% of the subjects. They are predominantly microadenomas. Only a small fraction of these small lactotroph neoplasms develop overt hyperprolactinemia by escaping tonic dopaminergic suppression from the hypothalamus, presumably via down-regulation of dopamine D2 receptor-mediated signaling pathway and/or bypassing the portal system for blood supply. Microprolactinomas predominantly affect women of childbearing age, with a female-to-male ratio of approximately 20:1. Macroprolactinoma, on the other hand, shows no sex predilection. Neoplastic transformation of lactotroph involves accumulation of genetic and epigenetic events. The best-understood candidate genes involved include the pituitary tumor transforming gene (PTTG) and the heparin-binding secretory transforming gene (HST). PTTG expression is positively regulated by estrogen.

Most prolactinomas occur sporadically. The vast majority of prolactinomas are benign, although they can be locally invasive. Malignant prolactinomas, as defined by the presence of extrapituitary metastases, are extremely rare. Familial cases, such as those associated with multiple endocrine neoplasia I (MEN-I) and familial isolated pituitary adenoma (FIPA), typically occur at a younger age and are more often macroprolactinomas that are locally invasive.

### Clinical Manifestations

Clinical manifestations of prolactinomas fall under two categories: systemic effects of hyperprolactinemia, and local compression symptoms.

### Symptoms of Hyperprolactinemia

Persistent hyperprolactinemia inappropriately recapitulates symptoms associated with normal pregnancy and nursing. In extreme cases, hyperprolactinemia has been associated with delusions of pregnancy in susceptible individuals, for example some women on psychotropic medications.

Menstrual abnormalities and infertility are the most common symptoms associated with hyperprolactinemia in women of childbearing age. These symptoms may be masked by use of oral contraceptive pills, which often delays diagnosis. The mildest cases include women presenting with infertility caused by shortened luteal phase despite preserved regular menses. As the degree of hypogonadism worsens, patients experience menstrual irregularities ranging from anovulatory cycles to oligomenorrhea and amenorrhea. Patients with amenorrhea may also experience psychological stresses and other menopausal symptoms like vaginal dryness and dyspareunia. Of note, high prolactin levels may sometimes mask vasomotor symptoms of menopausal and perimenopausal women with prolactinoma, who may develop hot flashes once they are successfully treated with dopamine agonists.

Galactorrhea occurs in up to 80% of cases of hyperprolactinemia. This will need to be differentiated from nipple discharges of other causes, especially those from breast neoplasms. Further evaluation with breast imaging and cytology is indicated when the discharge is unilateral, bloody, or associated with a breast mass. Galactorrhea is by definition milk-like in appearance, and when in doubt, Sudan Black B staining showing fat globules is confirmatory. Although considered a classic sign and symptom for hyperprolactinemia, galactorrhea per se is a poor predictor for hyperprolactinemia in the absence of additional symptoms, for it can be seen in about 10% of healthy women of childbearing age. If amenorrhea is present at the same time, the patient should be assumed to harbor a prolactinoma unless proven otherwise. The degree of galactorrhea is quite variable, from barely expressible to bothersome bra stain and copious free flow, and does not necessarily reflect the severity of hyperprolactinemia. In fact, the

majority of patients with galactorrhea and normal menses have normal prolactin levels. On the other hand, in some patients with extremely high levels of prolactin, galactorrhea could be masked by severe hypogonadism.

Men with hyperprolactinemia mainly present with impotence and diminished libido, which is not always corrected with testosterone replacement. As noted in the section on pathophysiology, these symptoms are not all caused by hypogonadism but may involve the central effects of prolactin. Other symptoms and signs of hypogonadism, such as loss of body hair and muscle bulk, are less common. Infertility could also occur with decrease in sperm count and morphology, although hyperprolactinemia is only present in approximately 5% of male patients seeking treatment for infertility.

For both male and female patients, persistent hypogonadism from hyperprolactinemia leads to osteoporosis and increased risk of fracture. This could be effectively treated with either sex hormone replacement or dopamine agonists.

### Mass Effects of Prolactinomas

Headache is the most common neurological symptom caused by pituitary tumors. It can occur even with microadenomas presumably caused by dural stretch. More severe headache results from larger tumors, especially those with extrasellar invasion, and occasionally from apoplexy.

Visual disturbance typically only happens with macroadenomas with suprasellar extension impinging on the optic chiasm leading to loss of visual acuity and visual field defects. The typical pattern of visual field defect is bitemporal hemianopsia, which usually starts from the upper field and progresses downward as the tumor impinges upward from below. Ophthalmoparesis typically happens in the setting of apoplexy and only rarely results from parasellar invasion of the cavernous sinus and impingement of cranial nerves III, IV, or VI.

By compressing the rest of the pituitary gland, including the stalk, prolactinoma can cause deficiencies of other anterior pituitary hormones including GH, thyroid-stimulating hormone (TSH), and adrenocorticotrophic hormone (ACTH), in addition to hypogonadism from the hyperprolactinemia. The degree of the risk is proportional to tumor size.

CSF rhinorrhea occurs when a macroprolactinoma invades inferiorly into the sphenoid sinus. Other rare compressive symptoms from giant prolactinomas include epilepsy (temporal lobe involvement), exophthalmos, and hydrocephalus. Life- and vision-threatening emergencies could arise from apoplexy and CNS infection.

### Laboratory Evaluation

#### Prolactin Assay and Pitfalls

Hyperprolactinemia is diagnosed by individual measurements of serum prolactin levels. Patients should be well rested, as physical activity stimulates prolactin secretion, but fasting is not needed. Dynamic tests such as TRH stimulation do not appear to add to diagnostic value and are not recommended. The level of prolactin may provide valuable diagnostic clues. Secondary hyperprolactinemia rarely exceeds 150 ng/mL. On the other hand, a prolactin level of greater than 100 ng/mL is highly suggestive, and severe hyperprolactinemia of greater than 500 ng/mL is virtually diagnostic for prolactinoma. On rare occasions, secondary hyperprolactinemia can produce prolactin levels in the prolactinoma range. For example, risperidone (Risperdal)-induced hyperprolactinemia could be as high as 250 to 500 ng/mL, and patients with end-stage renal disease who are on antipsychotics or antiemetics can have prolactin levels greater than 1000 ng/mL. The size of the prolactinoma shows a rough correlation with the serum prolactin level. Patients with microprolactinomas usually have prolactin levels in the range of 50 to 300 ng/mL, whereas those with macroprolactinomas have levels of 200 to 5000 ng/mL.

Most clinical laboratories measure prolactin using a two-site immunoassay. A capture antibody first affixes prolactin

in the sample to a solid matrix. Subsequently a second signal antibody is attached to the now immobilized prolactin. The signal antibody is engineered to carry either a radioisotope or a chemiluminescent enzyme to provide a readout. The assay is accurate within its designed linear range, which is typically under 10,000 ng/mL. Beyond this level both capture and signal antibodies could be saturated preventing the signal antibody to attach. As a result, signal outputs will be falsely diminished. This phenomenon, known as the hook effect, produces a falsely low reading that could lead to the misdiagnosis of a macroprolactinoma as a nonfunctioning pituitary tumor. This artifact can be circumvented by repeating the assay with a 100-fold diluted sample. Many laboratories also opt for an additional washout step to eliminate excess prolactin before adding the signal antibody, preempting the artifact.

Macroprolactinemia is another potential diagnostic pitfall masquerading as true hyperprolactinemia. Macroprolactins are biologically inactive prolactin aggregates that could accumulate in blood to a high level. Macroprolactinemia does not cause any morbidities but could contribute to analytical difficulties as the antibodies used in prolactin assays cross-react with macroprolactins. Most laboratories rely on polyethylene glycol (PEG) precipitation to determine the proportion of macroprolactins and the true concentration of monomeric prolactin. Up to 25% of monomeric prolactin can be also precipitated by PEG, potentially masking true hyperprolactinemia. Therefore patients with macroprolactinemia may still need to be further evaluated if clinical suspicion is high for true hyperprolactinemia.

### Other Supporting Laboratory Tests

After confirming hyperprolactinemia, a simple chemistry panel may reveal or suggest the underlying cause such as chronic kidney disease and cirrhosis. A pregnancy test (beta human chorionic gonadotropin [ $\beta$ hCG] level) is essential for women of childbearing age, and hypothyroidism needs to be ruled out with a TSH assay. Both pregnancy and hypothyroidism may have presenting symptoms of sellar mass and hyperprolactinemia and therefore be mistaken for prolactinoma.

For established prolactinoma cases it is important to also assess other pituitary axes. Up to 20% of GH-secreting tumors cosecrete prolactin, and IGF-1 level is an essential screening test for

these cases. If hypogonadism is suspected, levels of LH, FSH, and sex hormones (testosterone or estrogen) should be obtained. Screening for central hypothyroidism and secondary adrenal insufficiency should be done with TSH, free thyroxine (T4), and morning cortisol levels, respectively, for patients with pituitary tumors larger than 6 mm.

### Neuroimaging

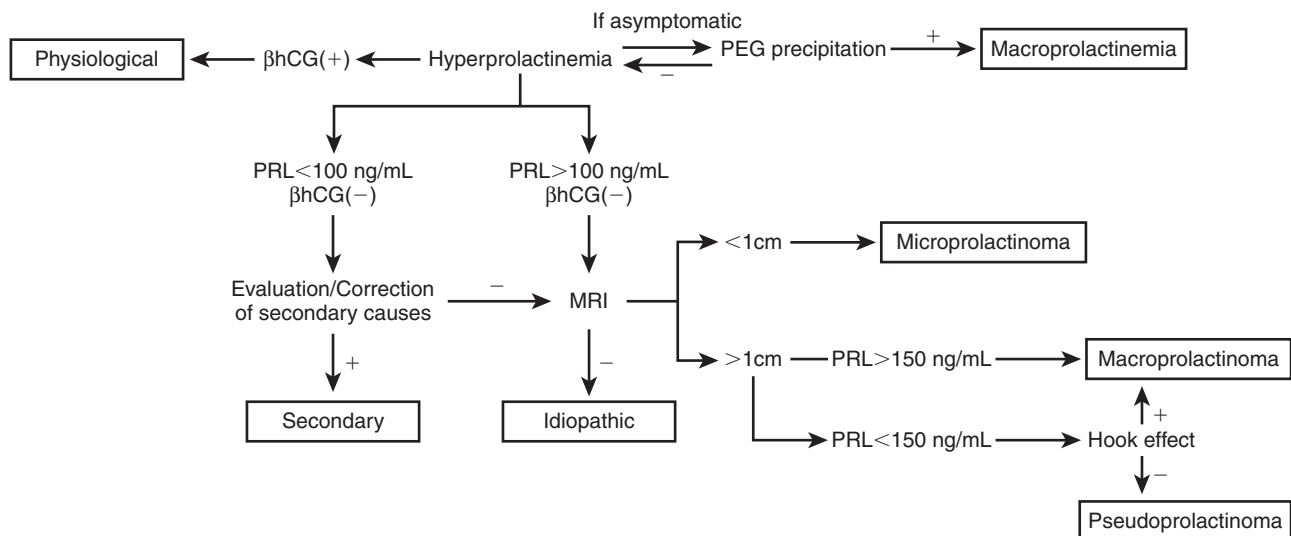

Pituitary imaging should be considered for all patients with unexplained significant hyperprolactinemia, especially if there are signs or symptoms of local compression. MRI with and without gadolinium contrast with dedicated pituitary protocol is the test of choice. Compared with other modalities MRI provides superior soft tissue contrast revealing the tumor's inner structure and its relationship to surrounding tissues, including cavernous sinus, pituitary stalk, and optic chiasm. Computed tomography (CT) scan still has a role for patients with metal implants or other contraindications for MRI, and is especially useful for revealing bony erosions and tissue calcification; its use is limited by suboptimal soft tissue contrast and exposure to ionizing radiation.

### Visual Field Testing

A formal visual field test with a perimeter is recommended when suprasellar extension of a pituitary adenoma brings it close to the optic chiasm. Improvement or worsening in visual field often precedes imaging evidence of tumor shrinkage or expansion during treatment. Therefore visual field testing is an excellent monitoring tool for patients under treatment for macroadenoma and visual impairment.

### Diagnosis

Prolactin testing is usually prompted by suggestive signs and symptoms of hyperprolactinemia such as menstrual abnormalities, infertility, and galactorrhea. A careful history, including medication use, physical examination, and routine laboratory evaluation (see preceding sections), is invaluable for uncovering secondary causes. Pituitary imaging should be performed when no other underlying causes are found especially if the levels of prolactin are higher than 100 ng/mL. A diagnostic algorithm shown in Figure 2 provides a framework for a structured and cost-effective workup of hyperprolactinemia.

**Figure 2** Diagnostic algorithm for hyperprolactinemia. If hyperprolactinemia occurs in the absence of relevant clinical symptoms and signs, one should rule out macroprolactinemia by PEG precipitation. When hyperprolactinemia is confirmed, pregnancy should be ruled out with a  $\beta$ hCG test. In the absence of pregnancy, if the PRL level is higher than 100 ng/dl, the pretest probability for a prolactinoma is high enough to justify a pituitary MRI scan, even if potential secondary causes exist. Regardless of prolactin levels, secondary causes should be carefully evaluated with medication history, physical examination, and laboratory tests such as thyroid function tests and chemistry panel, and appropriately treated. If hyperprolactinemia remains unexplained or persists despite correction of other contributing factors, a pituitary MRI is in order. Patients with negative sellar findings have idiopathic hyperprolactinemia. Patients with sellar mass may have either prolactinoma or pseudoprolactinoma. The latter is suggested by a discordant prolactin level less than 150 ng/mL for a large sellar, or a parasellar mass greater than 1 cm, after hook effect has been ruled out. *Abbreviations:*  $\beta$ hCG =  $\beta$  human chorionic gonadotropin; MRI = magnetic resonance imaging; PEG = polyethylene glycol; PRL = prolactin.

## Differential Diagnosis

An exhaustive list of etiologies has been provided in Table 1. A few entities deserve additional comments.

*Drug-induced hyperprolactinemia* is common and at times may produce serum prolactin levels matching those in patients with prolactinoma (see prior section on laboratory evaluation). A more typical range of prolactin level is 25 to 100 ng/mL for drug-induced hyperprolactinemia. It is not always possible to correlate in time the initiation of the culprit drug with the onset of symptoms, or rise of prolactin levels. The way to confirm medication-related hyperprolactinemia is to discontinue the putative offending agent(s) for three days before repeating a prolactin assay. Some medications may require a longer period of abstinence, and in such cases the level of prolactin can be retested later if the second value is reduced but still elevated. Before discontinuing psychotropic medications, one should consult with the prescribing psychiatrist to prevent worsening of the patient's mental symptoms.

*Pseudoprolactinoma* refers to a nonfunctioning sellar or suprasellar mass associated with hyperprolactinemia caused by stalk disruption. The prolactin level is seldom above 150 ng/mL. However, before making such a diagnosis, one must exclude hook effect with a 100-fold diluted sample. Prolactin levels are typically normalized within several days after initiation of dopamine agonists, as lactotrophs are still sensitive to dopamine, but local compressive symptoms do not improve. In contrast, patients with true macroprolactinoma experience more gradual decrease in prolactin levels after they are put on dopamine agonists, but they could expect improvement in compressive symptoms within 12 hours to days, and imaging evidence of tumor shrinkage in weeks.

*Polycystic ovary syndrome* (PCOS) and hyperprolactinemia are among the most common causes of menstrual irregularities and infertility, and affect women of similar ages. PCOS has also been associated with hyperprolactinemia. However, multiple studies have shown that the prevalence of hyperprolactinemia in women with PCOS is not significantly higher than that of matched populations. Although mild elevations of DHEA-S or DHEA are common in patients with hyperprolactinemia, hirsutism is rare, and when present is always associated with an increase in testosterone level, likely reflecting possible coexisting PCOS. Therefore the presence of hyperprolactinemia in patients with PCOS or hirsutism warrants additional evaluation.

## Management of Secondary Hyperprolactinemia

Treatment of secondary hyperprolactinemia should focus on correcting the underlying conditions, for example treating hypothyroidism, and resection of nonfunctioning pituitary tumors. For drug-induced hyperprolactinemia, the responsible medications should be removed or replaced with alternatives. Newer antipsychotics such as aripiprazole (Abilify) may be used in place of older agents such as risperidone (Risperdal) because they have better metabolic/hormonal profiles. For irreversible conditions such as end-stage renal disease, hyperprolactinemia can be effectively controlled with dopamine agonists. Ectopic prolactin secretion, which occurs in paraneoplastic syndrome, is a rare exception where dopamine agonists are ineffective, because extrapituitary production of prolactin is driven by alternative promoters, which do not respond to dopamine. Asymptomatic patients with modest hyperprolactinemia may not need treatment, however, and sex hormone replacement may be adequate for correcting hypogonadism if fertility is not desired.

## Management of Prolactinoma

The goals for managing prolactinomas are twofold: treating symptomatic hyperprolactinemia, and relief of tumor mass effects. Treatment thus needs to be tailored to the patient's unique clinical picture and the desired outcome. Mass effects are not a concern for microprolactinomas, whereas for patients with giant prolactinomas (defined as >4 cm or >2 cm of suprasellar

extension) and extreme hyperprolactinemia, normalization of prolactin levels is less likely, and treatment should focus on reversal or minimization of mass effects. The following are appropriate options in specific settings.

## Observation

Active surveillance is appropriate for patients with microprolactinoma who are asymptomatic or not troubled by galactorrhea, especially if fertility is not a concern. As long as regular menses are preserved, they seem to be spared from any long-term consequences from hyperprolactinemia. Bone mineral density appears to be preserved in these patients. It is noteworthy that a significant fraction of patients may have tumor resolution during surveillance without treatment. Tumor expansion is a rare event, and serial measurements of serum prolactin level are effective for monitoring interval tumor growth. Pituitary imaging is indicated when there is significant increase in prolactin level or emergence of local compression symptoms.

## Hormonal Replacement

For patients with microprolactinoma bothered only by symptoms related to hypogonadism including menstrual abnormalities, sexual dysfunction, and osteoporosis, but who no longer desire fertility, hormonal replacement is a valid alternative to dopamine agonists, especially when the latter are not tolerated or are contraindicated. This can be achieved with oral contraceptive pills in premenopausal women, or testosterone in men. This approach compares favorably to dopamine agonists in terms of cost and side effects. Patients may experience slight increases in prolactin level, but tumor progression has not been associated with use of oral contraceptive pills for up to 2 years. It would be prudent to use lower doses of estradiol ( $\leq 30 \mu\text{g/day}$ ) and closely monitor patients for prolactin level and tumor growth.

## Dopamine Agonists

Medical treatment with dopamine agonists has replaced surgery as the first-line treatment for prolactinomas, with excellent efficacy in achieving treatment goals and minimal risk. The therapeutic effects of dopamine agonists are mediated by dopamine D2 receptors in tumor cells, which inhibit prolactin synthesis and secretion, slow cell proliferation, and reduce tumor vascularity. Normalization of prolactin levels and reduction of tumor size can be expected in the majority of patients. A small fraction of prolactinomas is resistant to dopamine agonists, as defined by failure in normalizing prolactin level, reduction in tumor size by 50%, or restoration of gonadal function with standard doses. In general, microprolactinomas are more sensitive to dopamine agonists than macroprolactinomas are, and men are more likely to be drug resistant than are women. Rapid responders experience significant improvement of visual symptoms within 24–72 hours; some of them may develop complications resulting from the rapid receding of macroprolactinomas (uncorking), e.g., CSF leak, pituitary apoplexy, and optic chiasm hernia. For most patients, however, progressive reduction of tumor size occurs over the course of months to years, though some patients may never experience tumor shrinkage despite normalization of prolactin levels at the highest tolerated doses.

Patients with microprolactinoma may discontinue treatment upon menopause because their treatment goal has been fulfilled. Patients with macroprolactinoma, on the other hand, may require life-long treatment to prevent tumor regrowth. A meta-analysis showed that a small fraction of patients may enter long-term remission after discontinuing dopamine agonists (21% for microprolactinomas and 16% for macroprolactinomas). The odds are significantly improved if patients have been treated for at least 2 years and tumor size reduced by  $\geq 50\%$ . The 2011 Endocrine Society practice guidelines suggest that tapering or discontinuing dopamine agonists may be attempted in patients who have been

**TABLE 2** Use of Dopamine Agonists in Hyperprolactinemia

	ROUTE	DOSING FREQUENCY	STARTING DOSE	USUAL DOSE RANGE
Bromocriptine	PO intravaginal <sup>1</sup>	Twice a day	1.25 mg after dinner or before bed for 1 week, then twice a day	2.5–10 mg/day
Cabergoline	PO	Once to twice a week	0.25 mg twice a week or 0.5 mg once a week	0.5–2 mg/week

<sup>1</sup>Not FDA approved for this indication.

treated for at least 2 years and experienced complete biochemical and radiographic resolution. The risk for recurrence after drug discontinuation is related to the size of adenoma at the time of the diagnosis. For tumors larger than 2 cm, especially giant prolactinomas, tapering the dopamine agonists to a lower maintenance dose for life-long treatment after achieving maximal tumor reduction would be a better strategy for these patients. Tapering or withdrawal of dopamine agonists should be followed by close surveillance of prolactin levels and pituitary MRI when prolactin level increases, especially during the first year.

Three dopamine agonists are currently used for treating hyperprolactinemia, including bromocriptine (Parlodel), cabergoline (Dostinex), and quinagolide (available only in Europe). Bromocriptine was the first dopamine agonist available, and it has the best established safety record. It is still the only dopamine agonist approved by the Food and Drug Administration (FDA) to be used in pregnancy, when indicated. Cabergoline is a more specific agonist of the D2 dopamine receptor, and is superior in many respects to bromocriptine, for example, because of dosing convenience, tolerability, and treatment efficacy. Many patients not controlled with bromocriptine may achieve normal prolactin levels after switching to cabergoline, which has become the drug of choice for cases not involving pregnancy. The safety data for cabergoline are not as extensive as those for bromocriptine. Common side effects for this class of drugs include nausea, orthostatic hypotension, fatigue, mental fogging, and, less frequently, nasal stuffiness, Raynaud phenomenon, constipation, depression, and psychosis. Nausea is more common in patients taking bromocriptine; for these patients the intravaginal route<sup>1</sup> can be tried. Patients receiving higher doses of cabergoline are at risk of developing cardiac valvulopathy. This has so far been a concern for patients with Parkinson's disease, who may require much higher doses. However, the life-long exposure to high cumulative doses in patients with resistant prolactinoma is considerable, and regular echocardiogram surveillance is recommended for patients taking doses higher than 2 mg/week. Dosing regimens for bromocriptine and cabergoline are listed in Table 2. In general, patients should be started on the lowest doses and titrated upward monthly based on the serum prolactin level until treatment goals are reached.

### Surgery

With the availability of the second-generation dopamine agonists, surgery is mostly reserved for the following situations: (1) patients intolerant of, or resistant to, dopamine agonists; (2) women with macroprolactinoma who are planning for conception, to forestall tumor expansion during pregnancy; (3) pituitary apoplexy threatening neurological and visual functions if not managed urgently. Transsphenoidal tumor resection is the standard surgical approach. Perioperative mortality and morbidity are low in the hands of experienced pituitary surgeons in high-volume centers. Major surgical complications include visual loss, CNS infection, stroke, and oculomotor palsy. Craniotomy is occasionally needed for masses with extrasellar extensions that may be inaccessible by the transsphenoidal route, with higher risk for complications. Postoperatively patients need to be monitored for signs

of diabetes insipidus and secondary adrenal insufficiency, which may be transient or permanent.

### Radiotherapy

Radiotherapy is inadequate as a primary treatment for prolactinoma, as its efficacy is poor and latency long. It is also associated with long-term complications including permanent hypopituitarism, cerebrovascular accidents, and secondary intracranial malignancies. Currently it is reserved mostly for patients with aggressive and malignant prolactinomas failing medical/surgical treatment. Stereotactic radiosurgery is preferred over conventional fractionated radiotherapy for more convenient dosing, better efficacy, and lower rate of complications. However, radiosurgery should not be attempted for tumors in close proximity to the visual apparatus (less than 5 mm of clearance), as it is associated with an unacceptably high rate of vision loss.

### Management of Prolactinoma During Pregnancy

Mild hyperprolactinemia is part of normal pregnancy, and there are concerns for the safe use of dopamine agonists in pregnant women. There is convincing evidence that as long as bromocriptine is withdrawn within a week after confirmation of pregnancy, obstetric outcome is not altered. Less robust data to date suggest that continuing bromocriptine treatment till term is also safe. Despite its longer half-life, as long as cabergoline is discontinued in early pregnancy, it also has not been found to be associated with adverse outcomes. Until there is incontrovertible evidence for the absolute safety of these dopamine agonists, however, it is prudent to discontinue these drugs as soon as pregnancy is confirmed. Given its shorter half-life and established safety record, bromocriptine is the preferred agent for fertility induction in women with hyperprolactinemia, although cabergoline would also be acceptable if bromocriptine is not tolerated. The major indication to treat prolactinomas medically during pregnancy is the concern for tumor expansion. Such risk is negligible for microprolactinomas. For patients with macroprolactinoma, however, symptomatic tumor expansion during pregnancy can occur in up to about 30% of cases. This risk can be significantly reduced if the patient has been treated with a dopamine agonist for at least a year with evidence of tumor shrinkage, or has undergone pituitary surgery or radiotherapy prior to pregnancy. Until these conditions are met, women of childbearing age with macroprolactinomas should be advised to take nonhormonal contraceptive measures. For patients who fail to achieve tumor shrinkage with dopamine agonists or cannot tolerate them, prophylactic surgery prior to pregnancy may be considered, after careful discussion with the patient on surgical risks and the possibility of permanent hypopituitarism, which further impairs fertility. The Endocrine Society practice guidelines recommend against measurement of serum prolactin levels during pregnancy. Instead the patient should be followed clinically for any signs or symptoms of tumor expansion. MRI without gadolinium and visual field testing should be done when clinical suspicion arises. If tumor expansion is confirmed, the patient should be reinitiated on bromocriptine. Debulking surgery is reserved for patients failing or not tolerating medical treatment. Lactation usually does not cause tumor progression, and patients are encouraged to breastfeed their infants with close surveillance. They should not take either bromocriptine

<sup>1</sup>Not FDA approved for this indication.

or cabergoline, however, as both are secreted in the milk, and are effective lactation inhibitors.

### Management of Resistant and Malignant Prolactinoma

Several other treatment options are available for patients who fail the highest tolerated doses of dopamine agonists, surgery, and radiation. A small fraction of these patients have malignant prolactinoma, which is defined by extrapituitary metastasis; histopathologically, malignant prolactinomas can appear very similar to aggressive prolactinomas. An alkylating agent, temozolomide (Temodar)<sup>1</sup>, has been successfully used in the treatment of aggressive pituitary adenoma and pituitary carcinoma. Monotherapy with temozolomide has been established as the first-line chemotherapy for these conditions, following documented tumor growth despite standard therapies. Selective estrogen receptor modulators (SERMs), including raloxifene (Evista)<sup>1</sup> and tamoxifen (Nolvadex)<sup>1</sup>, have been found to be useful adjuncts that can reduce prolactin level and inhibit tumor growth.

<sup>1</sup>Not FDA approved for this indication.

## HYPERTHYROIDISM

Method of

William J. Hueston, MD

### CURRENT DIAGNOSIS

- Hyperthyroidism or thyrotoxicosis is most often caused by Graves' disease, toxic nodular goiter (Plummer's disease), or acute thyroiditis.
- Common symptoms in hyperthyroidism are tachycardia, elevated systolic blood pressure, tremor, and anxiety. Patients with Graves' disease also might exhibit exophthalmos. In contrast, elderly patients can present with apathetic hyperthyroidism, which can be confused with hypothyroidism.
- Hyperthyroidism should be suspected in all patients who present with atrial fibrillation, palpitations, panic disorder, or unexplained tremors.
- Thyroid storm is an acute, life-threatening condition usually occurring in patients with undiagnosed or untreated hyperthyroidism placed under physiologic stress.
- An elevated free T<sub>4</sub>, usually with a low thyroid-stimulating hormone is the hallmark of hyperthyroidism, and anti-thyroid-stimulating hormone antibodies can help identify Graves' disease.
- Ultimately, a thyroid scan and uptake are usually necessary to differentiate the cause of hyperthyroidism.
- Subclinical hyperthyroidism is an uncommon finding of uncertain long-term clinical significance but treatment for patients over 65 with cardiac disease or osteoporosis should be considered.

### CURRENT THERAPY

- In patients with Graves' disease or autonomous thyroid nodules (toxic nodular goiter), short-term treatment includes thyroid suppression medications (such as methimazole [Tapazole]) and  $\beta$ -blockers (such as propranolol [Inderal]<sup>1</sup>). Long-term management with radioiodine thyroid gland ablation is often pursued once symptoms are controlled.
- Patients with acute thyroiditis might need transient  $\beta$ -blockade but can often be managed expectantly until symptoms abate and thyroid hormone levels normalize. A small number of patients (~10%) have persistent hypothyroidism after an episode of illness.
- Thyroid storm is a medical emergency that requires close monitoring along with an antithyroid drug,  $\beta$ -blockers, corticosteroids, and iodine-potassium solution (Lugol's solution).

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

Hyperthyroidism is relatively uncommon and usually caused by three conditions: Graves' disease, toxic nodular goiter, or acute thyroiditis. Graves' disease is the most common cause of hyperthyroidism in the United States and usually affects younger patients from the teens to the 40s. Like other autoimmune diseases, women are at higher risk (seven to eight times) than men. Toxic nodular goiter accounts for 15% to 30% of hyperthyroid diagnoses. It usually occurs after age 50 years, is more common in women, and follows several decades of multinodular thyroid disease. A less-common cause is administration of amiodarone. Amiodarone is about one third iodine and can cause hyperthyroidism either through iodine-induced thyroid damage or from increased thyroxine synthesis owing to excessive iodine.

**BOX 1** Conditions Causing Hyperthyroidism**Graves' disease**

Autonomous thyroid nodule (toxic nodular goiter)

- Acute thyroiditis
- Hashimoto's thyroiditis
- Subacute granulomatous thyroiditis (de Quervain's thyroiditis)
- Subacute lymphocytic thyroiditis (silent or painless thyroiditis)
- Suppurative thyroiditis (bacterial infection of thyroid)
- Excessive exogenous thyroid use
- Over-replacement after thyroid ablation or for hypothyroidism
- Thyroxine (Synthroid) abuse for weight loss
- Iodine overconsumption
- Amiodarone administration

Subclinical hyperthyroidism, defined as an abnormally low TSH but normal free thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ) affects 1% to 2% of the population. This condition is most common with mild forms of hyperthyroidism but also can be observed transiently in thyroiditis. Subclinical hyperthyroidism is more common in individuals over age 70 and those with iodine-deficient diets.

**Risk Factors**

There are no known environmental or reversible risk factors for any of the causes of hyperthyroidism. Graves' disease is associated with a specific human leukocyte antigen (HLA) region on chromosome 6 (*CTLA 4*).

**Pathophysiology**

The most common causes of hyperthyroidism are shown in **Box 1**.

Graves' disease is an autoimmune disorder caused by antibodies against thyroid-stimulating hormone (TSH) receptors on the thyroid gland. Graves' disease is associated with many other autoimmune diseases, including pernicious anemia, vitiligo, type 1 diabetes mellitus, autoimmune adrenal disease, Sjögren's syndrome, rheumatoid arthritis, and lupus. As with these other disorders, the etiology is unknown.

Toxic nodular goiter, also known as Plummer's disease, results from the development of autonomous thyroid adenoma. Patients who develop a toxic nodular goiter usually have a long history of many other nodules that spontaneously burn out over time, but then develop a single large nodule (usually 2.5 cm or greater) that continues to produce thyroid hormone in such large quantities that patients become hyperthyroid. No clear cause is known for the development of the nodules.

Acute thyroiditis can also produce hyperthyroidism. Several different conditions can cause thyroiditis (see **Box 1**). The inflammation resulting in thyroiditis is thought to be related to subacute viral infections or autoimmune reactions; suppurative thyroiditis is a rare bacterial thyroid infection, usually caused by *Staphylococcus aureus*. During the acute period of thyroid inflammation, damage to the gland leads to the release of stored thyroxine from thyroid lakes, producing hyperthyroidism. However, after the initial release of thyroid hormone from the stored lakes, damage to the gland inhibits production of new thyroxine. After the initial surge in thyroid hormone levels, thyroxine levels drop, often to levels that can result in transient hypothyroidism. Most patients return to the euthyroid state after the thyroid gland heals, but about 10% of patients with acute thyroiditis remain chronically hypothyroid.

Other, less common causes of hyperthyroidism include excessive exogenous administration of thyroid medications. This is most commonly the result of over-replacement of thyroxine (Levoxyl, Synthroid) in patients with hypothyroidism, but it may be intentional for weight loss. Because thyroxine and

triiodothyronine ( $T_3$ ) are highly protein bound, over-replacement is most common if patients experience hypoproteinemia, such as in nephrotic syndrome, cirrhosis, or malnutrition.

Excessive iodine consumption, referred to as the Jod-Basedow effect, can also lead to thyrotoxicosis. The source of the iodine may include iatrogenic sources such as iodine-containing medications or radiologic contrast agents.

Several other medications, such as amiodarone (Cordarone), lithium, and interferon  $\alpha$  (Intron A) also can cause thyrotoxicosis by causing drug-induced thyroiditis.

**Prevention**

There are no known strategies to prevent hyperthyroidism. For patients with hypothyroidism, annual monitoring of TSH levels is recommended to ensure that patients receive the appropriate replacement dose and not over-replacement.

**Clinical Manifestations**

Patients with hyperthyroidism complain of a variety of symptoms that can include anxiety, tachycardia, wide-pulse pressure hypertension, palpitations, fine tremor, weight loss, heat intolerance, and, particularly in the elderly, confusion or delirium. Patients with Graves' disease also have ophthalmopathy characterized by lid retraction and exophthalmoses that can lead to optic nerve damage. In contrast, older patients can have few of the classic signs of hyperthyroidism and instead might complain of fatigue or weakness (apathetic hyperthyroidism), unexplained delirium, weight loss, heart failure, or isolated atrial fibrillation.

Some patients have a rapid escalation of symptom severity (thyroid storm) that is life-threatening if not identified and treated promptly. These patients usually have underlying thyrotoxicosis from Graves' disease complicated by a secondary physiological stressor such as infection, surgery, or trauma. This is a medical emergency and needs immediate attention, including hospitalization with close observation.

On physical examination, patients with hyperthyroidism due to Graves' disease or thyroiditis might have a diffusely enlarged and mildly tender thyroid gland. In suppurative thyroiditis, the thyroid gland is red, hot, and very tender and accompanied by a fever and other systemic signs of severe infection. Patients with toxic nodular goiter can have palpable nodules in their thyroid gland and often have a single palpable nodule.

**Diagnosis**

Hyperthyroidism is diagnosed by finding an elevation in the free thyroxine ( $T_4$ ) level accompanied by a low TSH level. Patients with Graves' disease often have positive anti-thyroid receptor antibody titers. Only anti-thyroglobulin receptor antibody testing is helpful because it can help differentiate Graves' disease from other causes. No other anti-thyroid tests are clinically indicated. Once the thyroid level abnormalities are found, a definitive diagnosis of the cause for the hyperthyroidism is needed to select the appropriate treatment strategy.

Other conditions can produce a depressed TSH but normal free  $T_4$  levels. These include  $T_3$  toxicosis and subclinical hyperthyroidism.  $T_3$  toxicosis refers to situations where triiodothyronine ( $T_3$ ) is produced in excess rather than thyroxine ( $T_4$ ); this can occur in any of the conditions that can cause hyperthyroidism, as well as in surreptitious triiodothyronine (Cytomel) ingestion.

Thyroid scanning and radiolabel uptake are usually necessary to differentiate the causes of hyperthyroidism. Thyroid scanning and uptake rely on the thyroid gland to concentrate radioactive molecules, such as iodine-131 ( $^{131}\text{I}$ ) or technetium. Because of the risk of thyroid storm with iodine administration, patients should be treated with antithyroid drugs for 2 to 8 weeks before a scan and the drugs should be stopped at least 4 days before the test. Patients with Graves' disease show increases in uptake and diffuse distribution of the tracer throughout the thyroid gland. Patients with toxic nodular goiter also have increased uptake, but the isotope is concentrated in a one or a few focal areas, with the remainder of the thyroid gland suppressed. In contrast, patients

**TABLE 1** Treatment Strategies for Hyperthyroidism

TREATMENT	DRUG	DOSAGE
<b>Graves' Disease and Toxic Nodular Goiter</b>		
Thyroid hormone suppression	Methimazole Propylthiouracil	Initial: 30–40 mg/d Maintenance: 5–15 mg/d Initial: 300–400 mg/d Maintenance: 100–300 mg/d
β-Blockade	Propranolol <sup>1</sup> Metoprolol (Lopressor) <sup>1</sup>	10 mg qid 50–100 mg bid
Thyroid gland removal	Radioactive iodine ablation Thyroidectomy	
<b>Acute Thyroiditis</b>		
β-Blockade transiently May need thyroid replacement long term		
<b>Thyroid Storm</b>		
Thyroid hormone suppression	Propylthiouracil	300–400 mg/d
β-Blockade	Propranolol <sup>1</sup>	1 mg/min IV to max 10 mg <sup>3</sup>
Iodine	Lugol's solution	1–2 gtt mixed in water tid
Cardiac and fluid monitoring	Dexamethasone (Decadron) <sup>1</sup>	2 mg q6h

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

with thyroiditis have decreased uptake of the radiolabel and a washed-out or mottled distribution on scanning.

**Differential Diagnosis**

Symptoms of hyperthyroidism also occur in patients with panic disorder and other anxiety conditions. These patients can have sinus tachycardia, tremor, and nervousness that mimic hyperthyroidism.

**Treatment**

Treatment depends on the cause of the hyperthyroidism (Table 1). In Graves' disease, immediate goals of treatment include reducing thyroid hormone production and blocking the peripheral effects of the excessive thyroid hormone. About 30% to 60% of patients, mostly adolescents, enter remission spontaneously, and the remission may be permanent. Remission rates are highest for those with a small goiter, no ophthalmopathy, thyroglobulin levels less than 50 µg/mL, and thyroxine levels less than 20 µg/dL. Signs of remission include a decreased ratio of T<sub>3</sub> to T<sub>4</sub>, lower thyroid-stimulating thyroglobulin levels, and decreased radioactive iodine uptake on rescanning. When remissions do occur, it is usually within a year of starting antithyroid medications.

For those who do not undergo spontaneous remission, which includes most adults, consideration should be given to thyroid gland ablation to permanently treat this condition. Although the dosage can be calculated to attempt to leave patients euthyroid, permanent hypothyroidism occurs in about half of all patients treated with radioactive iodine ablation.

The initial approach to toxic nodular goiter is similar to that for symptom control, but thyroid ablation should be recommended routinely because remissions are very rare.

Thyroid gland production of hormone can be reduced rapidly with either methimazole (Tapazole) or propylthiouracil. For treatment of Graves' disease, methimazole is the preferred

treatment and has the advantage of less frequent dosing, which improves compliance. Propylthiouracil is an alternative that is recommended for women in the first trimester of pregnancy and patients who cannot tolerate methimazole. However, the FDA issued a black box warning about the use of propylthiouracil in 2010 because of liver toxicity; physicians should be aware of this and use propylthiouracil only when methimazole is not suitable. With both drugs, clinicians need to be aware of drug-associated agranulocytosis, which can result in life-threatening bacterial infections. In patients on either of these medications who develop a sore throat, fever, or other signs of infection, a white blood cell count should be done immediately to ensure that they are not neutropenic. Additionally, antithyroid drugs are associated with drug-induced lupus syndromes and other forms of vasculitis.

In addition to reducing production of thyroid hormone, initial therapy for patients with Graves' disease and toxic nodular goiter should include a β-blocker to reduce the tachycardia, tremor, hypertension, and anxiety. A β-blocker that crosses the blood-brain barrier, such as propranolol (Inderal)<sup>1</sup> or metoprolol (Lopressor)<sup>1</sup>, is the best choice in this situation because these also reduce the central nervous system effects such as anxiety, as well as the vascular problems caused by thyroid hormones.

Thyroid storm requires immediate attention and should be managed in the hospital setting, especially in older patients where tachycardia and hypertension can lead to cardiac instability. Prompt administration of β-blockers and propylthiouracil along with cardiac monitoring for dysrhythmias and appropriate fluid management are essential for managing this life-threatening condition. Once antithyroid drugs have been administered, iodine-potassium solution (Lugol's solution) at a dose of 1 or 2 drops three times a day should be administered, which will further reduce thyroid hormone production and reduce peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Finally, corticosteroids also have been shown to rapidly reduce thyroid hormone levels in thyroid storm.

For long-term management, thyroid ablation with radioactive iodine (sodium iodide, <sup>131</sup>I) can restore patients to a permanent euthyroid state. However, radioactive iodine thyroid ablation often results in destruction of more thyroid than optimal, causing hypothyroidism. Radioactive iodine thyroid ablation is contraindicated in pregnancy. For patients in whom radioactive iodine is either contraindicated or not acceptable, thyroidectomy is an option. Thyroidectomy almost always results in permanent hypothyroidism, as well as having other risks inherent in surgery including hypoparathyroidism and recurrent laryngeal nerve damage.

In patients with hyperthyroidism associated with acute thyroiditis, symptoms often resolve by the time the evaluation is complete. In the interim, symptoms can be managed with β-blockers. β-Blocker therapy can be discontinued fairly rapidly (2 to 3 weeks) after the initial onset of symptoms.

Indications for the treatment of subclinical hyperthyroidism are less clear. Based on recommendations of the American Thyroid Association, patients with a persistently low TSH who are over age 65 or who have underlying cardiac disease or osteoporosis should be considered for treatment. The treatment strategy should be directed at the presumed cause of the condition and may include antithyroid medication for suspected Graves' Disease or thyroid ablation for toxic nodular goiter or a solitary autonomous nodule.

**Monitoring**

In patients on antithyroid drugs, thyroid hormone levels should be monitored frequently until they reach a stable euthyroid state. Any change in the patient's underlying health, especially changes that could alter protein levels, should prompt reevaluation. In addition, patients who have thyroid ablation need follow-up testing of TSH and free T<sub>4</sub> levels to ensure that sufficient thyroid tissue has been destroyed to reverse their hyperthyroidism but not make them hypothyroid. This should be done 6 to 8 weeks following ablation therapy.

<sup>1</sup>Not FDA approved for this indication.

## Complications

Complications of hyperthyroidism include acute and chronic conditions. Acutely, the most concerning complications are cardiac dysrhythmias, especially atrial fibrillation. Chronically, excessive thyroxine is associated with cardiomyopathy and osteoporosis. In patients with ophthalmopathy, untreated Graves' disease can lead to progressive vision loss and blindness.

Hyperthyroidism in pregnancy, even when adequately treated, has been shown to be an independent risk factor for cesarean section but not for any additional pregnancy complications. Some patients with existing hyperthyroidism may experience transient increases in free T<sub>4</sub> levels during pregnancy that can be associated with hyperemesis gravidarum. Assessing free T<sub>4</sub> levels in pregnant patients who have hyperthyroidism and develop hyperemesis may be useful.

## HYPOKALEMIA AND HYPERKALEMIA

Method of

Jie Tang, MD

### CURRENT DIAGNOSIS

- The “initial approach” to the evaluation of dyskalemia is to determine if it is secondary to transcellular shifts (in vitro or in vivo) of potassium (K) or a result of a true change in total body K.
- A thorough history and physical will provide useful information regarding the causes of hypokalemia and hyperkalemia, especially in cases of low or high intake of K, and transcellular shifts.
- Key steps in the diagnostic approach to hypokalemia include assessments of urinary K excretion and acid-base status.
- Key steps in the diagnostic approach to hyperkalemia include assessments of renal function and aldosterone activity.

### CURRENT THERAPY

- For both hypokalemia and hyperkalemia, it is critical to assess the underlying transcellular K shift, given the risk of rebound hyperkalemia after K repletion or hypokalemia after K restriction and removal.
- In cases of severe dyskalemia, close cardiac monitoring is needed.
- The aggressiveness of therapy for dyskalemia is directly related to the rapidity with which the condition has developed, the absolute level of serum K, and the clinical evidence of toxicity.
- In severe or symptomatic cases of hypokalemia, both intravenous and oral K repletion are often needed.
- In severe or symptomatic cases of hyperkalemia, supported by electrocardiogram (ECG) abnormalities, both immediate temporizing measures and definitive therapy for K removal are necessary.

## Epidemiology

Hypokalemia is defined as a serum K level of 3.5 mmol/L or lower. It is a common electrolyte disorder encountered in clinical practice. According to one study, serum K less than 3.6 mmol/L was found in up to 20% of hospitalized patients. The majority of these patients had serum K concentrations between 3.0 and 3.5 mmol/L, but as many as 25% had values less than 3.0 mmol/L. Even mild or moderate hypokalemia increases the risks of morbidity and mortality in patients with cardiovascular disease. Hyperkalemia is defined as a serum K of 5.5 mmol/L or higher. The prevalence among hospitalized patients not yet on dialysis was reported to be about 3.3%, and among them, up to 10% had significant hyperkalemia ( $\geq 6.0$  mmol/L). Hyperkalemia also carries a significantly increased risk of mortality.

## Risk Factors

People most at risk for hypokalemia are those who are malnourished, with poor oral intake; those who use certain medications, such as diuretics; and those who have uncontrolled vomiting or diarrhea. People most at risk for hyperkalemia are those with reduced kidney function, those who have a history of diabetes mellitus, or those who take certain medications, such as angiotensin-converting enzyme inhibitors.

## Pathophysiology

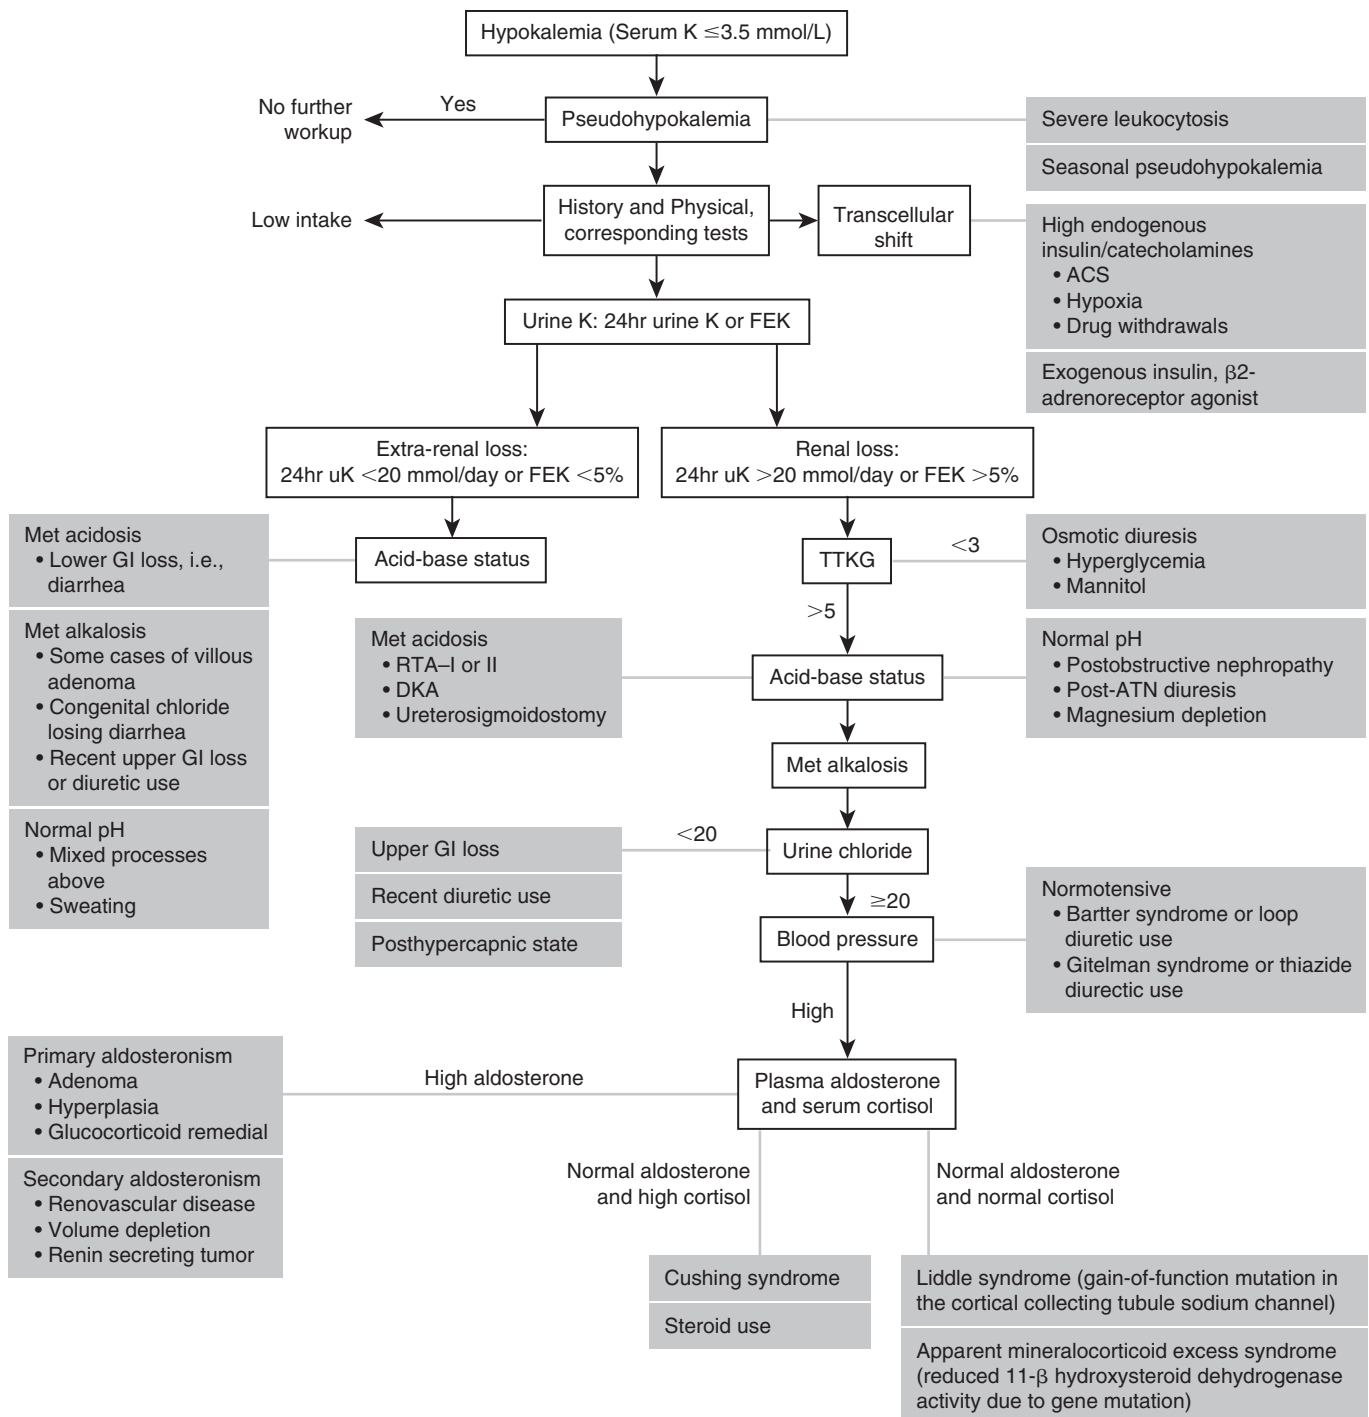

K is the most abundant cation in the human body. It regulates intracellular enzyme function and helps determine neuromuscular and cardiovascular tissue excitability. The total body store is approximately 55 mmol/kg of body weight. Over 98% of total body K is located in the intracellular fluid (primarily in muscle), and less than 2% in the extracellular fluid. A typical Western diet provides 40 to 120 mmol of K per day. Tight control of the serum K is primarily accomplished by the kidney, where approximately 95% of body K is excreted. Under normal circumstances, K losses in stool and sweat are small. In addition, the interplay of several hormonal systems (insulin, catecholamine), serum tonicity, and the internal acid-base environment contribute to the exchange of K between the extracellular fluid and intracellular fluid, which helps keep the serum K concentration tightly controlled. Hypokalemia occurs when there is a significant intracellular K shift or a reduced total body K store from poor intake, or excessive renal or extrarenal loss, whereas hyperkalemia develops when there is a significant extracellular shift, high body K load, or ineffective K elimination (aldosterone resistance/deficiency or reduced renal function).

## Prevention

For patients at risk for hypokalemia, adequate dietary K intake is essential. Additional K supplements may be needed for patients taking high doses of diuretics (especially thiazide diuretics) or experiencing prolonged vomiting or diarrhea. For patients with hyperkalemia and severe kidney dysfunction, dietary K restriction is critical in maintaining body K balance. Sometimes, the empirical use of K exchange resin is needed to prevent hyperkalemia. Lastly, medications that contribute to hypokalemia or hyperkalemia should be avoided if possible.

## Clinical Manifestations

Mild hypokalemia (serum K 3.0 to 3.5 mmol/L) is usually well tolerated. Moderate hypokalemia (serum K 2.5 to 3.0 mmol/L) may cause nonspecific symptoms, such as fatigue, weakness, muscle cramps, and constipation. When the serum K drops to less than 2.5 mmol/L, muscle necrosis and flaccid paralysis with eventual respiratory failure may occur. K depletion also causes supraventricular and ventricular arrhythmias, especially in patients on digitalis therapy. Although severe hypokalemia is more likely to cause complications, even minimal decreases in serum or total body K can be arrhythmogenic in patients with underlying heart disease or who are receiving digitalis therapy. Lastly, increases in systolic and diastolic blood pressures can occur in patients with hypokalemia while they are on a liberal salt diet. Overall, the

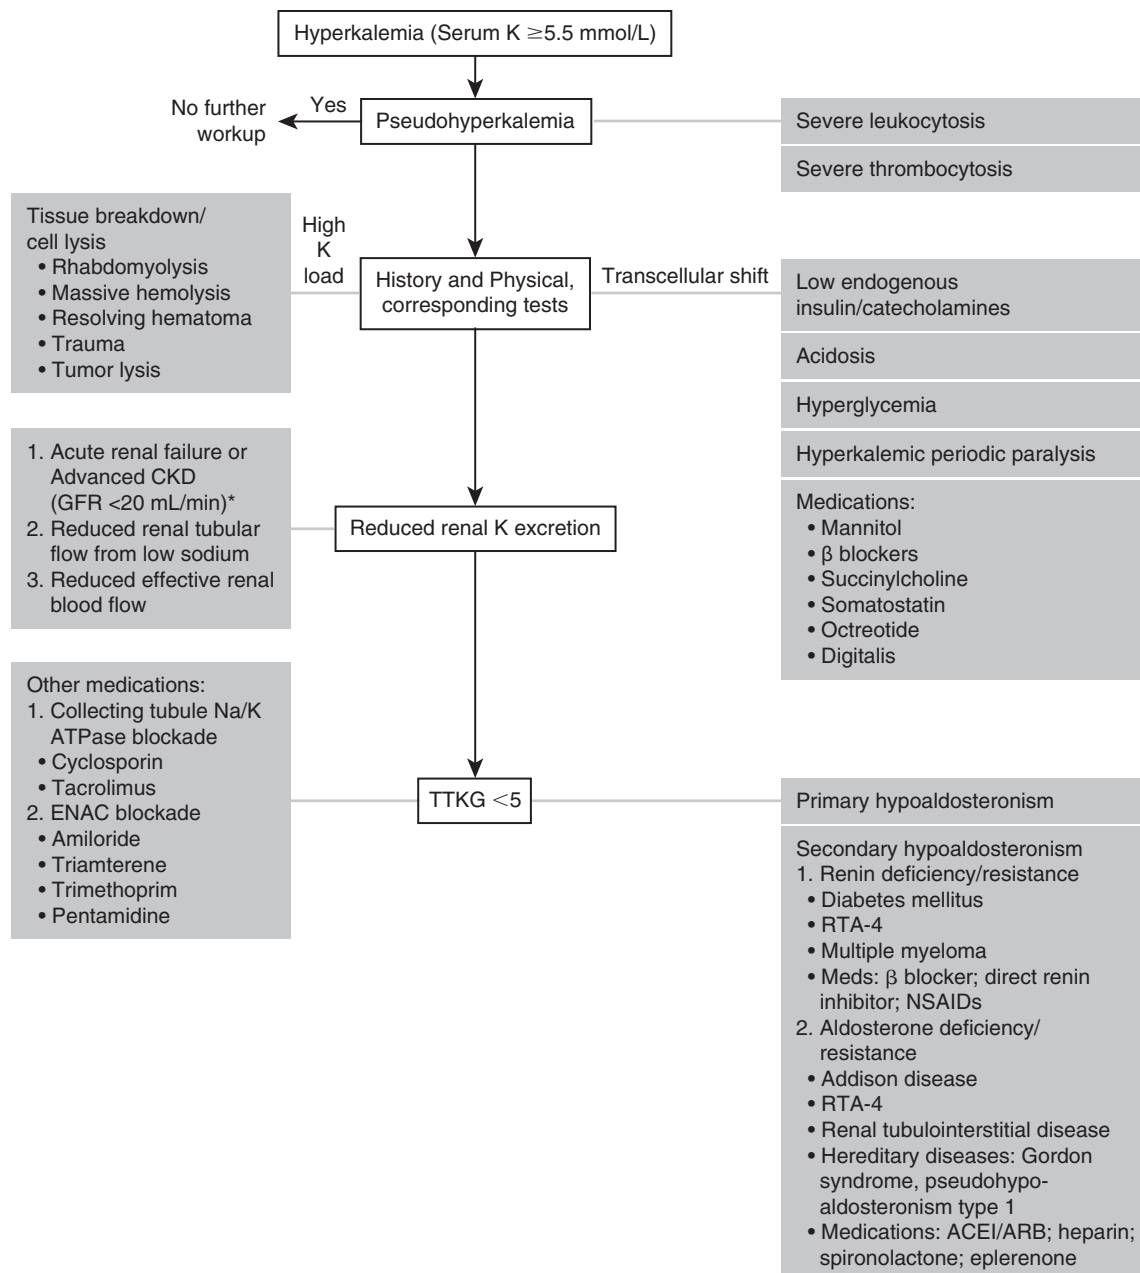

**Figure 1** The diagnostic approach to hypokalemia. ACS, Acute coronary syndrome; ATN, acute tubular necrosis; DKA, diabetic ketoacidosis; FEK, fractional excretion of K; GI, gastrointestinal; Met, metabolic; RTA, renal tubular acidosis.

likelihood of symptoms tends to correlate with the rapidity of the decrease in serum K. As with hypokalemia, patients with hyperkalemia may present with nonspecific complaints such as fatigue and malaise. But the predominant manifestations in more severe hyperkalemia are neuromuscular and cardiac. Neuromuscular symptoms range from muscle weakness to paralysis. Cardiac arrhythmias, including asystole, ventricular tachycardia or fibrillation, and pulseless electrical activity, can also occur in severe hyperkalemia.

### Diagnosis

Figures 1 and 2 illustrate the diagnostic approaches to hypokalemia and hyperkalemia. It is important to assess for pseudodyskalemia (in vitro shift of K) and dyskalemia from in vivo transcellular

shift of K because neither is associated with disturbances in total body K balance. Although cellular shift of K and changes in total body K occur as isolated problems, they frequently coexist. In hypokalemia, the assessment of renal K excretion is a key step in the initial diagnostic evaluation, followed by the assessment of acid-base status. In hyperkalemia, medical history and laboratory testing can help identify altered K distribution, reduced urinary K excretion, or an excessive K load from exogenous intake or transcellular leakage. Under normal circumstances, high K intake alone is not sufficient to lead to significant hyperkalemia unless there are other risk factors present such as reduced aldosterone action or significant loss of kidney function. Measurement of the transtubular potassium gradient (TTKG) has been widely used as a diagnostic tool in both conditions. However, recent evidence

**Figure 2** The diagnostic approach to hyperkalemia. \*Hyperkalemia may occur with higher GFR if K load is excessive. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; ENAC, epithelial sodium channel; GFR, glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; RTA, renal tubular acidosis.

suggests that the assumption inherent in the calculation of the TTKG lacks validity. That said, I still find it useful in the initial assessment.

### Differential Diagnosis

Figures 1 and 2 outline a diagnostic approach, including differential diagnosis, for hyperkalemia and hypokalemia.

### Therapy

The treatment of hypokalemia depends on the underlying cause, the degree of K depletion, and the risk of K depletion to the patient. In general, hypokalemia secondary to cell shift is managed by treating underlying conditions. For example, hypokalemia in the setting of catecholamine increases, as in chest pain syndromes, is managed with appropriate treatments for the pain. However, when cell-shift hypokalemia is associated with life-threatening conditions such as paresis, paralysis, or hypokalemia in the setting of myocardial infarction, the administration of K

is indicated. With K depletion, replacement therapy depends on the estimated degree of decreases in total body K. For example, decreases in total body K accompanied by a fall in serum K from 3.5 to 3.0 mmol/L are associated with a K deficit of 150 to 200 mmol. Decreases in serum K from 3 to 2 mmol/L are associated with 200- to 400-mmol additional decreases in total body K. K can be administered intravenously but in limited quantities (10 mEq/h into a peripheral vein; 15 to 20 mEq/h into a central vein). Larger K requirements can only be accomplished by oral therapy or with dialysis.

The acute management of hyperkalemia depends on the presence or absence of ECG and neuromuscular abnormalities. In the absence of symptoms or ECG abnormalities, hyperkalemia is treated conservatively—for example, by decreasing dietary K or withdrawing offending drugs. In the presence of ECG abnormalities or symptoms, the goal of therapy is to stabilize cell membranes. First-line therapy includes calcium gluconate, 10 to 30 mL IV as a 10% solution (onset of action

1 or 2 minutes). Although the mechanism remains undefined, calcium “stabilizes” the cardiac membranes. The dose can be repeated after five minutes if the ECG changes persist or recur. Other therapies include 8.4% IV sodium bicarbonate<sup>1</sup>, 50 to 150 mEq (onset 15 to 30 minutes), and rapid-acting insulin<sup>1</sup> 5 to 10 units intravenously (onset 5 to 10 minutes). Insulin increases the activity of the Na-K-ATPase pump in skeletal muscle and drives K into cells. Glucose 50%, 25 g intravenously, is given simultaneously with insulin to prevent hypoglycemia. Albuterol given as 0.5 mg in D5W IV or 10–20 mg in 4 mL normal saline by nebulizer (onset 15 to 30 minutes), also activates the Na-K-ATPase and drives K into cells. K driven intracellularly generally begins to move extracellularly again after approximately 6 hours, increasing the serum K concentration. Therefore, therapy to remove K from the body should be started simultaneously. Reductions in total body K may be achieved through a K exchange resin. The primary K resin used is sodium polystyrene sulfonate (Kayexalate). One gram of this medication binds approximately 1 mEq of K and releases 1 to 2 mEq of sodium back into the circulation. This medication may be given orally (onset 2 hours) or by enema with sorbitol to induce diarrhea (onset 30 to 60 minutes).

In 2015, patiromer, a polymer that exchanges calcium for potassium in the gastrointestinal tract, was approved by the Food and Drug Administration (FDA) for the management of hyperkalemia. In 2018, sodium zirconium cyclosilicate (SZC), a novel nonabsorbed, nonpolymer zirconium silicate compound that exchanges hydrogen and sodium for potassium and ammonium was also approved by the FDA for the same indication. Both agents are well tolerated and effective. Patiromer is administered orally at an initial dose of 10 g three times a day for up to 48 hours, followed by a maintenance dose of 10 g daily (maximum daily maintenance dose 15 g/day).

If renal function is adequate, volume expansion with simultaneous diuresis can be attempted. Finally, hemodialysis is very effective in removing excess K.

The chronic management of hyperkalemia starts with dietary K restriction. Other management options include the use of diuretics, cessation or dose reduction of renin-angiotensin-aldosterone system inhibitors, and/or intermittent use of Kayexalate. Both patiromer and SZC are also well tolerated, safe, and effective in the chronic management of hyperkalemia. Just as important, they may allow the optimal use of renin-angiotensin-aldosterone system inhibitors in patients who have been previously untreated, had their dose reduced, or stopped treatment altogether.

### Monitoring

Treatment for severe or symptomatic dyskalemia requires close cardiac monitoring and frequent laboratory testing to prevent overcorrection. If insulin and glucose are used in patients with hyperkalemia, blood sugars should be monitored for approximately 6 hours to identify and treat hypoglycemia from the insulin.

### Complications

Complications from dyskalemia include cardiac arrhythmias, neuromuscular events, and, rarely, death. There are potential treatment-related complications if pseudodyskalemia or dyskalemia from in vivo transcellular shift is not recognized.

## HYPONATREMIA

Method of

Beejal Shah, MD; and Susan L. Samson, MD, PhD

### CURRENT DIAGNOSIS

- Perform a thorough history and physical examination with focus on the accurate assessment of volume status, neurologic symptoms and signs, current medications, and concurrent illnesses.
- Classify the hyponatremia as hypovolemic, euvolemic, or hypervolemic.
- Determine whether the hyponatremia is acute or chronic, based on the history and the clinical manifestations.
- Order key laboratory tests, including a basic metabolic panel (serum sodium, glucose, blood urea nitrogen, and creatinine), plasma osmolality, urine osmolality, and urine sodium.

### CURRENT THERAPY

- Severe and symptomatic hyponatremia should be treated with hypertonic saline (3%) at 1 to 2 mL/kg per hour. Neurologic status and serum sodium should be monitored every 2 to 4 hours. The objective is to raise sodium by 2 mEq/L per hour (or to >125 mEq/L) until deleterious neurologic symptoms improve. After this, the rate of infusion should be titrated to increase the serum sodium by 0.5 to 1.0 mEq/L per hour, with a maximum increase of 6 to 8 mEq/L over 24 hours and no more than 18 mEq/L over 48 hours, to avoid precipitating osmotic demyelination.
- As a general rule, the treatment of hyponatremia should be adjusted for the serum sodium to increase by 0.5 to 1.0 mEq/L per hour with a maximum increase of 6 to 8 mEq/L over 24 hours and no more than 18 mEq/L over 48 hours.
- Acute hyponatremia (<48 hours) with neurologic symptoms should be treated more rapidly than chronic hyponatremia, a 4 to 6 mEq/L increase in serum sodium over 6 hours can reverse severe neurologic symptoms.
- Before a diagnosis of SIADH is made, rule out adrenal insufficiency and hypothyroidism.
- Most cases of euvolemic hyponatremia are caused by the syndrome of inappropriate antidiuretic hormone (SIADH), which usually can be managed with fluid restriction, salt tablets, and vasopressin receptor antagonists (“vaptans”) as indicated.
- Discontinue thiazide diuretics in all cases of hyposmolar hyponatremia.
- Hypovolemic and hypervolemic hyponatremia require therapy to correct the underlying cause (e.g., heart failure) and restore status to euvolemia.
- Vasopressin receptor antagonists (vaptans) are approved for short term management of euvolemic and hypovolemic hyponatremia. The same parameters apply for rate of sodium correction and monitoring as in conventional therapy.
- Overcorrection of hyponatremia should be recorrected in patients at high risk for osmotic demyelination.

Homeostasis maintains the concentration of sodium in the serum between 138 and 142 mEq/L (normal, 135–145 mEq/L) despite variations in water intake. Hyponatremia is defined as a serum sodium concentration of less than 135 mEq/L, although normal range values may differ slightly among laboratories, usually to a minimum normal sodium of 133 mEq/L. It is one of the most common electrolyte abnormalities found in the inpatient setting, occurring in up to 2.5% of patients, and it is a significant marker for mortality, associated with a 60-fold higher risk of death. It is not clear whether hyponatremia

itself is the cause of a more adverse prognosis or whether it echoes the degree of stress caused by illness. In the outpatient setting, chronic hyponatremia is most prevalent among the elderly and nursing home residents. The approach to management of hyponatremia is highly dependent on the underlying process. Establishing the correct etiology is critical, because inappropriate treatment can worsen hyponatremia. Therapy must be administered judiciously because of the risk of severe neurologic sequelae, including central nervous system demyelination. However, with a systematic approach to the differential diagnosis of hyponatremia, the correct diagnosis can be made and therapy initiated.

### Clinical Presentation

Acute hyponatremia is defined as hyponatremia of less than 48 hours in duration. Mild symptoms include headache, nausea, vomiting, confusion, and weakness, which usually occur with a sodium level of less than 129 mEq/L. More severe neurologic manifestations—seizure and coma—are seen usually below a threshold of 120 mEq/L, although there currently is no evidence-based critical sodium level above which neurologic sequelae do not occur. The neurologic manifestations of acute or recurrent symptomatic hyponatremia can be delayed, so continued monitoring is important.

In contrast, patients with chronic hyponatremia more often are asymptomatic or have blunted symptoms. In elderly patients with mild chronic hyponatremia, subtle neurocognitive manifestations can occur, with decreased balance, lowered reaction speed, memory loss, and directed gait. Mild hypoosmolar hyponatremia is not independently associated with increased morbidity and mortality. Even so, the underlying etiology needs to be determined because of the potential for other factors (e.g., new medications, dehydration, occult illness) to contribute to the development of more severe hyponatremia with its potential for neurologic injury.

### Regulation of Water Balance

Approximately two thirds of total body water is contained in the intracellular fluid (ICF) and one third as extracellular fluid (ECF). Plasma osmolality is tightly regulated between 280 and 290 mOsm/kg and reflects the osmolality of the ECF. A change in plasma osmolality results in a shift of total body water between the ECF and the ICF to maintain their osmolar equivalence. Because sodium is the major osmole in the ECF, hyponatremia most often is a manifestation of decreased osmolality, so-called hypoosmolar or hypotonic hyponatremia.

### Renal Handling of Water

The major osmoregulatory hormone is arginine vasopressin, also called antidiuretic hormone, which is synthesized in the paraventricular and supraoptic nuclei of the hypothalamus. It is transported along axons to the posterior pituitary, where it is processed and stored in vesicles. Vasopressin secretion is regulated by osmotic and nonosmotic stimuli. Secretion occurs with a 1% to 2% rise in osmolality (>288 mOsm/kg), as detected by receptors in the anterolateral walls of the hypothalamus adjacent to the third ventricle. Vasopressin secretion is inhibited when the plasma osmolality is lower than 280 mOsm/kg. The major nonosmotic stimulus is a decrease in effective circulating volume, which is detected by baroreceptors in the aortic arch and carotid sinuses. Although this mechanism requires a large drop (10%–15%) in blood pressure, the secretory response is more robust than for increases in osmolality. As such, acutely lowered blood pressure can override the inhibitory signal of low osmolality because of the need to maintain perfusion. Other physiologic nonosmotic stimuli include catecholamines and angiotensin II, but there is a long list of hormones and pharmacologic agents that induce or repress vasopressin secretion (Table 1).

The renal site of action of vasopressin is the V<sub>2</sub> receptors on the basolateral membrane of collecting duct cells in the distal nephron. The hormone-receptor interaction initiates intracellular signaling via cyclic adenosine monophosphate-dependent pathways, resulting in translocation of cytoplasmic aquaporon-2 channels to the surface of the collecting duct luminal membrane. These channels allow movement of water back into the cell for later reabsorption into the circulation. This results in a net concentration of urine and decreased plasma osmolality.

**TABLE 1** Molecules That Regulate Vasopressin Secretion

STIMULATE VASOPRESSIN RELEASE	INHIBIT VASOPRESSIN RELEASE
<b>Hormones and Neurotransmitters</b>	
Acetylcholine (nicotinic)	Atrial natriuretic peptide
Angiotensin II	γ-Aminobutyric acid
Aspartate	Opioids (κ receptors)
Cholecystokinin	
Dopamine (D <sub>1</sub> and D <sub>2</sub> )	
Glutamine	
Histamine (H <sub>1</sub> )	
Neuropeptide Y	
Prostaglandin	
Substance P	
Vasoactive inhibitory peptide	
<b>Pharmacologic Agents</b>	
Adrenaline (epinephrine)	Butorphanol (Stadol)
Cyclophosphamide (Cytoxan)	Ethanol
High-dose morphine	Fluphenazine (Prolixin) Glucocorticoids
Nicotine	Haloperidol (Haldol)
Selective serotonin reuptake inhibitors	Low-dose morphine
Tricyclic antidepressants	Phenytoin (Dilantin)
Vincristine (Oncovin)	Promethazine (Phenergan)

### Renal Handling of Sodium

In addition to renal water handling, sodium reabsorption and excretion are important for maintenance of water homeostasis. The renin-angiotensin-aldosterone system is activated by reduced arterial perfusion pressure sensed by the juxtaglomerular apparatus of the afferent renal arteriole. Reduced arteriole effective volume (low or perceived) is sensed by the juxtaglomerular apparatus, which secretes renin, activating the renin-angiotensin system. This cascade of events ultimately stimulates aldosterone secretion, which acts at the distal nephron to cause reabsorption of filtered sodium via Na<sup>+</sup>,K<sup>+</sup>-adenosine triphosphatase (ATPase)-dependent sodium channels.

### Central Nervous System Response to Hyponatremia/Hypoosmolality

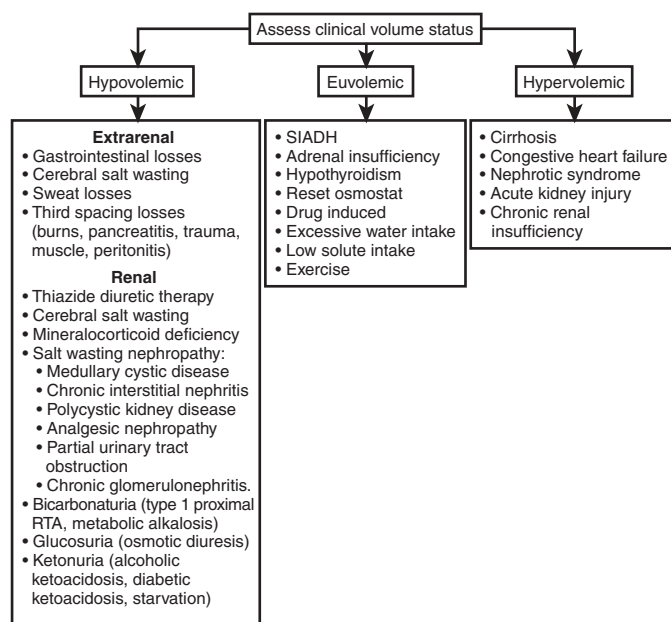

Osmolar equivalence between the ECF and ICF is closely maintained by shifts in water between the two compartments. The major symptoms and signs of hyponatremia are neurologic in nature and are a clinical manifestation of swelling of the cells in the central nervous system, which results in cerebral edema. The most devastating consequence is herniation due to anatomic limitations on brain volume within the confines of the skull. Premenopausal women are at the highest risk for brain injury from hyponatremia.

A major compensatory mechanism in the central nervous system is the extrusion from the cells of intracellular solutes, which prevents further water influx. In the first few hours, inorganic ions (potassium, sodium, chloride) move out of the cell. After a few days of persistent hypoosmolality, the cells further compensate by extruding organic osmoles (glutamate, taurine, inositol). The clinician must be aware of this protective adaptation, because it necessitates a slower time course of correction during treatment. A rapid rise in plasma osmolality from aggressive treatment causes water to rapidly shift out of the cells, resulting in demyelination of neurons. In the past, this was termed pontine demyelination, but

it has also been reported for extrapontine neurons and is now referred to as osmotic demyelination. The sequelae are permanent and devastating. There is clinical progression from lethargy to a change in affect, to mutism and dysarthria, and finally to spastic quadriparesis and pseudobulbar palsy.

### Classification and Differential Diagnosis of Hyponatremia

Initial evaluation of hyponatremia requires a systematic and sequential approach. First, a thorough history and physical examination are required. It is important to identify any history of brain injury, stroke, mental illness, or chronic illness and the patient's current medication usage. On examination, special attention should be paid to mental status and neurologic abnormalities; manifestations of cardiac, hepatic, or renal disease; and signs of adrenal insufficiency or hypothyroidism. From the assessment of volume status, the hyponatremia should be classified as hypovolemic, euvolemic, or hypovolemic; each of these conditions leads in a different direction for diagnosis and treatment of the underlying cause (Figures 1 and 2). Finally, it should be determined whether the hyponatremia is acute (<48 hours) or chronic, because this can determine the time course of treatment.

**Figure 1** The differential diagnosis of hyposmolar hyponatremia. *Abbreviations:* RTA = renal tubular acidosis; SIADH = syndrome of inappropriate antidiuretic hormone.

For the laboratory work-up, essential basic tests are the serum sodium and potassium levels, renal function tests with blood urea nitrogen (BUN) and creatinine, and liver function tests. It is likely that these tests have already been performed, motivating the assessment of hyponatremia. After this, the plasma osmolality ( $P_{Osm}$ ), urine osmolality ( $U_{Osm}$ ), and urine sodium concentration are key diagnostic tests.  $P_{Osm}$  is directly measured in the laboratory and also can be calculated. Calculated osmolality is the sum of the concentrations of the known major osmoles—sodium and glucose—in the ECF and the BUN:

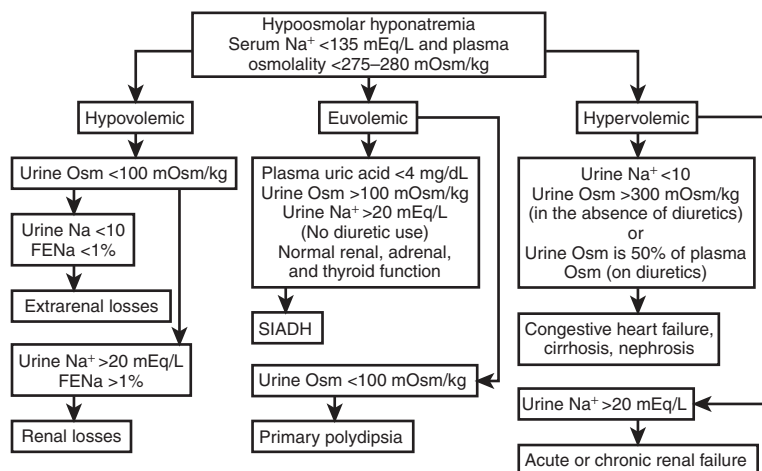

$$P_{Osm} = (2 \times Na) + (\text{glucose}) + (\text{BUN})$$

The calculation is done in SI units. For sodium, mEq/L is the same as the SI unit, mmol/L; if glucose and BUN values were reported in mg/dL, they must be divided by 18 and 2.8, respectively, to convert to SI units (mmol/L). The directly measured osmolality should be within 10 to 12 mOsm/kg of the calculated value; an increased osmolar gap compared with the calculated value points toward the presence of additional osmoles in the plasma that are causing hypertonicity.

Because hyponatremia usually is a reflection of plasma osmolality, most patients also have a low  $P_{Osm}$ , and the clinician often can proceed to the differential diagnosis of hyposmolar (or hypotonic) hyponatremia after excluding pseudohyponatremia (which usually has normal osmolality) and hyperosmolar hyponatremia. Pseudohyponatremia can occur if the plasma lipid or protein content is greatly increased in the plasma (usually to >6%–8% of volume), as in extreme hypertriglyceridemia and paraprotein disorders. These extra components decrease the aqueous portion of the plasma volume and thereby interfere with the laboratory measurement of sodium by dilutional, indirect methods such as flame photometry. Most laboratories now use direct measurement of sodium to avoid this problem.

Hyperosmolar hyponatremia can occur if there are additional osmoles present that cause water movement from the ICF into the ECF, resulting in ECF expansion and dilutional hyponatremia. Overall, the total body water and total body sodium are unchanged in this situation. An important clinical example occurs with hyperglycemia, and the reported sodium value should be corrected for high glucose by the clinician by adding 1.6 mEq/L to the measured Na for every 100 mg/dL rise in glucose above 200 mg/dL. Because glucose is included in the calculation of osmolality, there will be no significant osmolar gap.

Other osmotically active solutes encountered clinically are mannitol, which is used to manage increased intracranial pressure, and glycine, which is used for irrigation in urologic procedures. Mannitol and glycine are retained in the ECF and are not part of the calculated osmolality, so their presence results in an osmolar gap. High levels of alcohol or ethylene glycol also increase the osmolality, but these substances are so quickly metabolized that an osmolar gap may not be apparent by the time testing is performed.

**Figure 2** Laboratory findings in hyposmolar hyponatremia. *Abbreviations:* FENa = fractional excretion of sodium; Osm = osmoles; SIADH = syndrome of inappropriate antidiuretic hormone.

Once pseudohyponatremia and hypertonicity have been ruled out, the diagnosis is narrowed to hypoosmolar hyponatremia. The combined physical examination and laboratory results allow classification of the patient as having hypervolemic hyponatremia with excess total body sodium, hypovolemic hyponatremia with a deficit of total body sodium, or euvolemic hyponatremia with near-normal total body sodium.

### Hypovolemic Hyponatremia

The causes of hypovolemic hyponatremia can be classified as extrarenal or renal (see [Figure 1](#)). Signs of volume contraction are apparent on examination, including poor skin turgor, skin tenting (forehead), decreased or undetectable jugular venous pressure, dry mucous membranes, and orthostatic changes in blood pressure and pulse rate. If the volume status is not completely clear from the examination, laboratory values can be helpful (see [Figure 2](#)), but they need to be interpreted in the context of renal function tests. If the urine osmolality is less than maximally concentrated ( $<500$  mOsm/kg), an infusion of 0.5 to 1 L of isotonic saline over 24 to 48 hours may help with differentiation. With hypovolemia, the sodium will begin to correct and the patient should improve clinically. Conversely, if the patient is actually euvolemic, such as with syndrome of inappropriate antidiuretic hormone (SIADH), discussed later, the serum sodium level will remain constant or decrease due to retention of free water with a concomitant increase in urinary sodium.

Extrarenal causes of hyponatremia include gastrointestinal losses and third-space losses such as in severe burns and pancreatitis. In the volume-depleted state, with intact renal function, the urine sodium is low ( $<10$  mEq/L), reflecting a normal response by the kidney to maximally reabsorb sodium in response to volume depletion.

The renal causes of hypovolemic hyponatremia involve the inappropriate loss of sodium into the urine, and this is reflected by a urine sodium concentration of greater than 20 mEq/L.

Thiazide diuretics cause renal sodium loss, so the urine sodium is high. However, they also impair the kidney's diluting capacity, decreasing free water excretion and concentrating the urine. Only certain patients may be susceptible to hyponatremia while on thiazides. These patients may have an abnormally sensitive thirst response to the mild hypovolemia induced by the diuretics, causing increased water intake. Elderly women are the most susceptible, and hyponatremia can occur within days after initiation of thiazide therapy. Additional laboratory results reveal hypokalemia and a metabolic alkalosis. It is appropriate to stop the diuretic and restore potassium levels and volume status. Patients often have a recurrence of hyponatremia if rechallenged with thiazides. Loop diuretics, such as furosemide, are a less frequent cause of hyponatremia, which occurs only after long-term therapy.

In the absence of diuretic use, a urine sodium concentration greater than 20 mEq/L with hypovolemia is evidence for underlying renal pathology. Patients with salt-wasting nephropathy, from a number of causes (see [Figure 1](#)), usually have significant renal failure, with a creatinine value in the range of 3 to 4 mg/dL. Because of the large net sodium loss, this condition is treated with salt tablets. Renal tubular acidosis causes bicarbonaturia, which requires a compensatory excretion of urinary cations, mainly  $\text{Na}^+$  and  $\text{K}^+$ , to maintain electroneutrality. Similarly, excretion of ketones into the urine also demands additional electrolyte losses in spite of ECF volume depletion, leading to a loss of sodium.

Cerebral salt wasting (CSW), although it could be considered an extrarenal cause, also involves the renal loss of sodium ( $>20$  mEq/L). The biochemical presentation is very similar to that of SIADH, but the diagnosis of CSW is restricted to cases involving extreme central nervous system pathology. CSW is most commonly associated with subarachnoid hemorrhage but also has been reported with stroke, brain trauma, infection, metastases and after neurosurgery. Onset of CSW is usually within the first 10 days after the neurologic event.

CSW may be a protective mechanism against increased intracranial pressure. The proposed pathophysiologic mechanism of CSW is controversial, but one hypothesis is that the initiating event is a primary natriuresis, with renal loss of sodium, caused by the secretion of natriuretic peptides. Clinical studies have found both increased

brain natriuretic peptide and increased atrial natriuretic peptide in neurosurgical patients with hyponatremia. Both hormones are vasodilators that increase the glomerular filtration rate while suppressing the renin-angiotensin system. This increases renal sodium losses, as well as water excretion, resulting in volume depletion. Vasopressin levels rise in response to low volume, so that it becomes biochemically difficult to differentiate CSW from SIADH, with a urine sodium level greater than 20 mEq/L, low uric acid, and high urine osmolality. It is helpful if CSW patients have signs of volume depletion in combination with the laboratory results. Also, the hyponatremia of CSW responds to normal saline, whereas SIADH worsens with normal saline. CSW is relatively rare in most case series, and it is important to rule out other causes for natriuresis.

### Hypervolemic Hyponatremia

There are a variety of causes of hypervolemic hyponatremia (see [Figure 1](#)), all of which are a result of decreased effective circulating volume. To correct this imbalance, the ECF expands, leading to fluid retention and hyponatremia. In spite of the increased total body water and low serum sodium on testing, all of these patients have some degree of total body sodium excess. In many cases, volume overload is clinically evident from the presence of subcutaneous edema, ascites, elevated jugular venous pressure, or pulmonary edema.

In congestive heart failure (CHF), patients can develop hyponatremia with only 2 to 3 L of fluid intake per day despite normal renal function. The decreased filling pressures and cardiac output of CHF are perceived as volume depletion, detected by the baroreceptors. This stimulates vasopressin secretion, overriding the signal of low osmolality detected by the hypothalamic osmoreceptors. This lack of inhibition of vasopressin secretion is believed to be the most important contributing factor to the development of hyponatremia. In addition, decreased right atrial pressures result in inhibition of secretion of atrial natriuretic peptide, contributing to the water and sodium gain. With the low perfusion pressure, there is a decrease in the glomerular filtration rate, which is sensed by the juxtaglomerular apparatus, causing neurohumoral activation of the renin-angiotensin system and sympathetic nervous system. This leads to increased circulating levels of catecholamines, angiotensin II, and aldosterone, further stimulating tubular sodium and water reabsorption. In the absence of diuretics, the urine sodium level is very low ( $<10$  mEq/L) in patients with CHF because of activation of the renin-angiotensin-aldosterone system and maximal tubular reabsorption of sodium. Also, there is less than maximally dilute urine (usually  $>300$  mOsm/kg) in the absence of diuretic therapy. An elevated brain natriuretic peptide concentration helps to confirm the hypervolemia.

A similar mechanism is at work in cirrhotic patients, in whom the incidence of hyponatremia is even higher and is a strong predictor of poor outcome. In cirrhosis, low albumin results in third-spacing and decreased effective circulating volume. In addition, portal hypertension leads to splanchnic vasodilation, which also decreases the effective circulating volume. This serves to activate vasopressin secretion and the renin-angiotensin-aldosterone system.

Hyponatremia is less common in acute and chronic renal failure, but it can occur with a significant decrease in glomerular filtration rate accompanied by severe hypoalbuminemia. Interpretation of the laboratory results may be confounded by a high urine sodium concentration ( $>20$  mEq/L) that reflects the concomitant presence of tubular dysfunction. Hyponatremia can develop in stage IV or V renal failure when fluid intake is in excess of 3 L/day.

### Euvolemic Hyponatremia

Euvolemic hyponatremia is caused by impaired excretion of free water by the kidney. The differential diagnosis is more limited (see [Figure 1](#)) and the majority of cases are due to SIADH ([Table 2](#)). However, this often is a diagnosis of exclusion, and hypothyroidism and adrenal insufficiency must be ruled out clinically or biochemically in patients with euvolemic hyponatremia.

Hypothyroidism leads to reduced glomerular filtration rate and decreased flow to the distal nephron, causing maximal reabsorption of water to maintain arterial volume. Hypothyroidism has to be severe to cause hyponatremia and usually is obvious on

examination. However, in the elderly population, apathetic hypothyroidism may be difficult to diagnose. Hypothyroidism can be confirmed by the presence of a high level of thyroid-stimulating hormone and a low level of free T<sub>4</sub> (thyroxine). Treatment involves thyroid hormone replacement and supportive care.

In primary adrenal insufficiency (Addison's disease), the concomitant aldosterone deficiency results in hyponatremia combined with hyperkalemia, prerenal azotemia, a urine sodium concentration greater than 20 mEq/L, and a urine potassium level lower than 20 mEq/L. In secondary or central adrenal insufficiency, the adrenal zona glomerulosa remains intact for the secretion of aldosterone. However, glucocorticoid deficiency still causes impaired water excretion, which can lead to dilutional hyponatremia. Vasopressin release may be stimulated by the nausea, vomiting, and orthostatic hypotension that occurs with adrenal insufficiency. Finally, corticosteroids normally inhibit vasopressin release, so their deficiency leads to enhanced vasopressin release, causing retention of free water that further contributes to the hyponatremia. The appropriate diagnostic test is a 250- $\mu$ g ACTH (cosyntropin, Cortrosyn) stimulation test, although an extremely low 8 AM cortisol level (<3  $\mu$ g/dL) can be diagnostic. Treatment consists of glucocorticoid replacement.

### Syndrome of Inappropriate Antidiuretic Hormone

SIADH is the most common cause of euvolemic hypoosmolar hyponatremia. Edema, ascites, and orthostasis are absent, and thyroid, adrenal, and renal functions are normal. Recent diuretic use should be ruled out. The primary event is the release of vasopressin, which results in water retention. The increased intravascular volume stimulates a natriuresis, which actually is appropriate, but the resulting loss of sodium compounds the hyponatremia. There is an extensive list of causes of SIADH, usually involving pulmonary or central nervous system pathology (see Table 2). A number of medications also are known to stimulate vasopressin release or to potentiate its antidiuretic properties at the level of the kidney (see Tables 1 and 2).

The diagnosis of SIADH is suggested by a low P<sub>Osm</sub> (<280 mOsm/kg) with a high U<sub>Osm</sub> (>100 mOsm/kg), confirming water retention and an inappropriately concentrated urine. A spot urine sodium level will be greater than 20 mEq/L, and usually greater than 30 mEq/L. Other helpful laboratory findings include low plasma uric acid (<4 mg/dL), which has a positive predictive value of 73% to 100% for SIADH in this setting. In complicated cases confounded by use of diuretics, the fractional excretion of uric acid has a positive predictive value of 100% for SIADH when the calculated excretion is greater than 12%.

Reset osmostat can be considered a form of SIADH, but the hyponatremia is usually chronic, mild, and asymptomatic. Vasopressin release continues to be regulated, but at a lower threshold of plasma osmolality. The thirst threshold may be altered as well. Interventions to raise the sodium usually have short-lived effects, and the sodium resets at its previous value over time. Therefore, treatment is not recommended if the sodium level is stable and the patient is asymptomatic. A physiologic example of reset osmostat is seen in pregnancy, when the normal sodium range is lowered by 5 mEq/L.

### Other Causes of Euvolemic Hypoosmolar Hyponatremia

Primary or psychogenic polydipsia should be considered in patients presenting with hyponatremia and a history of psychiatric illness and treatment. Almost 6% to 7% of psychiatric inpatients are at risk for hyponatremia from increased water intake. The polydipsia may be related to a lowered osmolar threshold for thirst, below the threshold of suppression of vasopressin secretion. This can be further complicated by the side effect of dry mouth caused by many psychiatric medications, which compounds the increased thirst and water intake. Because the kidney is capable of excreting up to 15 to 20 L/day of dilute urine, the fact that hyponatremia develops in these patients may point toward an additional and inappropriate increase in vasopressin release or sensitivity. These patients are clinically euvolemic because of renal excretion of the excess water and have otherwise normal laboratory results except for a dilute urine (<100 mOsm/kg), which is caused by vasopressin suppression and helps differentiate primary polydipsia from SIADH. However,

**TABLE 2** Causes of SIADH

#### CNS Disorders

Mass lesions (tumors; CNS abscess; intracranial hemorrhage or hematoma)  
Stroke

<sup>2</sup>Not available in the United States.

**Abbreviations:** ACE = angiotensin-converting enzyme; AIDS = acquired immunodeficiency syndrome; CNS = central nervous system; COPD = chronic obstructive pulmonary disease; DDAVP = 1-deamino, 8-D arginine-vasopressin; MDMA = methylenedioxymethamphetamine; NSAIDs = nonsteroidal antiinflammatory drugs; SSRIs = selective serotonin reuptake inhibitors.

some patients have mildly concentrated urine (>100 mOsm/kg), in which case the psychiatric history helps with the diagnosis.

Exercise-induced hyponatremia (e.g., from marathon running) is a form of euvolemic hypoosmolar hyponatremia primarily caused by retention of water relative to fluid lost via sweating or renal excretion. Vasopressin levels are inappropriately increased during exercise-induced hyponatremia. Most importantly, it is an acute hyponatremia, developing in less than 24 hours, and should be treated accordingly.

Vasopressin levels also may be inappropriately high, secondary to pain or the use of NSAIDs, which remove prostaglandin inhibition of vasopressin release. Low solute intake combined with high fluid intake also can cause hyponatremia, as with beer potomania or a low-protein “tea and toast” diet in elderly patients. In both cases, the lack of solute in the urine does not allow retention of water in the filtrate, so the excess water is not excreted.

Hyponatremia also is common after pituitary surgery (trans-sphenoidal or by craniotomy) and may be a result of damage to the hypothalamic-pituitary tract that causes release of preformed vasopressin from damaged neurons. Often, hyponatremia occurs as the second phase of the classic triphasic response: transient diabetes insipidus, transient SIADH, followed by permanent diabetes insipidus. Hyponatremia can be delayed up to 1 week postoperatively, and sodium should be monitored during the second week as well. Contributions by central adrenal insufficiency and hypothyroidism also are considerations after pituitary surgery, although with these conditions there will be obvious clinical manifestations in addition to the hyponatremia.

### Management

The major considerations for choosing the type and time course of treatment for hyponatremia are the duration of hyponatremia (acute or chronic) and the presence of neurologic signs and symptoms, especially severe manifestations such as altered mental status or seizure (see Table 2). Treatment options for hyponatremia include fluid restriction, saline infusion (hypertonic or isotonic), vasopressin receptor antagonists and demeclocycline (Declomycin).<sup>1</sup> Also, treatment of the underlying abnormality, such as CHF or salt wasting, and correction of volume status are important for hypovolemic or hypervolemic patients. Autocorrection may occur after initiation of therapy, especially in cases of hypovolemia, adrenal insufficiency, or thiazide use. Once treatment is started, the contribution of the nonosmotic stimulation of vasopressin secretion is removed, and the patient is able to raise the sodium level by 2 mEq/L per hour over 12 hours.

### Acute Severe Symptomatic Hyponatremia

Acute severe hyponatremia is defined as a rapid fall in sodium in less than 48 hours to less than 120 mEq/L. Under these circumstances, most patients develop neurologic symptoms because of the rapid fluid shifts between the ECF and the ICF in the brain. If left untreated, it can result in irreversible neurologic damage and death. Because of the acute drop in sodium, initial rapid correction is acceptable and should not lead to osmotic demyelination. Treatment is aimed at raising the sodium enough to resolve the neurologic signs and symptoms. The goal is to raise the serum sodium by 1 to 2 mEq/L per hour or to greater than 125 mEq/L until symptoms resolve. Hypovolemic patients will respond to infusion of isotonic saline (normal saline 0.9%), especially if the urine sodium concentration is less than 30 mEq/L. If the neurologic findings are severe, hypertonic saline (3%) may be infused at rate of 1 to 2 mL/kg per hour, or even up to 4 to 6 mL/kg per hour if the imbalance is life-threatening. A loop diuretic can be combined with the saline to enhance solute-free water excretion. In exercise-induced hyponatremia, hypertonic (3%) saline is the preferred treatment to prevent cerebral edema due to water shifting into the brain along the osmotic gradient. A hypertonic (3%) saline 100 mL bolus can be given to promptly to decrease the osmotic gradient, which is promoting water entry into cells. Thereafter, in the inpatient setting, hypertonic (3%) saline infusion should be continued to promote correction of hyponatremia. Sodium levels should be monitored every 2 to 4 hours in patients undergoing hypertonic infusion. Once symptoms resolve, the rate of correction should be reduced to 0.5 to 1 mEq/hr, and the total rise in sodium should not exceed 18 mEq in 48 hours. Studies demonstrate a 6 mEq/L increase in serum sodium in 6 to 12 hours can reverse the most severe neurologic symptoms of acute hyponatremia. No benefit has been observed for faster rates of correction of hyponatremia, whether acute or chronic. Useful formulas to determine the rate of infusion

for fluids are provided in Figure 3. The formulas can only estimate the rate of correction, and sodium should be measured frequently.

### Chronic Hyponatremia

Chronic hyponatremia is defined as a gradual fall in sodium over more than 48 hours. By this time, the brain has begun to compensate for hypoosmolality by extrusion of solutes. However, the patient is at risk of osmotic demyelination if hyponatremia is treated too aggressively. If the duration of hyponatremia is unknown, the recommendation is to assume that it is chronic. However, as with acute hyponatremia, severe neurologic symptoms and signs need to be treated with hypertonic saline until they resolve, after which the rate of correction can be slowed to 0.5 to 1 mEq/L per hour. Most cases of osmotic demyelination occur with correction rates of greater than 12 mEq/L in 24 hours, but there are cases reported with increases of 9 or 10 mEq/day. Asymptomatic hyponatremia can be treated with an infusion of isotonic saline calculated to raise the sodium by 0.5 to 1 mEq/hour. If the patient has a dilute urine (<200 mOsm/kg), water restriction may be sufficient. Data support favorable outcomes for a maximum target rise in serum sodium of 6 to 8 mEq for any 24 hour period.

### Syndrome of Inappropriate Antidiuretic Hormone

The mainstays of treatment of SIADH are fluid restriction and treatment of the underlying cause. Mild SIADH usually can be controlled with fluid restriction alone.

In most cases of SIADH, the degree of fluid restriction required can be calculated. It is dependent on three factors: the daily osmolar load, the minimum  $U_{Osm}$ , and the patient's maximum urine volume. A typical diet has a daily osmolar load of 10 mOsm/kg of body weight. For a 70-kg person, this would be 700 mOsm/day. With SIADH, the urine osmolality is held constant for that particular patient, as revealed by a spot  $U_{Osm}$ . If the  $U_{Osm}$  is 500 mOsm/kg and the solute load is 700 mOsm, the fluid load has to be less than 700/500 or 1.4 L/day just to maintain the serum sodium level. Fluid intake above this amount will cause the sodium to decrease.

When needed, salt tablets (sodium chloride tablet 1-3 g taken once to three times daily) can help to make up for renal loss of sodium in SIADH. With symptoms and severe hyponatremia, short-term use of hypertonic saline may also be instituted to restore sodium to the ECF compartment. Loop diuretics (e.g., furosemide [Lasix]) can increase free water clearance when given with solute (e.g., hypertonic saline or salt tablets). In refractory cases, demeclocycline<sup>1</sup> (300–600 mg PO twice daily)<sup>3</sup> can be used. Demeclocycline (Declomycin) antagonizes the actions of vasopressin by inhibiting formation of cyclic adenosine monophosphate in the collecting duct. Long-term use is limited by the side effect of photosensitivity and by nephrotoxicity in patients with underlying liver disease. Vasopressin receptor antagonists also are important adjunct treatments (see later discussion). A less commonly used treatment is urea (powder or capsules),<sup>1,6</sup> which causes an osmotic diuresis and increased free water excretion. Preclinical data support that urea may decrease osmotic demyelination.

### Cerebral Salt Wasting

Management of CSW involves treatment of the underlying neurologic problem, as well as volume replacement. CSW often is difficult to differentiate biochemically from SIADH, but the rise in vasopressin in CSW is secondary to volume depletion. As a result, CSW responds to volume replacement with isotonic saline, suppressing release of vasopressin, whereas SIADH worsens with this therapy. The recommended correction rate is 0.7 to 1.0 mEq/L per hour, with a maximum of 9 mEq per 24 hours. Salt tablets may also be given to replete total body sodium. Fludrocortisone (Florinef 0.05 to 0.1 mg every 12 hours), an aldosterone receptor agonist, is a third-line treatment to encourage volume expansion and sodium retention, but the potassium concentration and blood pressure should be monitored. Fluid restriction is inappropriate for CSW and

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

<sup>6</sup>May be compounded by pharmacists.

### Parameters for acute or chronic hyponatremia:

Do not increase serum Na by more than 9 mEq in 24 hours and 18 mEq in 48 hours

### Symptomatic hyponatremia with severe neurologic symptoms (acute <48 hrs or chronic >48 hrs)

1. Correct serum Na at a rate of 1–2 mEq/l per hour (for 2 to 4 hours) until symptoms have resolved
2. Correct Na at a rate of less than 9 mEq/24 h

### Acute hyponatremia symptoms

1. Correct at rate of 0.5 to 1 mEq/L per hour to a maximum of 9 mEq/24 h

### Chronic hyponatremia with mild symptoms or asymptomatic

1. Correct at a rate of 0.5 mEq/L per hour with fluid restriction
2. Treat underlying etiology

### Calculation of the rate of infusion of saline to correct hyponatremia

1. Change in serum sodium per liter infusate  
$$(\Delta\text{Na/L}) = \frac{\text{Infusate [sodium]} - \text{Serum [sodium]}}{\text{TBW} + 1}$$
2. Amount of infusate (in L) required in 24 hours  
$$L = \frac{\text{desired change in sodium } (\Delta\text{Na}) \text{ over 24 hrs}}{\Delta\text{Na/L (from 1)}}$$
3. Rate of infusate to raise serum Na by desired amount  
$$\text{mL/hr} = \frac{L \text{ (from 2)} \times 1000 \text{ mL/L}}{24 \text{ hr}}$$
4. (Simplified) Hypertonic saline infused at 1–2 mL/kg per hour

### Monitoring:

1. Monitor frequently for clinical improvement or worsening of symptoms
2. If on hypertonic saline or severely symptomatic check sodium q2–4 hrs.
3. If undergoing treatment but asymptomatic, check sodium q6–12 h.

**Figure 3** Treatment of hyponatremia. *Abbreviation:* TBW = total body water.

Infusate	Infusate [Na] (mmol/L)
5% sodium chloride in water	855
3% sodium chloride in water	513
Isotonic saline (0.9%)	154
Ringer's lactate solution	130
0.45% sodium chloride in water	77
0.2% sodium chloride in water	34
5% dextrose in water	0

Total Body Water (TBW) is equal to 60% of body weight in young adult men and 50% in young adult women. Older patients have less TBW. In elderly males, TBW is equal to 50% of body weight and in elderly females it is 45%.

should be avoided, especially in patients with subarachnoid hemorrhage, because volume depletion can exacerbate cerebral vasospasm and cause infarction. The duration of CSW is usually 3 to 5 weeks.

### Vasopressin Receptor Antagonists

Vasopressin receptor antagonists, or vaptans, are a treatment option for clinically significant euvolemic hyponatremia defined as a serum Na <125 mEq/L or if hyponatremia is symptomatic and resistant to correction with standard therapy. Vaptans also can be used for asymptomatic hypervolemic hyponatremia, but the benefit must clearly outweigh the risk, and the patient should be refractory to standard therapy. There are currently two FDA-approved vaptans, conivaptan (Vaprisol) and tolvaptan (Samsca). Conivaptan is a dual V<sub>1a</sub>/V<sub>2</sub> arginine vasopressin receptor antagonist and tolvaptan is a selective V<sub>2</sub> arginine vasopressor receptor antagonist with about 29 times the affinity to the V<sub>2</sub> receptor compared to conivaptan. The primary action of both medications is to block the binding of vasopressin to its receptors in the distal nephron which leads to a decrease in translocation of the aquaporin-2 channels to the apical membrane of the collecting duct in the renal tubule. As a result, vaptans cause an increase in excretion of solute-free water resulting in a rise in serum sodium.

Conivaptan is an IV formulation approved for inpatient hospital use for euvolemic and hypervolemic hyponatremia. It is contraindicated for hypovolemic hyponatremia, euvolemic or hypervolemic hyponatremia with moderate to severe central nervous system (CNS) symptoms, and hypervolemic hyponatremia due to cirrhosis. Conivaptan should be used very cautiously in patients with hypervolemic hyponatremia due to heart failure because safety data are limited and efficacy has not been clearly established. Conivaptan is not recommended in those with severe renal impairment CrCl < 30 mL/min. Conivaptan is given intravenously with a bolus of 20 mg over 30 minutes in 100 mL of 5% dextrose in water (D5W) followed by a continuous infusion of 20 mg conivaptan diluted in 250 mL of D5W over 24 hours. After the initial day of treatment, conivaptan can be continued for an additional 1 to 3 days. Sodium is monitored every 2 to 4 hours and the dose may be titrated to 40 mg per 24 hours to obtain an increase in sodium of 0.5 to 1.0 mEq/L per hour. In clinical trials, the average rise in serum Na after 4 days of therapy is about 6 mEq/L. During conivaptan treatment, fluid restriction can be liberal or is not required. Close monitoring of the rate of sodium rise, neurologic status, and hemodynamic stability are required and treatment should be discontinued or resumed at a reduced dose if

clinically indicated. The most common side effects of conivaptan are infusion site reactions and to a lesser degree headache, hypotension, nausea, constipation, and postural hypotension.

Tolvaptan is an oral V<sub>2</sub> receptor antagonist that carries the same indications for use as conivaptan. Tolvaptan should be initiated only in the hospital setting for careful monitoring of potassium and the rate of Na rise, and then can be used in the outpatient setting. The starting dose is 15 mg once daily and can be titrated to 60 mg daily after the initial 24 hours. Patients should not be on fluid restriction for the first 24 hours of tolvaptan therapy and be advised to drink based on thirst. Tolvaptan carries a risk of serious liver injury. The FDA recommends that tolvaptan should not be used for durations longer than 30 days or in any patient with underlying liver disease. Monitoring parameters are equivalent to conivaptan the drug should be stopped promptly in patients with abnormal liver tests or symptoms of hepatotoxicity. In clinical studies, the average rise in serum Na after 4 days of therapy is 4.2 mEq/L and 5.5 mEq/L after 30 days of therapy. The vaptans are a substrate and potent inhibitor of cytochrome P-450 3A4 isoenzyme (CYP3A4). Prior to initiation of therapy drug-drug interactions should be reviewed with the pharmacists and vaptans are contraindicated with other CYP3A4 inhibitors.

### Overcorrection of Hyponatremia

If the correction of chronic hyponatremia exceeds our therapeutic limits over the course of 6, 12 or 24 hours, the approach to readjust treatment depends on the risk of osmotic demyelination. In acute hyponatremia, the risk of osmotic demyelination due to overcorrection is lower especially if the etiology is due to water intoxication. The risk for cerebral injury is greatest when hyponatremia is both longer in duration and at lower sodium levels (i.e., <120 mEq/L). Risk factors for osmotic demyelination with correction for chronic hyponatremia are serum sodium less than 105 mEq/L, hypokalemia, alcoholism, malnutrition and advanced liver disease. Overcorrection is prevented by careful monitoring of serum sodium and urine output at least every 4 to 6 hours. If the 24 hour increase has exceeded 8 mEq/L, active therapies to raise serum sodium should be held over the next 24 hours. In high risk patients for ODS where serum sodium correction is above 8 mEq/L over 24 hours, therapeutic re-lowering of serum sodium may be justified. In such cases, 2 to 4 µg of desmopressin (DDAVP)<sup>1</sup> in combination with 3 mL/kg infusion of 5% dextrose in water given over 1 hour

<sup>1</sup>Not FDA approved for this indication.

has been effective. A serum sodium should be checked after each infusion and therapeutic re-lowering repeated if indicated. In chronic hyponatremic patients not at high risk for ODS, studies have shown 10 to 12 mEq increases over 24 hours were still safe.

### Summary

Hyponatremia is a common electrolyte abnormality and is usually caused by decreased plasma osmolality. Accurate assessment of volume status is a key to determining the underlying cause and choosing the correct treatment approach. The biggest risk of hyponatremia and its treatment is the possibility of severe neurologic sequelae, including fatal cerebral edema and osmotic demyelination. Therefore more aggressive initial treatment is needed in patients with neurologic manifestations (hypertonic saline), but a more conservative approach (e.g., fluid restriction) is needed for less symptomatic patients. Vasopressin antagonists are additional tools for the treatment of euvolemic or hypervolemic hyponatremia refractory to more conservative measures. In patients at high risk for ODS, overcorrection of serum sodium should be avoided and recorrected with holding active therapy or treating with desmopressin and D5W.

## HYPOPITUITARISM

Method of

Fabienne Langlois, MD; Elena V. Varlamov, MD; and Maria Fleseriu, MD

### CURRENT DIAGNOSIS

- Hypopituitarism is rare and occurs most commonly due to sellar tumors and their subsequent treatment (pituitary surgery and radiation); less commonly hypopituitarism is due to infiltrative disease, cancer immunotherapy, traumatic brain injury, and congenital and other disorders.
- Heightened awareness is required, as clinical manifestations are often nonspecific and insidious, and patients can deteriorate and experience adrenal crisis if hypopituitarism is not detected and treated.
- Diagnosis is based on a combination of low baseline peripheral gland hormones (cortisol, thyroid hormone, insulin-like growth factor-1 [IGF-1], testosterone, and estrogen) and low or inappropriately normal pituitary hormones as well as complementary dynamic testing for adrenal insufficiency (AI) and growth hormone (GH) deficiency.
- Pituitary imaging should be performed when a biochemical diagnosis is confirmed or pituitary disease is suspected based on neurologic symptoms (headaches and peripheral vision loss).

### CURRENT THERAPY

- Glucocorticoid (GC) replacement is the most critical of all replacements for hypopituitarism; in such cases hydrocortisone is the preferred medication.
- Physiologic replacement of each pituitary deficiency is individualized and monitored with clinical assessment and/or laboratory measurements.
- Of note: interactions exist between different hormones, thus changes or replacement in one hormonal axis may affect other axes.

### Epidemiology

Hypopituitarism results from a partial or complete pituitary hormone deficiency. Current epidemiology is not well known. A 2001 Spanish population study showed a prevalence of 45.5 cases per 100,000 and an incidence of 4.2 per 100,000 individuals per year. This estimate is likely conservative, as clinical awareness, imaging studies, and overall understanding of hypopituitarism pathophysiology have improved over the last two decades.

### Pathophysiology

The pituitary gland is a small endocrine gland (~1 cm in size) located in sella turcica of the sphenoid bone at the base of the brain; its mechanism of action is closely linked to the hypothalamus and is controlled by various neurohormonal and nonhormonal inputs. The pituitary secretes hypophyseal hormones into the systemic circulation, stimulating target peripheral glands to produce specific hormones, which in turn feed back to the hypothalamic-pituitary system and maintain a highly regulated homeostasis (Figure 1).

The pituitary is composed of two functionally distinct structures that differ in embryologic development and anatomy: the adenohypophysis (anterior pituitary) and the neurohypophysis (posterior pituitary). The anterior pituitary is responsible for GH, prolactin, ACTH, TSH, LH, and FSH. The posterior pituitary stores vasopressin (or antidiuretic hormone [ADH]) and oxytocin, which are produced in the hypothalamus. Therefore any damage to the hypothalamic-pituitary unit can cause an isolated or combined hormonal deficiency (Table 1).

Different etiologies affect various hormonal patterns. In approximately 70% of cases, the anterior pituitary is affected by a locally expanding tumor, causing mass effect. The most frequent pituitary hormonal deficiency related to sellar tumors is growth hormone (GH) deficiency, followed by gonadal axis hormones (luteinizing and follicle-stimulating hormones [LH/FSH]), and thyroid-stimulating hormone (TSH) deficiencies. However, in other etiologies, the pattern of pituitary deficiency differs. For example, in immunotherapy-related hypophysitis, adrenocorticotropic hormone (ACTH) is the first and most common deficiency noted. In contrast, lymphocytic hypophysitis preferentially affects the adrenal and gonadal axes. Infiltrative diseases can also manifest as diabetes insipidus (DI) and/or anterior pituitary dysfunction. Congenital diseases may affect one or more axes and usually present in childhood; for example, an *ANOS1* mutation results in isolated hypogonadotropic hypogonadism (Kallmann syndrome) and failure to go through puberty, whereas a *PROP-1* mutation presents with low GH, TSH, and LH-FSH.

In severe illness, functional hypopituitarism may cause low GH, hypogonadism, and central hypothyroidism, which are transient and may recover with acute stress resolution. Traumatic brain injury may cause hypopituitarism in up to 30% to 40% of cases, most commonly as GH deficit with or without gonadal dysfunction. Many deficiencies resolve within a year. Surgery in the pituitary region can lead to one or complete pituitary hormone deficit, including transient or permanent DI.

**Figure 1** Relationships between hypothalamic hormones, pituitary hormones, and target organs. Numerous hormone-releasing and hormone-inhibiting factors formed in the arcuate and other hypothalamic nuclei are transported to the anterior pituitary by hypophysiportal vessels. In response to hypothalamic hormones, the anterior pituitary secretes the following: corticotropin, which evokes corticosteroid secretion by the adrenal cortex; growth hormone (*GH*), which elicits production of insulin-like growth factors by the liver; follicle-stimulating hormone (*FSH*), which stimulates spermatogenesis and facilitates ovarian follicle development; luteinizing hormone (*LH*), which elicits testosterone secretion by the testes, facilitates ovarian follicle development, and induces ovulation; thyroid-stimulating hormone (*TSH*), which stimulates thyroxin secretion by the thyroid gland; and prolactin, which induces breast tissue growth and lactation. The posterior pituitary hormones, which are formed in the supraoptic and paraventricular nuclei, are transported by nerve axons to the posterior lobe, where they are released by physiologic stimuli. Oxytocin induces the ejection of milk from the breast and stimulates uterine contractions during labor. Vasopressin increases water reabsorption by the kidneys. *ACTH*, Adrenocorticotropic hormone. From Brenner GM, Stevens CW: *Brenner and Stevens' Pharmacology*, 5th ed., pages 359–365. Elsevier; 2018.

### Prevention

In most cases, hypopituitarism is not preventable. Awareness is most important for early diagnosis, as the development of hormonal deficiencies is often insidious and characterized by nonspecific symptoms such as fatigue or weight changes. Pituitary surgery should be performed by a high-volume pituitary neurosurgeon to decrease the risk of surgery-related hypopituitarism. High-dose or prolonged glucocorticoid (GC) therapy suppresses the hypothalamic-pituitary-adrenal (HPA) axis and may also alter the gonadal and thyroid axes. Prolonged opioid use can also induce hypopituitarism, especially adrenal insufficiency (AI) and hypogonadism. Limiting GCs and opioids to the lowest effective dose and for the shortest possible time allows for a reduction in the risk of HPA axis suppression.

### Clinical Manifestations

Signs and symptoms of hypopituitarism vary depending on the type and severity of the pituitary hormones affected and also disease duration.

Signs and symptoms may include the following:

- **ACTH deficiency**—generalized fatigue, weakness, nausea, loss of appetite, failure to thrive, hypotension, hyponatremia, and hypoglycemia (note that mineralocorticoid secretion is intact; thus hyperkalemia, the hallmark of primary AI, is not present).
- **TSH deficiency**—fatigue, weight gain, cold intolerance, dry skin, bradycardia, and constipation.
- **Gonadotropin deficiency**—decreased sex drive; infertility; in women, oligo- or amenorrhea; in men, erectile dysfunction and loss of libido; gynecomastia; muscle atrophy; and decreased exercise capacity.
- **GH deficiency**—failure to thrive and short stature in children; some adults are symptomatic, experiencing fatigue, abdominal fat deposition, weight gain, and decreased concentration, memory, productivity, and quality of life.
- **Prolactin**—inability to lactate.
- **ADH deficiency**—polyuria, polydipsia with excessive thirst, hypernatremia if uncompensated.

## Detailed Diagnosis

The diagnosis of hypopituitarism is based on a combination of high clinical suspicion, imaging studies, and demonstration of inappropriate pituitary hormone in the setting of low levels of a target peripheral gland hormone.

In most cases, once a single pituitary hormone deficit is confirmed, other axes should be tested and pituitary magnetic resonance imaging (MRI) performed. In cases of peripheral vision deterioration with or without headaches, imaging should not be delayed.

### Corticotropin (Adrenocorticotropic Hormone)

AI is confirmed when low cortisol level is measured early in the morning, before 9 a.m. An early-morning serum cortisol level greater than 15 µg/dL in a patient who is not critically ill is usually sufficient to rule out AI, and a level below 3 µg/dL to 5 µg/dL is strongly suggestive of AI. Additionally, serum cortisol testing should be repeated and interpreted in the clinical context (e.g., time of day, acute illness status) and also according to levels of cortisol binding proteins (lower in malnutrition and hypoalbuminemia and higher in hyperestrogenic states). If the serum cortisol level is between 5 µg/dL and 15 µg/dL, an ACTH stimulation test should be performed to confirm diagnosis. An ACTH stimulation test evaluates adrenal reserve that is diminished without the presence of ACTH. A standard high-dose test involves administering 250 µg of cosyntropin (Cortrosyn) and then measuring serum cortisol levels after 30 and 60 minutes. A cortisol level of higher than 18 µg/dL to 20 µg/dL at 30 or 60 minutes is considered normal. In an alternative low-dose (1 µg) test,<sup>1</sup> cortisol is measured 20 to 30 minutes after cosyntropin administration. This test has been suggested to be more sensitive for the diagnosis of secondary than primary AI. Nevertheless, the high-dose test is preferred. Of note, lower cortisol cutoffs (14 µg/dL to 17 µg/dL) have been proposed recently for new, more selective assays (liquid chromatography/mass spectrometry and monoclonal rather than polyclonal immunoassays), which have less cross-reactivity with cortisol precursors; however, these cutoffs need further validation. The serum ACTH level is measured concurrently with baseline cortisol to distinguish between primary and secondary AI. A low or normal ACTH level is consistent with the diagnosis of central AI, while a high ACTH level (typically greater than twice above the upper limit of normal) with primary AI (refer to AI section for further details).

### Thyrotropin (Thyroid-Stimulating Hormone)

The key to a diagnosis of secondary (central) hypothyroidism is inappropriately low or normal TSH in the presence of low free T<sub>4</sub>. Occasionally, in pituitary or hypothalamic disease, TSH is minimally elevated (usually less than 5 mU/L) and often has lower bioactivity. In contrast, in primary hypothyroidism caused by thyroid gland disorders, TSH is markedly elevated. Therefore TSH levels alone are not sufficient for diagnosis in central hypothyroidism. It is therefore important to measure paired TSH and T<sub>4</sub> levels.

### Gonadotropins (Follicle-Stimulating Hormone and Luteinizing Hormone)

In men, central hypogonadism is diagnosed by low testosterone levels when measured between 8 a.m. and 10 a.m. in conjunction with inappropriately normal or low LH and FSH. In premenopausal women, irregular or absent periods (after exclusion of pregnancy) along with low estrogen and low or inappropriately normal gonadotropins indicate central hypogonadism. Hyperprolactinemia, thyroid dysfunction, and hyperandrogenic states (in females) and hemochromatosis (in males), should be excluded as a cause of gonadal dysfunction. In contrast, in primary hypogonadism and in the postmenopausal state, FSH and LH are markedly elevated.

### Growth Hormone

GH secretion is pulsatile, and a single low measurement of GH is not diagnostic of GH deficiency (GHD). Low age- and sex-adjusted

IGF-1 in adults is suggestive of GHD; however, normal IGF-1 does not rule out GHD. Provocative testing with glucagon (GlucaGen),<sup>1</sup> GH-releasing hormone (GHRH), arginine (R-Gen 10), macimorelin (Macrilen), or insulin tolerance tests are recommended for the diagnosis of GHD in adults. Diagnostic cutoffs differ for different tests and for different body mass indices; therefore careful interpretation is important for accurate diagnosis. When three or more pituitary deficiencies are present along with low IGF-1 levels, confirmatory provocative testing is not required.

### Vasopressin (Antidiuretic Hormone)

Hypernatremia in DI may occur due to low ADH, although it is not always present in compensated states if the patient has unlimited access to free water. When hypernatremia is suspected by polyuria and polydipsia, simultaneous measurement of serum and urine osmolality is recommended as an initial test for DI. High serum osmolality (>295 mOsmol/L) and concurrent low urine osmolality (<300 mOsmol/L) are diagnostic of DI. In subtle or unclear cases, a water deprivation test should be performed. Measurement of serum copeptin level after water deprivation, hypertonic saline, or with arginine stimulation using specific cutoffs can be helpful in diagnosis. Copeptin is derived from ADH prohormone and is more stable than ADH; however, copeptin assays may not be available in some countries.

### Differential Diagnosis

Hypopituitarism causes secondary endocrine organ failure and should be distinguished from primary failure (primary AI, primary hypothyroidism, and primary hypogonadism), where the corresponding pituitary hormone will be elevated. An ACTH stimulation test can be normal for more than 2 weeks in patients with an acute onset of central AI, such as pituitary apoplexy or after pituitary surgery, because the adrenal cortex is able to respond to stimulation for several weeks until it undergoes atrophy in the presence of low ACTH. Critical illness may result in temporary suppression of TSH, GH, and gonadotrophins and does not require hormonal replacement in the acute period. Obesity can be a cause of male hypogonadotropic hypogonadism. Central DI should be distinguished from nephrogenic DI and primary polydipsia by means of a water deprivation test or other confirmation testing.

### Treatment

#### Glucocorticoid Replacement

Oral hydrocortisone (Cortef) is the preferred GC. A typical replacement regimen is 15 mg/day to 20 mg/day as a single or divided dose (e.g., two-thirds in the morning and one-third in the early afternoon) due to its short half-life. Single doses in the morning can also be used in patients with central AI. A once-daily dual-release hydrocortisone formulation has been designed to mimic physiologic cortisol production; this is available in Europe but not in the United States. Of note, GC replacement at physiologic doses does not require treatment for bone protection or gastric ulcer prophylaxis.

Longer-acting GCs (prednisone, dexamethasone [Decadron]) may be used in patients who remain severely symptomatic in the evenings or early morning hours or who are unable to comply with a multidose hydrocortisone regimen. However, in such cases the risk of overreplacement is much higher.

Patients and families should be educated about the “sick day regimen” (i.e., to double or triple their daily dose for 3 days to 5 days according to the degree of physical stress or illness). In cases of repeated vomiting or deterioration of illness, it is recommended that patients administer injectable GC (hydrocortisone [Solu-Cortef] 100 mg IM or dexamethasone [Decadron] 4 mg IM) and seek immediate medical attention.

Minor surgical stress (e.g., cataract removal) requires additional administration of intravenous (IV) 25 mg hydrocortisone on the day of surgery only. The suggested dose for moderate stress

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

(e.g., cholecystectomy) is 50 mg to 75 mg IV in divided doses on the day of surgery and the first postoperative day. Severe stress (e.g., coronary bypass surgery) requires 100 mg to 150 mg IV in divided doses for 2 days to 3 days with a subsequent rapid taper to the daily maintenance dose in an uncomplicated surgery (refer to the earlier section on adrenal insufficiency for further details).

Adrenal crisis and critical illness in adrenally insufficient patients are managed by administering a 100-mg IV bolus of hydrocortisone followed by 50 mg to 100 mg every 6 hours to 8 hours or continuous infusion of 200 mg/24 hours with the dose gradually decreased as the patient's condition improves. Additionally, it is recommended that patients wear a medical bracelet indicating AI risk.

### Thyroid Deficiency

Central hypothyroidism is treated by T<sub>4</sub> replacement (levothyroxine [Euthyrox, Levoxyl, Synthroid]). A standard replacement dose for complete central hypothyroidism is 1.6 µg/kg/day; however, lower doses are needed in cases of partial deficiency. TSH should not be used as a marker of adequacy of replacement. Instead, one should adjust the dose to target free T<sub>4</sub> levels in the mid to upper half of the normal range and consider a lower target in elderly patients and in those with comorbidities in an effort to avoid over replacement.

Thyroid replacement should be administered only after corticosteroids have been replaced or adrenal function has been confirmed to be normal. Thyroid replacement in untreated AI can provoke an adrenal crisis.

### Sex Hormone Deficiency

Testosterone replacement in men and estrogen (plus progesterone if the uterus is present) replacement in women is appropriate in symptomatic patients without contraindications after a discussion regarding risks and benefits. Combined oral contraceptive or hormone replacement therapy may be offered to premenopausal women. Premenopausal women not receiving estrogen replacement have an increased risk of cardiovascular disease and osteoporosis. Testosterone improves libido, sexual function, anemia, and bone density in men. Prostate, breast, and uterine cancer are contraindications to sex steroid replacement. Patients at high risk for thrombotic and cardiovascular events, including smokers, are poor candidates for hormone replacement.

### Growth Hormone Deficiency

GH replacement (somatropin [Genotropin, Humatrope]) is administered as a daily injection; longer-acting formulations are in development. In GH-deficient adults, GH replacement improves body composition, has a modest effect on the maintenance of bone density, and improves quality of life. Although mortality in patients with hypopituitarism is increased, GH replacement has not been shown to improve mortality. Side effects of treatment include worsening of insulin resistance, joint pain, and peripheral edema. Although GH replacement has not been directly linked to cancer development or tumor regrowth, replacement is contraindicated in cases of active cancer.

### Diabetes Insipidus

Desmopressin (DDAVP) therapy is individualized based on the patient's symptoms (severity or persistence of polyuria and polydipsia) and serum sodium levels especially during the initiation phase of therapy due to risk of hyponatremia from overcorrection. Desmopressin may be administered orally, intranasally (in some countries), or via a sublingual route; in a hospital setting it may be given via an IV or subcutaneous route. A low dose is used at initiation to avoid hyponatremia. Some patients with partial DI are only mildly symptomatic and prefer no treatment while keeping sodium levels normal with adequate water intake.

### Monitoring

Patients should be periodically assessed for signs of GC over-replacement (weight gain, facial rounding, hyperglycemia, and osteoporosis) or under-replacement (nausea, fatigue, joint pain) and the GC dose adjusted accordingly.

Monitoring for thyroid, GH, gonadal deficiencies includes periodic clinical assessment and measurement of hormone levels (free T<sub>4</sub>, IGF-1, and testosterone). Regular follow-up by an endocrinologist is warranted.

Interaction exists between the various hormone replacements. For example, thyroid replacement and GH affect GC metabolism and may cause AI in patients with low adrenal reserve. Higher maintenance hydrocortisone doses may be required in patients who initiate GH or thyroid replacement. Oral estrogen can increase cortisol- and thyroid-binding globulins, resulting in an increase of the total cortisol and thyroxine levels and relative decrease in the bioavailable free hormone; therefore careful interpretation of test results is necessary.

### Special Circumstances

#### Fertility and Pregnancy

New assisted reproductive techniques have led to the increased prevalence of women with hypopituitarism achieving fertility, and birth rates seem to be high in women with hypopituitarism achieving pregnancy. During pregnancy, many continuous adjustments in pituitary hormonal replacement should be considered.

Although GCs, levothyroxine, and desmopressin are safely prescribed during pregnancy, GH treatment regimens vary significantly between countries. GH is not approved for use in pregnancy, but several publications have shown that it can improve outcomes in women pursuing fertility.

In women with hypopituitarism who desire to be pregnant, close monitoring is needed, and such patients will benefit from an evaluation at a tertiary center of excellence.

### Complications

Complications arise from a failure to diagnose hypopituitarism, especially in the event of an acute onset or severe illness or trauma, as untreated AI can result in cardiovascular collapse, organ failure, and death. Insufficient chronic replacement can lead to persistent symptoms and poor quality of life, whereas over replacement can result in the development of iatrogenic Cushing syndrome, iatrogenic hyperthyroidism, and other complications.

### Conclusion

Early recognition and treatment of hypopituitarism is essential to reduce morbidity and mortality and improve quality of life. Care for patients with multiple pituitary deficiencies is often complex and requires expert management by an endocrinologist in conjunction with a pituitary neurosurgeon when surgical treatment for pituitary lesion is required. Although some pituitary deficiencies except adrenal and thyroid may recover or may not necessitate treatment, most patients require lifelong hormonal replacement and follow-up.

## HYPOTHYROIDISM

Method of

William J. Hueston, MD

### CURRENT DIAGNOSIS

- Hypothyroidism is more common in women as they age.
- The signs and symptoms of hypothyroidism are nonspecific and can mimic other diseases found in the elderly, so clinicians need to have a high index of suspicion.
- The key diagnostic test is to find a low free T<sub>4</sub>. The presence of an elevated TSH indicates primary hypothyroidism, and a low TSH indicates secondary hypothyroidism.
- There is insufficient evidence for screening for hypothyroidism in asymptomatic adults.

### CURRENT THERAPY

- Thyroxine replacement with L-thyroxine (Synthroid, Levoxyl) is the treatment for hypothyroidism. Medication should be titrated to normalize the thyroid-stimulating hormone (TSH) level, which is usually achieved at an overall dose of 100 to 150 µg.
- Initial dosing for those with potential cardiac disease should be started low (25–50 µg/day) and advanced slowly every 6 to 8 weeks.
- Partial substitution of triiodothyronine (Cytomel) for thyroxine should be reserved for elderly patients with persistent neurocognitive dysfunction despite normalization of their TSH.
- Patients who have subclinical hypothyroidism with a TSH >10.0 should be considered for treatment. Patients with a TSH lower than this do not require therapy.

### Epidemiology

Hypothyroidism is second only to diabetes in the prevalence of endocrine disorders in adults in the United States. Hypothyroidism occurs in up to 18/1000 population, with women outnumbering men by approximately 10:1. Rates of hypothyroidism increase dramatically with age, so that about 2% to 3% of all older women have hypothyroidism, and the prevalence is up to 5% in nursing home populations.

The prevalence of subclinical hypothyroidism, defined as an elevated TSH in the presence of normal free thyroxine (T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>) levels increases with advancing age. Women, individuals over 65, and those from European heritage are at higher risk for subclinical hypothyroidism.

### Risk Factors

Thyroid conditions are more common in patients who have a family history of thyroid disorders. In addition, hypothyroidism, as well as thyroid cancers, are more common in patients who had neck irradiation in childhood. However, most cases of hypothyroidism occur in people who have no risk factors.

### Pathophysiology

Several conditions can lead to hypothyroidism (Box 1). Two categories, hypothyroidism after thyroiditis and iatrogenic hypothyroidism secondary to treatment of Graves' disease, account for the overwhelming majority of cases of hypothyroidism in the United States.

The most common non-iatrogenic condition causing hypothyroidism in the United States is Hashimoto's thyroiditis. Most idiopathic hypothyroidism also represents Hashimoto's thyroiditis that has followed an indolent course. Hashimoto's thyroiditis, also called chronic lymphocytic thyroiditis, is the most common of the inflammatory thyroid disorders and the most common cause of

goiter in the United States. The prevalence of Hashimoto's thyroiditis has been increasing dramatically since the 1960s in the United States, but the cause for this rise is unknown. In patients with acute thyroiditis, either subacute granulomatous (also known as de Quervain's) and subacute lymphocytic (also known as silent or painless), transient hypothyroidism is common after an acute attack, and 10% of these patients also develop long-term hypothyroidism.

Another common cause of hypothyroidism is a medical intervention to treat Graves' disease or thyroidectomy for chronic fibrocytic thyroiditis (Riedel's struma). Radioactive iodine ablation of the thyroid for Graves' disease often results in underproduction of thyroxine in the remaining tissue, necessitating thyroid replacement.

A third uncommon cause of hypothyroidism that should not be overlooked is secondary hypothyroidism due to hypothalamic or pituitary dysfunction. These conditions are seen primarily in patients who have received intracranial irradiation or surgical removal of a pituitary adenoma.

Finally, a variety of other conditions including infiltration of the thyroid (amyloidosis, sarcoidosis), iodine deficiency, or medications (such as amiodarone [Cordarone] or interferon) can cause hypothyroidism.

### Prevention

There are no known interventions to prevent hypothyroidism. According to their 2015 analysis, the US Preventive Services Task Force found insufficient evidence to support early detection through routine screening of asymptomatic persons.

### Clinical Manifestations

Individual who have hypothyroidism can present with a variety of symptoms, many of which are not specific. Consequently, clinicians must have a high index of suspicion for hypothyroidism when patients come in with any one or combination of the symptoms that could signal hypothyroidism.

Symptoms of hypothyroidism include lethargy, weight gain, hair loss, dry skin, constipation, poor concentration, trouble thinking or forgetfulness, and depression (Box 2). In older patients, hypothyroidism easily can be confused with Alzheimer's disease or other conditions that cause dementia. Patients who present with depression also should have their thyroid function assessed.

The thyroid examination in most patients with hypothyroidism is completely normal. Patients might have a painless goiter; tenderness in the thyroid is generally a sign of active inflammation consistent with acute thyroiditis. Once the thyroid inflammation has subsided, thyroid function might return to normal. Other physical findings that can occur with hypothyroidism include low blood pressure, bradycardia, nonpitting edema, generalized hair loss especially along the outer third of the eyebrows, dry skin, and

### BOX 1 Conditions Causing Hypothyroidism

#### Thyroiditis

Hashimoto's thyroiditis  
Subacute granulomatous thyroiditis (de Quervain's thyroiditis)  
Subacute lymphocytic thyroiditis (silent or painless thyroiditis)

#### Iatrogenic Hypothyroidism

Radioactive iodine treatment of Graves' disease  
Thyroidectomy

#### Secondary Hypothyroidism (Pituitary Dysfunction)

Pituitary surgery  
Intracranial radiation  
Congenital panhypopituitarism

#### Other Causes

Infiltrative diseases (sarcoidosis, amyloidosis, hemochromatosis)  
Drugs (lithium, interferon, amiodarone [Cordarone])  
Iodine deficiency

**Common Symptoms**

Lethargy  
 Weight gain  
 Constipation  
 Slowed mentation, forgetfulness  
 Depression  
 Hair loss  
 Dry skin  
 Neck enlargement or goiter

**Physical Examination Findings**

Goiter  
 Low blood pressure and slow pulse  
 Hair thinning or loss  
 Dry skin  
 Confusion  
 Depressed affect  
 Non-pitting edema

a lag in the relaxation phase of reflexes that can be assessed most easily in the ankle jerk reflexes.

Finally, there is an association between hypothyroidism and obstructive sleep apnea although it is unclear if this is a causal relationship.

Subclinical hypothyroidism usually has no, or very subtle clinical symptoms which could be explained by other conditions. The primary finding in subclinical hypothyroidism is the abnormal laboratory values. Subclinical hypothyroidism in pregnancy is associated with increases in pregnancy loss, premature rupture of membranes, and neonatal death, but limited evidence does not show a reduction in these risks with thyroid supplementation during pregnancy.

**Diagnosis**

The diagnosis of hypothyroidism is based on finding a low free thyroxine ( $T_4$ ) level, usually with an elevation in the thyroid stimulating hormone (TSH) levels. For patients with hypothyroidism due to pituitary dysfunction, also called secondary hypothyroidism, both the free  $T_4$  and the TSH levels are low.

One situation where clinicians need to be wary is evaluating thyroid status in patients who are severely ill. During times of acute physiological stress, patients may have mildly elevated TSH levels that suggest hypothyroidism but are, in fact, euthyroid. This condition, called euthyroid sick syndrome, does not require treatment with thyroid replacement and resolves within a few weeks of recovery, but it may be difficult to distinguish from preexisting or new-onset hypothyroidism. Clinicians need to use other clinical symptoms to try to differentiate euthyroid sick syndrome from hypothyroidism. Even though it does not require treatment, the presence of euthyroid sick syndrome in a critically ill patient is a poor prognostic sign.

In contrast to hyperthyroidism, there is no role for thyroid scans or iodine uptake testing in patients with hypothyroidism. The only exception to this is when the clinician identifies a mass on physical examination. In that situation, scanning or other imaging is essential to determine the malignancy potential of the mass.

**Differential Diagnosis**

The differential diagnosis for hypothyroidism is broad and depends on the primary complaints given by patients. For patients with slowed mentation, depressed affect, or confusion, clinicians should suspect depression. Patients with lethargy and a slow pulse and low blood pressure might have adrenal insufficiency. Patients with constipation need to have colonic obstruction from a mass considered as well. In the elderly, common drugs that can cause depression (such as centrally acting antihypertensive agents), bradycardia (such as  $\beta$ -blockers or calcium channel blockers),

constipation (calcium channel blockers), hair loss, or confusion also should be considered.

In patients with pituitary failure, other pituitary hormones are likely to be deficient as well, so clinicians should look for evidence of adrenal and gonadotropic failure.

**Treatment**

The treatment for hypothyroidism is thyroxine replacement (Synthroid, Levoxyl). The usual dose required to achieve full replacement is between 100  $\mu\text{g}$  and 150  $\mu\text{g}$ , although patients who are treated with radioactive iodine and have some remaining thyroid activity might require lower doses. For patients with known heart disease or at risk for heart problems, doses should be initiated at 25 to 50  $\mu\text{g}$  with increases of 25  $\mu\text{g}$  every 4 to 6 weeks guided by TSH levels. Young patients who are at low risk for cardiac problems can be started at doses of 100  $\mu\text{g}$ .

In choosing an agent to use for thyroid replacement, there is good evidence that generic substitutes are just as effective as brand-name drugs. A detailed study examining the metabolic effectiveness of a variety of generic drugs compared with a brand-name medication demonstrated no clinical or subclinical differences among preparations. So even though clinicians often hear that they should use a brand-name drug to maintain the stability of the replacement dose, this is not supported by the evidence.

One area of uncertainty is whether the addition of triiodothyronine ( $T_3$ , Cytomel) adds additional benefit to thyroid replacement with thyroxine. In some studies with elderly patients, subjects with continued neurocognitive dysfunction benefited from the addition of  $T_3$  at a dose of 125  $\mu\text{g}$ , with a concomitant decrease in the  $T_4$  dose of 50  $\mu\text{g}$ . However, subsequent studies of younger patients (aged 29–44 years) failed to find any benefits of partial  $T_3$  substitution. Furthermore, studies of patients on doses of  $T_4$  adequate to restore TSH levels to normal have been found to have normal  $T_3$  levels. At this time, routine use of  $T_3$  cannot be recommended; however, for selected elderly patients who have lingering confusion, depression, or slow mentation on adequate doses of  $T_4$ , a trial of  $T_3$  partial substitution might be tried. Both the American Thyroid Association and European Thyroid Association recommend a trial of combination therapy for patients who are using single therapy with thyroxine alone who are persistently dissatisfied with their therapy.

Another situation where there is controversy is the use of thyroid replacement in patients with a mildly elevated TSH and a normal free  $T_4$ . This condition, called subacute hypothyroidism or mild hypothyroidism, is more common in white, elderly women. It has been observed that thyrotropin (TSH) levels naturally rise with age, however. In many instances these changes are simply due to aging and do not represent a pathologic process.

While some studies have shown clinical improvement in symptoms when low doses of  $T_4$  are given to these patients, these patient populations tend to be those with preexisting thyroid disease (such as Graves' disease), and studies have had only a small number of patients. Expert panels in the US and Europe have suggested using the TSH level and the presence of anti-thyroid antibodies as guides for therapy, but that most patients with this condition will not require any therapy. Additional evidence against routine treatment is provided by a systematic review, and meta-analysis showed no improvement in quality of life or thyroid-related symptoms in patients with subclinical hypothyroidism who received levothyroxine supplementation.

When considering treatment for subacute thyroiditis, patients with a TSH under 7 generally do not require any therapy unless there are other individual patient risk factors such as existing cardiac disease or cognitive symptoms. Treatment is reasonable in those with a TSH level of 10.0 because these patients may be most symptomatic and have a progression rate of 5% to overt hypothyroidism.

When the TSH is  $<7$ , almost half of all patients will revert to normal within 2 years. Patients with a TSH  $<10$  do not require any therapy unless there are other individual patient risk factors such as existing cardiac disease or cognitive symptoms. Treatment is reasonable in those with a TSH level of 10.0 because these patients may be most symptomatic and have a progression to overt hypothyroidism of 5%.

### Monitoring

In general, once a patient receives a full replacement dose of  $T_4$  (usually between 100 and 150  $\mu\text{g}$ ) and has a TSH consistently in the normal range, there is little likelihood that their thyroid requirement will change over time. Although many advocate annual retesting of TSH to ensure patients are euthyroid, there is no evidence to show this is necessary.

Some conditions do warrant closer monitoring of the TSH level. Because  $T_4$  and  $T_3$  are highly protein bound, any conditions where a patient's serum protein status changes should prompt additional testing. This includes conditions that lower serum protein levels, such as liver disease, nephrotic syndrome, or malnutrition, as well as those where serum proteins are increased, such as pregnancy or initiation of estrogen therapy. Because patients' dietary protein usually decreases with advancing age, older patients whose diet declines can also require monitoring and a lowering of their  $T_4$  dose over time.

Patients with subclinical hypothyroidism also might benefit from annual retesting of their free  $T_4$  levels. Approximately 10% of patients with subacute hypothyroidism progress to hypothyroidism within 3 years of diagnosis. Because of this, yearly testing is recommended. Also, 50% of patients with subacute hypothyroidism have positive anti-thyroid antibodies; however, routine testing for these is not recommended.

### Complications

Most of the complications of hypothyroidism are associated with undertreatment or overtreatment. Patients with inadequately treated hypothyroidism are at higher risk for cardiac disease. On the other hand, over-replacement of thyroxine increases the risk of both atrial fibrillation and osteoporosis.

In addition, Hashimoto's thyroiditis is associated with other endocrine autoimmune diseases such as Addison's disease and pernicious anemia. Clinicians should be aware of these associations and not overlook new endocrine disorders that might have clinical features similar to hypothyroidism.

Finally, patients with Hashimoto's hypothyroidism also are at higher risk for the future development of lymphoma. Clinicians should educate patients about the need to have newly enlarged lymph nodes evaluated and be aggressive about evaluating symptoms or signs consistent with the development of a lymphoma.

## OBSESITY IN ADULTS

Method of

Meera Shah, MBChB, MRCP (Edin)

### CURRENT DIAGNOSIS

- The diagnosis of obesity is based on the patient's body mass index (BMI), which is a ratio of weight to height. However, there are recognized limitations to using BMI alone when defining obesity.
- Waist circumference can aid the identification of patients who are not obese by BMI criteria but who are still at heightened metabolic risk.
- Certain ethnic groups, such as Asians, have a higher body fat content at a lower BMI and are therefore defined as being overweight or obese at lower BMI cutoffs.
- Diagnosing obesity early, and recognizing it as a chronic disease, allows for discussion and formulation of a plan to mitigate health risks associated with this disease.

### CURRENT THERAPY

- The cornerstone of any weight management program is lifestyle intervention that focuses on calorie restriction, an increase in physical activity, and behavioral modification. A multidisciplinary team approach offers the greatest benefit.
- The most effective pharmacotherapies for obesity modulate appetite regulation.
- Pharmacotherapy for obesity can be considered as an adjunct to lifestyle modification in the appropriate patient, after having a thorough discussion about benefits and associated risks.
- Weight loss procedures can be considered in patients with medically complicated obesity. This tends to be the most effective way of losing weight but is also associated with the highest risk. Therefore appropriate patient selection is key.

Obesity was recognized as a complex, chronic disease by the American Medical Association in 2013. The designation of obesity as a disease recognizes that obesity develops in response to an aberration in physiology, and its designation as a chronic disease recognizes that obesity is often present for a time period greater than a year and often requires ongoing medical attention and impairs activities of daily living.

### Epidemiology

Obesity is a global phenomenon. At the current rate of growth, it is projected that by the year 2030, almost one in two adults in the United States will have a BMI of greater than 30  $\text{kg}/\text{m}^2$ . With a higher prevalence of obesity comes a greater burden of obesity-associated chronic disease and comorbidities. Managing obesity is therefore a public health priority.

### Obesity and Health Disparity

Obesity disproportionately affects certain racial, ethnic, and socioeconomic groups. Between 2017 and 2018, non-Hispanic Black adults (49.6%) had the highest age-adjusted prevalence of obesity, followed by Hispanic adults (44.8%), non-Hispanic White adults (42.2%) and non-Hispanic Asian adults (17.4%). Within these racial and ethnic differences, prevalence of obesity was lowest in women with college degrees compared with people with lower educational attainment, while in men there was no observable difference in obesity prevalence based on education level.

Among non-Hispanic White and Hispanic men, obesity prevalence was lower in the lowest and highest income groups

compared with the middle-income group. Conversely, obesity prevalence was higher in the highest income group than in the lowest income group among non-Hispanic Black men. Among non-Hispanic White, non-Hispanic Asian, and Hispanic women, obesity prevalence was lower in the highest income group than in the middle and lowest income groups. Obesity prevalence was not affected by income in non-Hispanic Black women.

The reasons for these health disparities in adults with obesity are complex. However, there is widespread recognition of the fundamental importance of preventing childhood obesity, as children with obesity are more likely to become adults with obesity.

### Diagnosis

The current definition of obesity is based on the body mass index (BMI). The BMI is defined as follows:

$$\frac{\text{Weight (kg)}}{\text{Height (m}^2\text{)}}$$

BMI is a practical measure of an individual's degree of adiposity and generally correlates well with comorbidities. However, it is well-recognized that BMI has several limitations with regard to body composition and weight distribution and may therefore be misleading if taken as the only measure of obesity, particularly at lower BMI values.

Waist circumference roughly correlates with visceral adiposity and can be an important adjunct when assessing risk associated with obesity in patients with a BMI below 35 kg/m<sup>2</sup>. In adults with a BMI of 25 to 34.9 kg/m<sup>2</sup>, waist circumference of greater than 102 cm (40 in.) for men and 88 cm (35 in.) for women is associated with greater risk of developing hypertension, type 2 diabetes, and coronary heart disease. Waist circumference is measured with the measuring tape situated above the iliac crest and snugged up against the skin. There is significant intraoperator variability, which limits the reproducibility and use of this metric in the longitudinal assessment of patients with obesity.

BMI cutoffs (Table 1) are applicable to the general population in the United States. Certain ethnic group such as Asians have a higher body fat content at a lower BMI and are therefore defined as being overweight or obese at lower BMI cutoffs (23–24.9 kg/m<sup>2</sup> and greater than 25 kg/m<sup>2</sup>, respectively).

### Assessing the Patient With Obesity in the Office

Once the patient has been diagnosed with obesity, effort then should turn toward understanding the etiology of the disease in the individual patient and assessing for comorbidities associated with obesity.

The following components in the patient's history should be elicited:

- Age of onset of weight gain
- Weight loss attempts
- Changes in dietary patterns
- History of exercise and activity in general
- A comprehensive medication history

The dietary assessment should ideally be performed by a registered dietitian.

A comprehensive medication history may identify medications that are associated with weight gain. Chief among these are psychotropic medications, antidepressants, antiepileptics, insulin secretagogues, and glucocorticoids. Progestational hormones and implants, antihistamines, and oral contraceptives may contribute to weight gain in some patients. Wherever possible, the potential for weight gain should be considered when starting patients with obesity on a new medication. If a weight-neutral alternative exists, effort should be made to switch the patient from a medication that could be contributing to weight gain as long as the underlying disease process remains adequately managed on the

**TABLE 1** BMI Classification and Weight

CLASSIFICATION	BODY MASS INDEX, kg/m <sup>2</sup>
Underweight	≤18.5
Normal Weight	18.5–24.9
Overweight	25.0–29.9
Obesity, Class I	30.0–34.9
Obesity, Class II	35.0–39.9
Obesity, Class III	≥40

new medication regimen. This can be difficult to achieve particularly when dealing with psychotropic medications and requires careful coordination with the patient's other prescribers.

The physical examination of the patient should focus on assessing for a pattern of weight distribution that may confer higher risk (i.e. higher waist circumference than BMI alone would confer) as well as physical findings that may elude to a secondary cause of obesity such as glucocorticoid excess, thyroid dysfunction, or dependent edema.

### Comorbidities Associated With Obesity

#### Type 2 Diabetes

It is estimated that about 85% patients with type 2 diabetes are in the overweight or obese category.

The prevalence of diabetes has increased over the years in line with the increase in population-level obesity. The risk of developing type 2 diabetes in people with obesity increases when there is a strong family history of the disease, a prior history of gestational diabetes, or a weight distribution that is metabolically unfavorable (i.e., high waist circumference). Certain high-risk groups such as South Asians are 30% to 50% more likely to develop diabetes than their White counterparts despite having a lower BMI.

A fasting plasma glucose concentration of greater than or equal to 126 mg/dL or hemoglobin A1c of greater than or equal to 6.5% on two separate occasions can be used to make a diagnosis of type 2 diabetes.

When considering treatment for patients with type 2 diabetes and obesity, careful attention should be paid to the choice of antihyperglycemic agent. Weight-neutral options or medicines that actively promote weight loss such as GLP-1 receptor agonist or SGLT-2 inhibitors should be prioritized where possible. Conversely, patients on medications that can promote weight gain such as sulfonylureas or insulin should be counseled on alternative regimens. In patients with type 2 diabetes, weight loss of 5% to 10% is associated with hemoglobin A1c reductions of 0.6% to 1.0% and reduced need for diabetes medications.

Prevention of type 2 diabetes is possible with modest weight loss. Participants in the Diabetes Prevention program who were at high risk for developing type 2 diabetes and who were able to lose about 7% body weight through lifestyle intervention delayed development of diabetes by approximately 35%. In overweight and obese adults at risk for type 2 diabetes, average weight loss achieved with lifestyle intervention of 2.5 kg to 5.5 kg over 2 years reduces the risk of developing type 2 diabetes by 30% to 60%.

#### Thyroid Dysfunction

The 2021 guidelines published by European Society of Endocrinology recommends thyroid function testing in all patients with obesity, even in the absence of a clinical suspicion for hypothyroidism. The guideline is an acknowledgment of a relatively simple diagnostic test, low risk treatment, and potential for untreated hypothyroidism to adversely affect weight loss efforts. Thyroid-stimulating hormone (TSH) is the first thyroid hormone that should be measured. If this is elevated, free thyroxine (free T4) should be measured to accurately classify the disease process.

### Reproductive Dysfunction

Obesity in women increases the risk for menstrual dysfunction, infertility, and adverse outcomes in pregnancy. Obesity is an independent risk factor for erectile dysfunction in men. Weight loss has been shown to improve several aspects of reproductive function in both men and women.

### Cardiovascular Disease

Obesity increases the risk of coronary heart disease, heart failure, and overall cardiovascular mortality. People with obesity have a higher likelihood of developing risk factors that lead to cardiovascular disease such as hypertension and dyslipidemia.

Hypertension is a common chronic disease. Obesity has been shown to worsen hypertension; conversely there is a dose-response relationship between weight loss and improvements in blood pressure. Hence, even modest weight loss of less than 5% body weight can improve blood pressure in a clinically meaningful way.

Screening for dyslipidemia is best performed with a fasting lipid profile. Treatment guidelines for dyslipidemia are based on underlying comorbidities and calculated risk for developing atherosclerotic cardiovascular disease. Modest weight loss (less than 3 kg) leads to improvement in serum triglycerides and high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol. In the presence of obesity, other modifiable risk factors such as smoking, hypertension, and sedentary lifestyle should be aggressively targeted.

### Obstructive Sleep Apnea

Obstructive sleep apnea is a common but underrecognized complication of obesity. Patients with obesity who present with clinical features suspicious for sleep apnea or a neck circumference of greater than 17 inches in men or 16 inches in women should be screened for sleep apnea. Untreated sleep apnea has numerous health consequences related to the cardiorespiratory system and may also make it difficult for the patient to successfully lose weight. In addition to sleep apnea, obstructive lung disease, apnea-hypopnea syndromes, and restrictive lung disease are common complications of obesity that improve with weight loss.

### Fatty Liver Disease

End-stage liver disease from nonalcoholic fatty liver disease is one of the most common reasons for liver transplantation in the world. The prevalence of nonalcoholic fatty liver disease increases as BMI increases, and up to 80% of patients with a BMI of greater than 40 kg/m<sup>2</sup> are estimated to have steatosis. The diagnosis of fatty liver disease is made on imaging, most commonly ultrasound. Weight loss is the first line of treatment for fatty liver disease; 5% to 10% weight loss has been shown to improve liver biochemistries and liver histology.

### Mechanical Complications From Weight

Patients with overweight and obesity are at high risk of developing degenerative joint disease in weight-bearing joints. This in turn can promote further weight gain, and a vicious cycle therefore develops. A multidisciplinary approach comprising calorie restriction, behavioral therapy, physical therapy, and pain management is often necessary to achieve successful weight loss in this group of patients.

Gastroesophageal reflux is another mechanical complication from carrying excess weight, resulting from increased intra-abdominal pressure from visceral adiposity. Patients who lose weight often see improvements in reflux symptoms.

### Risk of Cancer

A number of malignancies are associated with obesity. In 2012 in the United States, about 28,000 new cases of cancer in men (3.5%) and 72,000 in women (9.5%) were due to overweight or obesity. The risk of developing esophageal, stomach, liver, kidney, gallbladder, pancreas, and colorectal cancers is higher in people who are overweight or obese. Endometrial carcinoma, breast cancer (in postmenopausal women), and ovarian cancer occur more commonly in women who are overweight

or obese. Obesity also worsens several aspects of cancer survivorship such as quality of life, recurrence, progression, and prognosis.

### Psychosocial Functioning

Patients with obesity frequently face stigma in areas such as education, employment, and healthcare, resulting in inequity and loss of opportunity. Patients with obesity often correlate their mental health and well-being with their ability to lose weight, and this can be a challenging situation to navigate. One condition that has been shown to correlate with obesity is seasonal affective disorder. Patients with this diagnosis are prone to gaining weight in the wintertime.

### Treatment

Weight loss can only occur with the creation of an energy deficit in an individual. The cornerstone of any weight management program is lifestyle intervention that focuses on calorie restriction, increase in physical activity, and behavioral modification. Other modalities that can help promote weight loss include pharmacotherapy and weight loss procedures. These can be considered adjuncts to lifestyle intervention if lifestyle intervention alone does not produce the desired outcomes.

Successful management of obesity involves a multidisciplinary team working in partnership with the patient. Prior to making specific recommendations, the patient encounter should address the following:

1. Assessing the patient's readiness for change. The clinician can ask, "How prepared are you to make changes in your diet, to be more physically active, and to use behavior change strategies such as recording your weight and food intake?" A patient who is not ready to engage in changes will not be receptive to counseling on lifestyle changes.
2. Identification of barriers. Limitations to activity because of mechanical joint pain or lymphedema are relatively common and specific strategies to manage these may be necessary. Time and financial resources are also common barriers to successful weight loss. Identifying and acknowledging barriers can help build trust and forge a partnership with the patient.
3. Goal-setting. Patients are often overwhelmed by the amount of weight they need to lose. Clarifying that small but meaningful weight loss will improve health can be helpful to the patient. Aiming for 5% to 10% weight loss over 6 months is a reasonable initial goal.

### Lifestyle Intervention Program

The key components of a lifestyle intervention prescription are listed in [Table 2](#). An individualized lifestyle intervention program, based on the patient's dietary preferences, physical activity ability, and underlying motivation is most likely to result in successful weight loss.

### Pharmacotherapy for Weight Loss

Appetite regulation is a complicated process that involves peripheral gut signaling, central coordination of those signals, and modulation by the environment, emotion, and behavior. Pharmacotherapy for weight loss primarily focuses on central appetite regulation and the most effective weight loss medications are appetite suppressants. Thus they act to reduce caloric intake while simultaneously often reducing cravings.

Current US Food and Drug Administration (FDA)-approved weight loss medications are indicated for individuals with a BMI  $\geq 30$  kg/m<sup>2</sup> or BMI  $\geq 27$  kg/m<sup>2</sup> with at least one obesity-associated comorbid condition who are motivated to lose weight, as an adjunct to comprehensive lifestyle intervention to help achieve targeted weight loss and health goals.

The FDA-approved weight loss medications, their dosing, and their side effect profile are listed in [Table 3](#). All current FDA-approved weight loss medications, with the exception of weekly semaglutide, have an average reported clinical efficacy of 5% to 10% weight loss over 6 months. Because these weight loss medications are relatively similar in efficacy, choice of therapy is

typically guided by the principle of minimizing medication interactions and side effects. All current FDA-approved weight loss medications are category X in pregnancy, and patients should be counseled to avoid pregnancy while taking these medications.

Phentermine (Adipex-P) is a short-acting sympathomimetic that has been approved for short-term weight loss (i.e., 12 weeks). However, phentermine is often used off-label for longer periods of time in patients who show a response to the medication in both weight loss and weight maintenance phases. Retrospective analyses of phentermine users demonstrated no increase in cardiovascular morbidity and no increase in addictive potential with phentermine use. If phentermine monotherapy is being considered as a long-term weight loss medication, the risks and benefits of this approach should be thoroughly discussed with the patient and an appropriate monitoring plan instituted.

**TABLE 2** Components of a Lifestyle Intervention Program

COMPONENT	
Diet	<p><i>Calorie restriction of 300–500 kcals/day.</i>            Goal for most women: 1200–1500 kcals/day.            Goal for most men: 1500–1800 kcals/day.            There is no specific dietary macronutrient composition that promotes long-term weight loss. The best predictor of weight loss is dietary adherence; hence patients should be counseled on dietary strategies that are most likely to be sustained.</p>
Physical activity	<p><i>Goal: ≥150 minutes a week of moderate-intensity exercise</i>            Patients should be encouraged to increase physical activity wherever able. The first goal may be to decrease sedentary time. Patients can aim for 10 minutes of activity at a time.            Self-monitoring of activity, such as using a step-counter, can be helpful.            Patients with multiple comorbidities and limitations to activity may benefit from a specific physical activity prescription from a physical therapist.</p>
Behavioral therapy	<p>Behavioral modification is key to ensuring long-term success. Daily monitoring of food and activity can help patients make behavioral changes. Ideally, patients will also be enrolled in a structured behavioral modification curriculum supervised by a behavioral psychologist. Patients benefit from regular feedback and support of their efforts.</p>

Adapted from Heymsfield SB, Wadden TA. Mechanisms, pathophysiology, and management of obesity. *N Engl J Med.* 2017;376(15):1492.

Topiramate (Topamax) monotherapy is also used off-label to assist with weight management. Topiramate is a carbonic anhydrase inhibitor that has beneficial effects on appetite suppression and satiety. A meta-analysis on the efficacy and safety of topiramate in weight loss showed that patients on topiramate on average were able to lose an additional 5.3 kg over patients on placebo. Most common side effects with topiramate were noted to be paresthesias (tingling of the fingers), changes in taste, and psychomotor impairment.

Semaglutide (Ozempic) is a once-weekly GLP-1 receptor agonist that has been FDA approved for the treatment of obesity and for type 2 diabetes. In early 2021, a number of phase three randomized, placebo-controlled trials using semaglutide at a dose of 2.4 mg once weekly (weight loss dose) were published. The Semaglutide Treatment Effect in People with Obesity (STEP) randomized controlled trials were designed to study the weight loss effect of high-dose semaglutide in patients with and without type 2 diabetes (STEP 1, 2, and 3) and weight maintenance in patients without type 2 diabetes (STEP 4 and 5). On average, participants taking 2.4 mg semaglutide subcutaneously once weekly were able to achieve 15% weight loss compared with patients on placebo who achieved 2% to 5% weight loss. Overall, the gastrointestinal (GI)-related side effect profile was higher in the semaglutide group (nausea, constipation, diarrhea, gallbladder-related conditions), and treatment discontinuation was seen in approximately 3% of participants in that group.

#### Monitoring Patients on Weight Loss Medications

Patients on weight loss medications should be evaluated early and often to ensure continued efficacy of the drug and to monitor for side effects. The best predictor of overall response to a weight loss medication is weight loss achieved in the first 3 months. In general, 5% weight loss in the first 3 months is indicative of a “responder.” If a patient with a previously upward weight trend is able to maintain their weight on the new medication after 3 months of use, then that patient may still be considered a responder. Patients who have had significant changes to their health, overall medication regimen, or physical activity routine may not achieve the goal of 5% weight loss over 3 months; in these situations a longer duration of follow-up might be necessary to determine whether the patient is a responder to the medication.

Except for the scenarios listed above, patients who do not achieve a 5% weight loss over 3 months have several options. If appetite suppression is inadequate per clinical history, then a higher dose of the drug or a different weight loss medication could be considered. Patients could also benefit from meeting with a dietitian to ensure that their dietary plan is adequately calorie-restricted. If a patient has significant side effects from the medication, then an alternative weight loss medication could be considered.

**TABLE 3** FDA-Approved Pharmacologic Agents for Weight Loss

NAME/TRADE NAME	DOSING	COMMON SIDE EFFECTS
Orlistat/ Xenical <sup>TM</sup>	120 mg TID with meals	Bloating, abdominal cramps, diarrhea, steatorrhea
Phentermine-Topiramate ER/ Qsymia <sup>®</sup>	3.75/23 mg daily for 2 weeks, then 7.5/46 mg daily thereafter High dose therapy is 11.25–69 mg daily for 2 weeks, then 15–92 mg daily thereafter	Phentermine side effects: Constipation, dry mouth, tachycardia, insomnia, hypertension Topiramate side effects: Paresthesias, dizziness, cognitive dysfunction, kidney stones, glaucoma
Naltrexone-SR/bupropion-SR/ Contrave <sup>®</sup>	Each tablet contains 8 mg naltrexone and 90 mg bupropion. Titrate by 1 tablet a week until maximal therapeutic dose of 2 tablets twice daily	Nausea, constipation, dry mouth, headache
Liraglutide/Saxenda <sup>®</sup>	Titrate by 0.6 mg daily every week until maximal therapeutic dose of 3 mg daily subcutaneously	Nausea, abdominal discomfort, constipation, or diarrhea.
Semaglutide/Wegovy <sup>®</sup>	Start at 0.25 mg subcutaneously weekly for 4 weeks; then 0.5 mg weekly for 4 weeks; then 1 mg weekly for 4 weeks; then 1.7 mg weekly for 4 weeks; then 2.4 mg weekly	Nausea, vomiting, constipation or diarrhea, gallbladder-related symptoms

Patients should be seen every 3 to 6 months to assess their weight loss trends and monitor for side effects and the potential for new medication interactions. Patients with a clinically meaningful weight loss can also be retested for improvements in their metabolic profile (e.g., fasting glucose), as this may affect therapeutic decision making.

Weight loss typically slows down after about 6 months of therapy, sometimes referred to as a “weight plateau”; this is a physiologic adaptation to weight loss. Specifically, it is estimated that for each kilogram of lost weight, calorie expenditure decreases by about 20 to 30 kcal/day whereas appetite increases by about 100 kcal/day above the baseline level prior to weight loss. Hence, the default trend is for weight loss followed by weight regain. This is an important phenomenon to highlight with patients who can become frustrated that their efforts are not yielding results. Patients may be more willing to engage in modifications to their dietary intake or energy expenditure to overcome this when they understand how metabolic adaptation occurs with weight loss.

## Procedural Interventions for Weight Loss

### Endoscopic Interventions

Endoscopic weight loss procedures, such as the endoscopic sleeve gastropasty (ESG) and endoscopic intragastric balloon are increasing in popularity because of their efficacy and noninvasive nature.

The ESG is a procedure whereby the patient’s stomach capacity is endoscopically reduced, creating a gastric sleeve the size of a small banana. A systematic review and meta-analysis to evaluate the efficacy and safety of ESG in adults showed the average total body weight loss to be approximately 17%. 2.2% of patients in this cohort experienced side effects, most commonly GI-related.

Most patients included in the analysis had a BMI between 30 and 40 kg/m<sup>2</sup>, thus this procedure may not yield similar results in patients with class III obesity (BMI greater than 40 kg/m<sup>2</sup>). The procedure is also technically challenging and may therefore not be widely available. Patients interested in the ESG should continue to be counseled on making sustainable lifestyle changes following the procedure to ensure long-term weight maintenance.

Intragastric balloon devices are approved to treat obesity in patients with a BMI greater than 30 kg/m<sup>2</sup>. In this procedure, a gastric balloon is endoscopically inserted and filled with saline. It remains in place for 6 months, after which it is removed following endoscopic deflation. The intragastric balloon increases satiety and decreases gastric emptying, thus promoting decreased caloric intake and ultimately weight loss. Total body weight loss at 12 months is approximately 10%; patients who lose weight with the balloon in place often see some degree of weight regain following balloon removal. Adverse effects are most commonly seen in the first week following balloon placement and consist of nausea and constipation. Balloons that are left in place for greater than 6 months run the risk of causing gastric erosion.

### Cellulose and Citric Acid (Plenity®)

Plenity is an FDA-cleared, prescription-only aid for weight management. It is made from naturally derived cellulose and citric acid, forming a three-dimensional (3D) matrix in the stomach when ingested with water, and is not absorbed systemically. This product is indicated in overweight and obese adults with a BMI of 25 to 40 kg/m<sup>2</sup>, when used in conjunction with diet and exercise.

It is currently the only FDA-approved weight loss aid that can be used in patients with a BMI as low as 25 kg/m<sup>2</sup>. Access to Plenity is currently limited but should become broader by late 2021.

In a multicenter, double-blind, placebo-controlled 24-week study of 436 patients with a mean BMI 33 to 34 kg/m<sup>2</sup>, patients were randomized to either 3 Gelesis100 (former name of Plenity) capsules taken with 500 mL water 20 to 30 minutes before lunch and dinner or placebo. Participants were prescribed a hypo caloric diet and asked to do 30 minutes of moderate-intensity exercise a day. Mean weight loss achieved was 6.4% in the treatment arm versus 4.4% in the placebo arm. Approximately 60%

of participants in the treatment arm achieved at least a 5% weight loss, a threshold that is considered clinically relevant. Adverse GI effects were higher in the treatment arm (38% vs. 28%), but the dropout rate was similar in both groups.

### Bariatric Surgery

Bariatric (or metabolic) surgery results in significant weight loss leading to remission or resolution of several weight-related comorbidities. Compared with usual obesity care, bariatric surgery has also been shown to prolong life expectancy. Bariatric surgery is indicated in patients with a BMI greater than 40 kg/m<sup>2</sup> or in patients with a BMI greater than 35 kg/m<sup>2</sup> with associated weight-related comorbidities. There is compelling data that patients with diabetes with a BMI as low as 27 kg/m<sup>2</sup> may benefit from bariatric surgery, but this has not been adapted into practice.

Candidacy for bariatric surgery is determined on medical and psychological grounds. Patients interested in bariatric surgery should be motivated and ready for the significant and lifelong changes that occur after surgery. Psychological contraindications to pursuing surgery include untreated major depression or psychosis, other active psychiatric illness including chemical dependency, binge-eating disorders, and the inability to comply with nutritional requirements including lifelong vitamin supplementation.

There are several types of bariatric surgeries. Here we present the two most common, which are the laparoscopic Roux-en-Y gastric bypass (RYGB) and the laparoscopic sleeve gastrectomy (Figure 1).

### Roux-en-Y Gastric Bypass

In this surgery, a small “pouch” is formed from the proximal part of the stomach, which is divided and separated from the distal part of the stomach. The pouch has a capacity of approximately 1 tbsp at the time of creation. The small intestine is divided approximately 100 cm distal to the pylorus; one end forms the anastomosis with the pouch and the other end is anastomosed at the jejunum about 75 to 100 cm distal to the pouch. These anatomic alterations result in restriction of food intake and decrease absorption capacity of the small intestine, thus leading to weight loss. The average weight loss seen after gastric bypass surgery is approximately 30% of total body weight.

Patients who undergo gastric bypass surgery often develop an aversion to high sugar content and fatty foods (i.e., calorie-dense foods). This in turn does help decrease total caloric intake. Patients can often develop lactose intolerance as well, which limits their total dairy consumption.

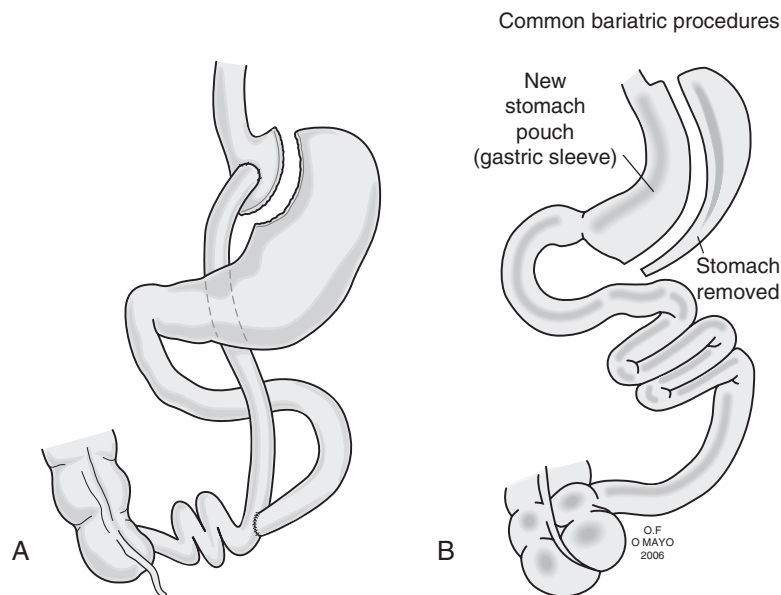

Guidelines for multivitamin supplementation following RYGB is outlined below (Table 4).

Complications from RYGB can be categorized as either surgical complications or nutritional complications. In the immediate postoperative period, anastomotic ulcerations and strictures may occur, requiring reintervention. Longer-term surgical complications may include the development of intestinal obstruction from internal hernias or adhesions. Overall, the mortality from bariatric surgery is less than 1%. Nutritional deficiencies after RYGB most commonly involve deficiencies of iron, vitamin D, and calcium. This is partly driven by the exclusion of the proximal duodenum, which is the major site of absorption of these specific nutrients.

### Sleeve Gastrectomy

The sleeve gastrectomy is the most widely performed bariatric procedure worldwide. In this surgery, approximately 80% of the body of the stomach is removed, leaving behind a tubular structure that resembles a shirtsleeve. The average weight loss seen with the sleeve gastrectomy is approximately 15% to 25% of total body weight. The sleeve gastrectomy is the preferred bariatric procedure in patients who have a need to be consistent with absorption of specific medications, for example antirejection medications after organ transplantation.

Guidelines for multivitamin supplementation following sleeve gastrectomy is outlined below (Table 4).

**Figure 1** Techniques commonly used for the surgical treatment of obesity: (A) Roux-en-Y gastric bypass; (B) laparoscopic sleeve gastrectomy.

Postoperative complications of the sleeve gastrectomy include staple line leak or dilation of the gastric sleeve. Approximately 15% of patients who undergo sleeve gastrectomy can develop new or worsening gastroesophageal reflux symptoms. Patients who have undergone a sleeve gastrectomy often do not develop food aversion and are able to continue eating a wide variety of foods.

### Monitoring After Bariatric Surgery

#### Nutrition

Patients who have undergone bariatric surgery should obtain annual levels of complete blood count, ferritin, 25 hydroxy vitamin D, fasting glucose, and lipid profile (if indicated). B12 levels should be checked if the patient is not taking a parenteral formulation of B12 as absorption in the altered GI anatomy can be variable. Patients who have undergone more malabsorptive procedures such as the biliopancreatic diversion/duodenal switch or very long limb RYGB may be screened for deficiencies in vitamins A, zinc, and copper.

Patients who have undergone gastric bypass surgery and other malabsorptive bariatric procedures should also have annual measurements of 24-hour urine volume, calcium, creatinine, and oxalate excretion. This is the most reliable way of ensuring adequate calcium absorption while screening for hyperoxaluria.

An annual dietitian review is strongly recommended to ensure that patients are adhering to nutritional guidelines and meeting their nutritional goals.

#### Physical Activity

Patients should be encouraged to pursue moderate intensity physical activity for at least 150 minutes a week (i.e., 30 minutes a day). When advising on the intensity of physical activity, patients can be guided to choose options that result in the following: “Your breathing quickens, but you’re not out of breath. You develop a light sweat after about 10 minutes of activity. You can carry on a conversation, but you can’t sing.”

Data from the National Weight Control Registry shows that the majority of nonsurgical weight loss patients engage in a structured and consistent daily physical activity program to successfully maintain their weight.

#### Weight

In a recent prospective, long-term study of patients who had undergone RYGB, 93% of patients maintained at least a 10% weight loss from baseline, 70% maintained at least a 20% weight loss, and only

SUPPLEMENT	DOSING AND SUPPLY
200% of recommended daily allowance for vitamins and minerals	Two chewable multivitamins daily Patients with renal impairment may need dose adjustment
Elemental calcium	1500–2000 mg daily with meals, in divided doses. If supplements are required, calcium citrate is better absorbed in a low acid environment such as post-gastric bypass
Vitamin D	3000–5000 units of vitamin D3 daily, total through dietary intake and supplements
B12	1000 mcg deep subcutaneous injection monthly OR 500–1000 mcg orally daily

40% maintained at least a 30% weight loss after 12 years. Weight regain is therefore a reality that tends to occur after the second postoperative year in a proportion of patients who undergo bariatric surgery. Weight regain may lead to relapse of weight-related comorbidities and can be psychologically difficult for the patient.

When a patient who has undergone bariatric surgery presents with weight regain, a number of factors should be considered. The patient’s dietary habits should be evaluated by a dietitian familiar with bariatric surgery. The patient’s physical activity habits should also be evaluated and assistance from a physical therapist can be considered for patients with significant limitations to exercise. Anatomic changes such as dilation of the gastrojejunal anastomosis or the presence of a gastro-gastric fistula can contribute to excess calorie intake and weight regain; these can be detected with an upper GI contrast study. The patient’s medication record should be carefully evaluated to identify medications that may predispose to weight gain. Finally, a psychology evaluation may uncover behaviors that may be predisposing to weight regain, for example graze-eating, nighttime eating, or binge-eating.

Patients who experience weight regain after bariatric surgery should be offered a multidisciplinary approach to management. In addition to dietary and behavioral intervention, patients may also be candidates for antiobesity medications or procedures that revise their postbariatric surgery anatomy.

## Specific Complications of Roux-en-Y Gastric Bypass

There are number of unique complications that can occur following RYGB as a result of anatomic alterations. Here, we will highlight two—nephrolithiasis and alcohol use disorder.

### Nephrolithiasis

The risk for nephrolithiasis after gastric bypass surgery is moderately high, with reported prevalence rates of 7.65% to 13%. Solely gastric restrictive operations such as the gastric sleeve are not associated with higher risk for kidney stone formation beyond that attributed to obesity alone. Nephrolithiasis can present as early as the first year after surgery; as such, patients should be counseled on interventions to prevent kidney stone formation soon after surgery. Current guidelines recommend completing a 24-hour urine super saturation between 6 and 12 months after surgery. This can assess for adequacy of hydration status, calcium ingestion, oxalate excretion, and citrate excretion (low urinary citrate predisposes to kidney stone formation).

Patients with nephrolithiasis should be counseled on adequate fluid intake (1500–2000 mL of urine output per day), a low-fat diet, a low oxalate diet, and adequate dietary or supplemental calcium with meals. Hypocitraturia may be treated with potassium citrate salts. Patients with nephrolithiasis after gastric bypass may benefit from more frequent visits with a dietitian to help meet the patient's nutrition and hydration goals.

### Alcohol Use Disorder

Alcohol use disorder is a rare complication that can occur in the long-term after gastric bypass. Changes in the gastrointestinal anatomy following gastric bypass surgery alter the pharmacokinetics of alcohol metabolism, leading to early and higher blood alcohol concentration peaks accompanied by a greater feeling of drunkenness. Additionally, there is decreased clearance of alcohol through the first pass mechanism. In practical terms, peak blood alcohol levels achieved after consuming about two drinks in women who have had RYGB surgery resembles that observed after consuming about four drinks in women who have not had surgery.

Large prospective observational studies show that the prevalence of alcohol use disorder after RYGB increases over time since surgery. Risk factors for developing alcohol use disorder after gastric bypass surgery include male sex, younger age, smoking, and any alcohol consumption presurgery. Although baseline alcohol consumption is a risk factor, about 20% of patients diagnosed with alcohol use disorder within 5 years of RYGB reported no alcohol consumption the year prior to surgery. Patients undergoing gastric bypass surgery should therefore be routinely screened for and counseled on the effects of alcohol use after surgery.

## PARENTERAL NUTRITION IN ADULTS

Method of

Meetal Mehta, MD; Kris M. Mogensen, MS; and Malcolm K. Robinson, MD

### CURRENT DIAGNOSIS

- Reserve parenteral nutrition (PN) for patients with intestinal dysfunction or failure.
- Reserve PN for conditions such as short-bowel syndrome, severe malabsorption, ileus or intestinal dysmotility, intractable vomiting, and severe diarrhea.
- Always reevaluate the need for PN and work toward a transition to enteral nutrition or an oral diet, if possible, to limit complications associated with PN.

### CURRENT THERAPY

- Correct electrolyte abnormalities and hyperglycemia prior to the initiation of PN.
- Start with no more than 150 to 200 g dextrose on the first day of PN; start with 100 to 150 g dextrose for patients with diabetes or patients at risk for the refeeding syndrome.
- Advance PN by 100 to 150 g dextrose daily until the goal is achieved.
- Maintain blood glucose <180 mg/dL.
- Monitor electrolytes, including phosphate and magnesium, until stable; the frequency of laboratory monitoring can be decreased based on stability.
- Monitor closely for complications associated with PN: electrolyte abnormalities, hyper/hypoglycemia, PN-associated liver disease, and central line infections.

Since the inception of parenteral nutrition (PN) in the 1960s, the science of PN has matured in a number of ways. The initial excitement of being able to feed basic nutrients, vitamins, and trace elements intravenously has been tempered by the realization that indiscriminate use of PN can be harmful. Although PN can still be lifesaving, it is imperative that it be used judiciously and only as long as necessary. This chapter discusses the current use of PN in adult patients.

### Indications and Contraindications

Enteral nutrition (EN) is the preferred method of nutrition support, primarily because it is associated with fewer infectious and metabolic complications. However, total PN (TPN), which is the provision of all nutrient requirements intravenously, may be indicated when feeding through the gastrointestinal (GI) tract is not possible. PN may be appropriately initiated in those who cannot receive enteral nourishment and are malnourished or at risk for developing malnourishment. Malnourishment can be defined as unintentional loss of more than 10% of usual body weight or greater than 7 to 10 days of inadequate nutrient intake. The body stores of well-nourished persons are generally sufficient to provide the essential nutrients, resist infection, promote wound healing, and support other necessary physiologic functions for this time period. In patients who are anticipated not to be able to receive adequate EN for longer than 10 days, it is not necessary to wait 10 days before initiating PN. This may include patients with short-bowel syndrome and others who are expected to have prolonged GI dysfunction.

According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, EN is contraindicated in conditions such as diffuse peritonitis, intestinal obstruction, early stages of short-bowel syndrome, intractable vomiting, paralytic ileus, severe GI bleeding, and severe diarrhea and malabsorption

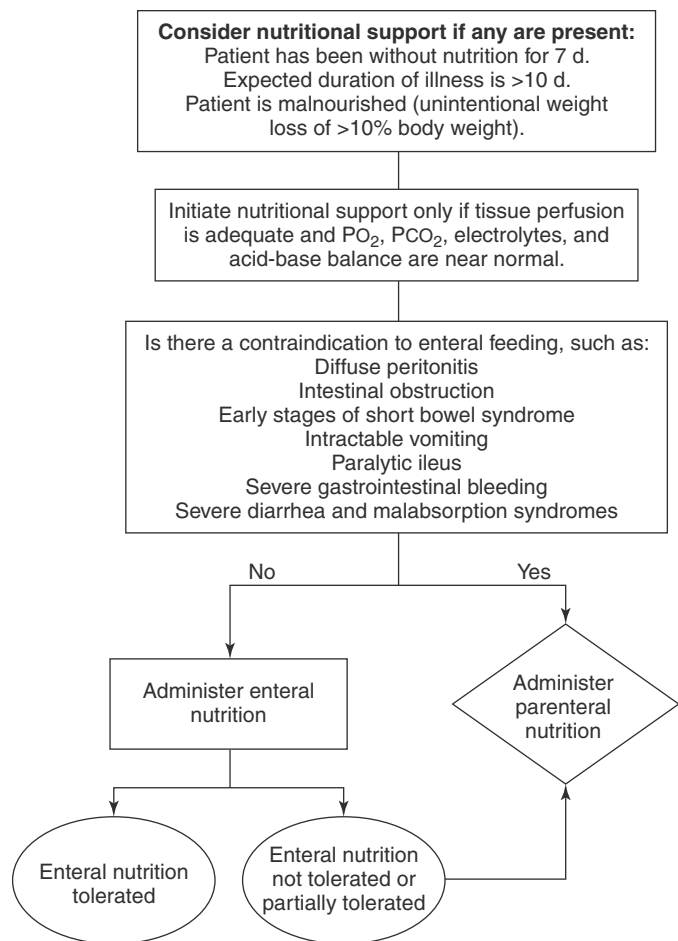

Figure 1 Determining route of feeding.

syndromes. Other relative contraindications to EN include severe pancreatitis and enterocutaneous fistulas, although depending on the clinical circumstances, EN may be indicated. PN and EN may be provided concomitantly, although in patients who are critically ill, PN should not be started until all strategies to maximize enteral feeding (such as the use of postpyloric feeding tubes and motility agents) have been attempted. PN support is unlikely to benefit a patient who will be able to take EN within 4 or 5 days after the onset of illness or who has a relatively minor injury (Figure 1).

There are four key steps to consider before initiating PN, including assessing nutritional status, determining energy needs, evaluating GI function, and estimating the length of time a patient will require PN (Box 1).

### Assessment of Nutritional Status

Nutrient depletion is associated with increased morbidity and mortality, and up to 60% of hospitalized patients are estimated to have malnutrition. Therefore it is imperative to identify patients who have or are at risk for developing protein-energy malnutrition or have specific nutrient deficiencies. A patient's risk of developing malnutrition-related medical complications needs to be quantified, and it is necessary to monitor the adequacy of nutritional therapy.

Nutrition assessment begins with a thorough history and physical examination in conjunction with select laboratory tests aimed at detecting specific nutrient deficiencies in patients who are at high risk for future abnormalities. The nutrition assessment should establish whether the patient will need maintenance therapy or nutrition repletion and should assess the status of the patient's GI tract, especially if nutrition support will be required.

A thorough history includes an assessment of recent weight changes, dietary habits, GI symptoms, and changes in exercise tolerance or physical abilities that would indicate functional

**BOX 1** Decision-Making Steps When Initiating Parenteral Nutrition

Assess the patient's nutritional status. Nutrition support (PN or EN) should not be initiated in well-nourished patients unless they have received a suboptimal diet for more than 7 days.

Determine whether the patient has extreme energy needs (hypermetabolism) that warrant the early use of nutrition support (PN and/or EN) within 7 days of injury or illness. These are typically critically ill patients who have suffered severe burns or trauma.

Evaluate the function of the GI tract; if it is intact and can be used safely, PN should be avoided. PN support is indicated until enteral access is established and the patient can meet nutrient needs via tube feedings.

Estimate how long the patient will require PN support. If GI function is expected to return within 5 days, there is no known benefit of initiating PN.

EN, Enteral nutrition; GI, gastrointestinal; PN, parenteral nutrition.

capacity deficiencies. Screening for malnutrition risk, using a validated nutrition screening tool (e.g. Mini Nutritional Assessment, Malnutrition Screening Tool, Malnutrition Universal Screening Tool, Nutritional Risk Index, Nutrition Risk Screening-2002, etc.), may identify these relevant changes. Diagnosis of malnutrition includes further history taking and a physical examination. This includes inspection for subcutaneous fat and muscle wasting, which indicate a loss of body energy and protein stores; edema and ascites, which can also indicate altered energy demands or decreased energy intake; and signs of vitamin and mineral deficits such as dermatitis, glossitis, cheilosis, neuromuscular irritability, and coarse easily pluckable hair.

Several nutritional biomarkers have traditionally been used to quickly assess nutritional status. The serum proteins prealbumin, transferrin, and retinol-binding protein have a rapid turnover rate and short half-lives and therefore may be used as indicators of recent nutritional intake. However, these proteins are affected by the metabolic responses to stress and illness, as well as other conditions, including iron status (transferrin) and renal status (retinol-binding protein, prealbumin). This can limit their usefulness in acute and chronic inflammatory states.

Prealbumin is least affected by fluctuations in hydration status and by liver and renal function compared with other plasma proteins. However, prealbumin levels drop in acute inflammatory conditions during which the liver prioritizes production of positive acute-phase reactants, decreasing negative acute-phase reactants such as prealbumin. A rise in C-reactive protein, a protein synthesized by the liver as part of the acute-phase response, indicates an active inflammatory state. Thus C-reactive protein, when measured along with prealbumin, can help differentiate a low prealbumin due to nutritional inadequacy versus low prealbumin due to an acute-phase response.

The serum albumin, another negative acute-phase reactant, has traditionally been used as an indicator of nutritional status. Although it is a good preoperative predictor of outcome for patients undergoing surgery, its sensitivity to many variables in the acute care setting make it an unreliable marker to assess nutritional status under such conditions or in the immediate postoperative period. Additionally, redistribution of albumin, increases in GI and renal losses, and alterations in tissue catabolism during inflammatory states affect its intravascular concentrations.

Notably these serum markers are affected only after weeks of starvation in noninflammatory states and do not increase with adequate nutritional support, making it a poor initial indicator of nutritional status or muscle mass. However, they may be used to indicate inflammatory status and nutritional risk, instead of nutritional status and muscle mass.

A simple and practical index of malnutrition is the degree of weight loss. Unintentional weight loss of greater than 10% within the previous 6 months indicates protein-energy malnutrition and is a good prognosticator of clinical outcome. Weight can also be compared with an ideal or desirable weight, or an index of body weight relative to height. The body mass index (BMI), reported as weight in kilograms divided by height in meters squared, is the best known such index, and can be used to detect both undernutrition and overnutrition. This index is dependent on height, and the same standards apply to both men and women. A BMI of 18.5 to 25 kg/m<sup>2</sup> is considered normal, 25 to 29.9 kg/m<sup>2</sup> is considered overweight, and greater than 30 kg/m<sup>2</sup> is considered obese. Patients with a normal or high BMI can still have nutrient deficiencies and therefore can be malnourished if they have recently lost a significant amount of weight. In addition, a BMI of 18 kg/m<sup>2</sup> or less in an adult indicates moderate malnutrition and a BMI less than 15 kg/m<sup>2</sup> is associated with increased morbidity.

Another practical tool for evaluating nutritional status is the subjective global assessment (SGA) that encompasses historical, symptomatic, and physical parameters. The SGA technique determines whether nutrient assimilation has been restricted because of decreased food intake, maldigestion, or malabsorption; whether any effects of malnutrition on organ function and body composition have occurred; and whether the patient's disease process influences nutrient requirements. The findings of the history and physical examination are subjectively weighted to rank patients as being well nourished, moderately malnourished, or severely malnourished and are used to predict their risk for medical complications (Box 2).

### Estimating Nutritional Requirements

Historically, TPN often provided nutrients in excess of actual requirements. This was based on the assumption that patients requiring nutritional intervention were severely depleted and required aggressive repletion; hence, the misnomer "hyperalimentation." Overfeeding is associated with increased carbon dioxide production and difficulty weaning from a ventilator as well as metabolic complications, such as hyperglycemia, which can lead to increased infection, morbidity, and mortality. Thus nutritional support should be titrated to match actual metabolic requirements.

In addition, there are times when *underfeeding* calories may be necessary and beneficial. In such cases, this is referred to as "permissive" underfeeding to distinguish it from underfeeding that occurs due to the unintentional inadequate delivery of nutrients. For example, permissive underfeeding may be appropriate for some critically ill patients with obesity who are receiving adequate protein. Such permissive underfeeding for critically ill patients with obesity is now the recommendation of ASPEN and the Society of Critical Care Medicine (SCCM).

### Energy Requirements

There are four components of daily energy requirement. The first is the basal metabolic rate (BMR), which is the amount of energy expended under complete rest shortly after awakening and in a fasting state (12–14 hours). BMR varies with age, sex, and body size; correlates roughly with body surface area; and is proportional to lean tissue mass. This relationship holds true even among persons of different ages and sexes. Resting metabolic rate or resting energy expenditure (REE) represents the amount of energy expended 2 hours after a meal under conditions of rest and thermal neutrality. Although it is often used synonymously with BMR, the REE is typically 10% higher.

The second component of daily energy expenditure is the thermic effect of exercise or the energy used in physical activity. The contribution of this component increases markedly during intense muscular work. However, admission to a hospital generally results in a marked decrease in physical activity. Hospital activity in ambulatory patients accounts for a 20% to 30% increase in BMR. Critically ill patients who are on a ventilator generally have low activity levels (BMR increases by only 5%–10%) because the ventilator performs the work of breathing, and they are not ambulatory.

Select the appropriate category with a checkmark, or enter a numeric value where indicated by #.

**History**

- Weight change  
Overall loss in past 6 months: amount = # \_\_\_\_ kg; % loss = # \_\_\_\_  
Change in past 2 weeks: \_\_\_\_ increase, \_\_\_\_ no change, \_\_\_\_ decrease
- Dietary intake change (relative to normal)  
\_\_\_\_ No change  
\_\_\_\_ Change duration = # \_\_\_\_ week.  
\_\_\_\_ Type: \_\_\_\_ suboptimal solid diet, \_\_\_\_ full liquid diet, \_\_\_\_ hypocaloric liquids, \_\_\_\_ starvation
- Gastrointestinal symptoms (that persisted for >2 weeks)  
\_\_\_\_ None, \_\_\_\_ nausea, \_\_\_\_ vomiting, \_\_\_\_ diarrhea, \_\_\_\_ anorexia
- Functional capacity  
\_\_\_\_ No dysfunction (e.g., full capacity)  
\_\_\_\_ Dysfunction duration = # \_\_\_\_ week  
\_\_\_\_ Type: \_\_\_\_ working suboptimally, \_\_\_\_ ambulatory, \_\_\_\_ bedridden
- Disease and its relation to nutritional requirements  
Primary diagnosis (specify): \_\_\_\_  
Metabolic demand (stress): \_\_\_\_ no stress, \_\_\_\_ low stress, \_\_\_\_ moderate stress, \_\_\_\_ high stress

**Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe)**

- # \_\_\_\_ Loss of subcutaneous fat (triceps, chest)
- # \_\_\_\_ Muscle wasting (quadriceps, deltoids)
- # \_\_\_\_ Ankle edema
- # \_\_\_\_ Sacral edema
- # \_\_\_\_ Ascites

**SGA Rating (select one)**

- \_\_\_\_ A = Well nourished
- \_\_\_\_ B = Moderately (or suspected of being) malnourished
- \_\_\_\_ C = Severely malnourished

The third component of energy expenditure is diet-induced thermogenesis, the increase in BMR that follows food intake. The digestion and metabolism of exogenous nutrients, whether delivered to the gut or vein, result in an increase in metabolic rate. The magnitude of the thermic effect of food varies depending on the amount and composition of the diet and accounts for approximately 10% of daily energy expenditure.

Finally, acute illness adds an additional stress factor to the daily energy expenditure and correlates with disease severity. For example, a patient's metabolic rate increases by 10% to 30% after a major fracture, from 20% to 60% with severe infection, and from 40% to 110% with a severe third-degree burn. In addition, fever accelerates chemical reactions, and the BMR rises approximately 10% for each degree Celsius increase in temperature. Alternatively, cooling of febrile patients produces a reduction in BMR of approximately 10% per degree Celsius.

The first step of estimating energy requirements is to estimate the BMR. This is usually accomplished using one of several predictive equations. The most commonly used method is based on the predictive equations reported by Harris and Benedict in 1919. The Harris-Benedict equations are as follows:

$$\text{BMR (men)} = 66.47 + 13.75(W) + 5.0(H) - 6.76(A)$$

$$\text{BMR (women)} = 655.1 + 9.56(W) + 1.85(H) - 4.68(A)$$

where  $W$  is weight in kg,  $H$  is height in cm, and  $A$  is age in years.

After the BMR is calculated, it is adjusted for the level of stress induced by injury or the disease process and activity level. Activity factors for hospitalized patients are 1.0 to 1.1 for intubated patients, 1.2 for patients confined to bed, and 1.3 for patients out of bed. Stress factors may vary from 1.1 for patients with minimal stress, 1.3 for patients with moderate stress, up to 2.0 for patients with severe burns. Therefore the patient's energy requirements (total energy expenditure [TEE]) are finally calculated:

$$\text{TEE} = \text{BMR} \times \text{Activity factor} \times \text{Stress factor}$$

The thermic effect of feeding is generally not included in the calculation of energy requirements for hospitalized patients.

Alternatively, some clinicians estimate energy requirements based on actual body weight, providing about 25 to 30 kilocalories (kcal)/kg administered to critically ill patients. Predicting energy expenditure in patients with obesity can be difficult because using predictive formulas with actual body weight can lead to high TEE and potentially to overfeeding. Determining energy requirements for critically ill patients with obesity is discussed later in this chapter. The Harris-Benedict equation using the average of actual and ideal weight and a stress factor of 1.3 predicts REE in acutely ill patients with obesity with a BMI of 30 to 50 kg/m<sup>2</sup>.

Indirect calorimetry is a more precise, clinically practical, and individualized method to determine energy expenditure, particularly in patients in whom estimating requirements through predictive equations is difficult, such as those who continue to lose weight despite what appears to be an adequate caloric intake, who are critically ill, or who have rapidly changing energy needs. Indirect calorimetry measures changes in oxygen consumption and carbon dioxide production to calculate the REE. As indirect calorimetry accounts for the effects of disease state, stress, and trauma, a stress factor is not necessary in calculating energy needs. However, the measurement occurs at rest, and therefore an activity factor of 1.0 to 1.3, depending on whether the patient is intubated, bedridden, or ambulatory, must be applied.

**Nutrient Requirements**

The recommended daily protein allowance for most healthy persons who are not hospitalized is 0.8 g/kg, or about 60 to 70 g of protein each day. The stressed, critically ill patient generally needs a higher dose of protein in the range of 1.2 to 2.0 g/kg/day. For most patients, providing protein beyond 1.5 g/kg/day is not beneficial. In fact, providing excess protein does not enhance uptake and can lead to increased ureagenesis, which can cause renal injury in some patients.

The calorie-to-nitrogen ratio for most PN solutions is typically about 150:1, with an acceptable range of 100:1 to 180:1. Nitrogen content is used as a marker for protein, and, hence, the two terms are used interchangeably. Usually, 6.25 g of protein is equal to 1.0 g of nitrogen. The conversion factor is slightly higher (6.4) for PN solutions, such as those with higher concentrations of crystalline amino acids.

Vitamin and mineral requirements are altered in certain disease states due to increased losses, greater use, or both. Guidelines for parenteral vitamin and trace elements, developed by the Nutrition Advisory Group of the American Medical Association, were approved by the US Food and Drug Administration (FDA) in 1979 and amended in 2000 (Table 1).

**Composition of Central and Peripheral Venous Solutions**

Central venous access is required for providing TPN because of the hypertonicity of the formulas infused (1900 mOsm/kg). The infusion of a hypertonic solution into a peripheral vein, known as *peripheral parenteral nutrition* (PPN), can result in thrombophlebitis and venous sclerosis unless the PN is drastically diluted to lower the tonicity. To minimize the hypertonicity of PPN solutions, dextrose is limited to 5% to 10%, and amino acids are limited to 2.5% to 3.5%. Lipids are isotonic and therefore provide a significant portion of the caloric substrate of PPN formulas.

**TABLE 1** Recommended Daily Doses of Parenteral Vitamins and Trace Elements

MICRONUTRIENT	PARENTERAL DOSE
<b>Vitamins</b>	
Vitamin A	3300 IU
Vitamin D	200 IU
Vitamin E	10 IU
Vitamin K	150 µg
Ascorbic acid (vitamin C)	200 µg
Folic acid	600 µg
Niacin	40 mg
Riboflavin (vitamin B2)	3.6 mg
Thiamine (vitamin B1)	6 mg
Pyridoxine (vitamin B6)	6 mg
Cyanocobalamin (vitamin B12)	5 µg
Pantothenic acid	15 mg
Biotin	60 µg
<b>Trace Elements</b>	
Zinc	2.5–5 mg
Copper	0.3–0.5 mg
Chromium	10–15 µg
Manganese	60–100 µg
Selenium	20–60 µg

Data from American Medical Association, Department of Foods and Nutrition: Multivitamin preparations for parenteral use. A statement by the Nutrition Advisory Group. *JPEN J Parenter Enteral Nutr* 3:258–62, 1979; Food and Drug Administration: Parenteral multivitamin products: Drugs for human use: Drug efficacy study implementation: Amendment. *Federal Register* 65(77):21200–21201, 2000.

Central venous solutions, which are prepared by the hospital's pharmacy, typically combine carbohydrate in the form of dextrose, protein as crystalline amino acids, and lipids. Lipid emulsions come in many forms, with differing oil sources which provide varying amounts of essential fatty acids and phytosterols. The first lipid emulsion approved for PN uses a polyunsaturated long-chain triglyceride soybean oil base. It provides adequate essential fatty acids but has inflammatory properties due to its high phytosterol and omega-6 fatty acid content, which may play a role in PN-associated liver disease. Newer lipid emulsions have been approved by the FDA that provide different types of oils including a blend of soybean, medium chain triglyceride, olive, and fish oils (SMOFlipid®, Fresenius Kabi USA, Melrose Park, IL); soybean and olive oils (Clinolipid, Baxter, Deerfield, IL); and fish oil (Omegaven®, Fresenius Kabi USA, Melrose Park, IL; currently only approved for use in children in the United States). Fish oil and mixed lipid emulsions have more favorable, anti-inflammatory profiles and studies suggest that they may prevent or reverse PN associated liver disease. For this reason, these newer lipid emulsions should be considered in patients who are at risk for developing PN associated liver disease.

Vitamins, electrolytes, and trace elements are added to the formulation as needed. Typical substrate profiles of carbohydrate, protein, and lipids in central PN are shown in Table 2. A usual PN prescription administers 1 to 2 L of a solution each day. Administration of 500 mL of a 20% fat emulsion 1 day each week is sufficient to prevent essential fatty acid deficiency. Alternatively, if additional calories from lipids are needed on a daily basis, they can be administered as a separate infusion or most

commonly as part of the mixture of dextrose and amino acids, a technique known as *triple mix* or *three-in-one*.

Including lipid injectable emulsion into a parenteral admixture changes the conventional nutritional solution into an emulsion. Various electrolytes and micronutrients can adversely influence emulsion stability, and therefore their concentration in three-in-one solutions is limited to prevent “cracking” of the PN solution, in which microscopic or macroscopic precipitates are formed. The higher the cation valence, the greater the destabilizing influence to the emulsifier. Therefore trivalent cations such as ferric ion (iron dextran) are more disruptive than divalent cations such as calcium or magnesium ions, which are more disruptive than monovalent cations such as sodium or potassium. No concentration of iron dextran is safe in triple-mix formulations. In-line filters prevent infusion of precipitates and are necessary for all PN solutions (including triple-mix solutions) because it is impossible to visually detect precipitates until they are grossly incompatible and unsafe for infusion.

Once the basic solution is created, electrolytes are added as needed (Table 3). Sodium or potassium salts are given as chloride or acetate depending on the patient's requirements. Normally, equal amounts of chloride and acetate are provided. However, if chloride losses from the body are increased, which can occur in patients who have nasogastric tubes, then most of the salts should be given as chloride. Similarly, more acetate should be given to patients when additional base is required because acetate generates bicarbonate when it is metabolized. Sodium bicarbonate is incompatible with PN solutions and cannot be added to the mixture. Phosphate may be given as the sodium or potassium salt. Lipid injectable emulsions contain an additional 15 mmol/L of phosphate.

Commercially available preparations of fat-soluble and water-soluble vitamins, minerals, and trace elements are added to the nutrient mix unless they are contraindicated. Adequate thiamine is essential for patients receiving PN and can be provided separately. Vitamin K is now a component of standard IV multivitamin preparations. Trace element preparations that include copper, manganese, selenium, and zinc are added to the PN solution in amounts consistent with the American Medical Association guidelines (Table 1). Manganese accumulation can be toxic, and overexposure can lead to progressive neurodegenerative damage. Manganese is usually supplied in the PN solution at a daily dose of 0.5 mg as part of a multiple trace element additive. Because manganese is primarily eliminated via biliary excretion, patients with biliary obstruction or cholestasis can accumulate potentially toxic levels of manganese. Hence, manganese should be removed from the PN of patients with hyperbilirubinemia. Higher doses, 10 to 15 mg/day, of zinc are provided to patients with excessive GI losses.

Iron is not a part of commercial additive preparations because it is incompatible with triple-mix solutions and can cause anaphylactic reactions when it is given intravenously. Patients who need this trace element should receive it orally or by injection. Iron is avoided in patients who are critically ill because hyperferremia can increase bacterial virulence, alter polymorphonuclear cell function, and increase host susceptibility to infection.

PPN is less commonly used than central PN and can be disadvantageous. Because of the low concentration of dextrose, greater volumes (typically >2 L/day) are required to provide sufficient calories, which might not be feasible in fluid-restricted patients. PPN generally does not approximate a patient's energy needs because PPN provides only 1000 to 1500 kcal/day, and a large percentage of the calories (60%) are derived from fat. High-fat infusions are undesirable because they are associated with impaired reticuloendothelial system function and are potentially immunosuppressive. There is no evidence that lipid injectable emulsions improve outcomes or significantly decrease nitrogen losses. Generally, PPN should be avoided unless it is combined with enteral feeding in patients who cannot tolerate full enteral feeding, patients who

**TABLE 2** Central Versus Peripheral Parenteral Nutrition

PROPERTY	CENTRAL NUTRITION	PERIPHERAL NUTRITION
Volume of fluid required (mL)	1500–2500	2500–3500
Duration of therapy (d)	>7–14	5–14
Route of administration	Dedicated central venous catheter	Peripheral vein or multiuse central catheter
Substrate profile	150–600 g/day dextrose	150–300 g/day dextrose (5%–10% of final concentration) 50–100 g/day amino acid (3% of final concentration)
Osmolarity (mOsm/L)	1300–1800	600–900

**TABLE 3** Electrolyte Concentrations in Parenteral Nutrition

ELECTROLYTE	RECOMMENDED PN DOSES
Potassium	1–2 mEq/kg
Sodium	1–2 mEq/kg
Phosphate	20–40 mmol
Magnesium	8–20 mEq
Calcium	10–15 mEq
Chloride	As needed*
Acetate (mEq/L)	As needed*

\*Depending on acid-base balance

cannot get a central venous catheter, or patients with low body weights in whom PPN can meet at least two-thirds of estimated needs.

### Administration and Venous Access

Typically, central PN solutions are administered into the superior vena cava. Access to this vein can be achieved by cannulation of the subclavian or internal jugular veins. Peripherally inserted central venous catheters (PICCs), typically inserted via an antecubital vein and advanced into the superior vena cava, are the most commonly used central venous access devices for providing PN. PICC placement offers the advantage of central venous access, while avoiding the risks associated with accessing the subclavian or jugular veins, such as hemothorax, pneumothorax, and arterial injury.

Tunneled catheters or catheters with indwelling ports should be considered for patients who will need prolonged central venous nutrition (e.g., >6 weeks). Patients who will be using their catheters solely for daily central PN and who require home IV nutrition may be best served by a tunneled catheter rather than an indwelling port. Tunneled catheters may be more easily used and cared for, which can minimize the risk of infection.

Inserting a dedicated line for infusing hypertonic solutions requires strict aseptic technique and maximal barrier protection: hat, mask, gown, and gloves must be worn. The position of the catheter tip in the superior vena cava is confirmed by chest x-ray before any concentrated solutions are administered. Once the position of the tip has been confirmed, the line should be used exclusively for administering the hypertonic nutrient solution.

Multiple-lumen central venous catheters are most commonly used. Although at least one lumen is dedicated to the infusion of the PN solutions, the other(s) may be used for monitoring, blood drawing, or medication. The rate of catheter sepsis associated with multiple-port catheters may be the same as or slightly greater than the rate associated with the use of single-port catheters.

However, multiple-port PICCs are used to infuse PN solutions for a shorter period of time, which can minimize their inherent risk. Multiple-port catheters should be carefully maintained, including dressing changes, maintaining the dedicated lumen, careful handling of the other lumens, and removing the catheter as soon as it is no longer needed.

### Infusion and Patient Monitoring

It is advisable to start with 1 L of central PN and increase the volume as needed, depending on the patient's metabolic stability. Blood glucose levels should be closely monitored and maintained at <180 mg/dL, tissue perfusion should be adequate, and PO<sub>2</sub>, PCO<sub>2</sub>, electrolytes (especially potassium, phosphate, and magnesium) and acid-base balance should be near normal before starting or advancing to the goal solution. The solutions should be administered using a volumetric pump set at a constant rate. It is important not to modify the infusion rate during any given day to try to compensate for excess or inadequate administration of the PN solution, such as when the PN solution arrives later than expected. A cyclic schedule (10–16 hours/day) for patients requiring long-term PN can be initiated once the patient is metabolically stable. In situations when the central PN solution must be suddenly discontinued, a 10% dextrose solution may be given at the same infusion rate as was used for the PN unless the patient is severely hyperglycemic. PN solutions may be administered at one-half the infusion rate to patients who are undergoing surgical procedures because circulating glucose and electrolyte levels are easier to control.

In addition to hyperglycemia, metabolic complications include hyper- and hypophosphatemia, hyper- and hypokalemia, hyper- and hypomagnesemia, and hyper- and hypocalcemia. Thus it is important to monitor the patient's serum electrolytes closely, especially when initiating TPN. In the inpatient setting, once the patient stabilizes on the individual nutritional prescription, serum chemistries should be obtained at least twice weekly to measure chloride, CO<sub>2</sub>, potassium, sodium, blood urea nitrogen, creatinine, calcium, and phosphate levels and once weekly for a full profile that includes liver function, magnesium, and triglyceride levels. Stable home PN patients may have less frequent chemistry monitoring, typically starting with once per week monitoring, then decreasing to twice per month and then monthly, depending on overall stability and clinical status.

### Patients With Special Needs

#### Glucose Intolerance

Hyperglycemia is the most common metabolic complication related to PN, and glucose regulation may be especially difficult in patients who have diabetes mellitus or who develop insulin resistance in response to severe stress or infection. Control of blood glucose levels is important for all patients who receive PN because uncontrolled hyperglycemia may be associated with complications such as fluid and electrolyte

disturbances and increased infection risk due to impairment of host defenses, including decreased polymorphonuclear leukocyte mobilization, chemotaxis, and phagocytic activity. Intensive insulin therapy, maintaining blood glucose concentrations between 80 and 110 mg/dL, was once considered standard practice for critically ill patients. However, more recent literature has demonstrated significant morbidity and mortality with this approach. For hospitalized patients, a target blood glucose of 140 to 180 mg/dL is recommended. Select circumstances may require more stringent blood glucose goals (110–140 mg/dL) if this can be maintained without hypoglycemic episodes.

Patients with difficult glycemic control may best be managed by continuous insulin infusion, which is safe, effective, and more timely than subcutaneous insulin therapy. Hypoglycemia that occurs during this type of infusion generally is short lived and more easily corrected than hypoglycemia resulting from subcutaneous insulin administration. A separate IV insulin infusion can be used rather than adding incremental doses of insulin to the PN bag every 24 hours in patients for whom glycemic control is difficult. Many intensive care units (ICUs) have an insulin drip infusion protocol in which there are frequent checks of serum glucose and adjustments of the insulin infusion drip (e.g., every 1–2 hours) to maintain target glucose levels. The conventional approach of using sliding scale insulin to cover high blood glucose levels may be unsafe and ineffective, and repetitive doses of subcutaneous insulin in the edematous patient can have a cumulative effect leading to prolonged hypoglycemia. In addition, adjusting insulin in the PN bag every 24 hours might not achieve the desired rapid correction of hyperglycemia deemed appropriate based on the literature, which indicates worse outcomes for those with poor glucose control.

Abrupt discontinuation of PN can lead to hypoglycemia and should be avoided. Instead, it is recommended to decrease the PN infusion rate by one-half for the last hour of infusion prior to discontinuation to prevent rebound hypoglycemia.

### Pancreatitis

Most cases of pancreatitis are mild, and nutritional support is not needed. However, 10% to 20% of patients with pancreatitis develop severe disease that results in a hypermetabolic, hyperdynamic, systemic inflammatory response syndrome that creates a highly catabolic stress state. In an evidence-based report evaluating nutrition support in acute pancreatitis patients, EN delivered to the small intestine (distal to the ligament of Treitz) is preferred over PN; EN patients are less likely to suffer from multiorgan failure, systemic infections, and death.

Initiation of PN should be delayed in patients with acute pancreatitis who cannot tolerate EN even though they might eventually require PN. Providing PN within 24 hours of admission has been shown to worsen outcome, and providing PN after resuscitation and abatement of the acute inflammatory process appears to improve outcome compared with standard therapy. Consequently, if EN is not feasible, the initiation of PN should be delayed for at least 5 days after admission to the hospital, when the peak period of inflammation has abated.

### Acute Kidney Injury and Chronic Kidney Disease

Acute kidney injury (AKI) is associated with severe nutritional deficits. Most patients with AKI are catabolic and have energy requirements 50% to 100% greater than resting requirements, likely the result of other coexisting conditions such as sepsis, trauma, and burns. Energy is provided to patients with AKI in sufficient quantities to minimize protein degradation, generally in the range of 20 to 30 kcal/kg/day. Lipid injectable emulsions can be used as a source of concentrated energy in patients who require a fluid restriction.

Protein loss is accelerated and protein synthesis is impaired in patients with AKI. Loss of amino acids in the dialysate and renal

replacement therapies add to the protein deficit and increase individual protein needs. Approximately 10 to 12 g of amino acids are lost with each dialysis therapy, depending on the type of dialyzer membrane, blood flow rate, and dialyzer reuse procedure, and approximately 10 to 16 g/day of amino acids are lost through continuous renal replacement therapies (CRRT). The provision of protein at 1.2 g/kg/day and up to 2.5 g/kg/day is recommended for AKI patients receiving hemodialysis and CRRT, respectively.

Protein is provided with a standard solution containing both essential and nonessential amino acids. Although some data suggest essential amino acids alone may be beneficial compared with a mixture of both essential and nonessential amino acids, the efficacy of using essential amino acid solutions remains uncertain. The goal is to provide adequate protein while treating the patient aggressively with dialysis to prevent the accumulation of nitrogenous waste products.

Fluid and electrolyte balance are often impaired in patients with AKI. The amount of fluid from the PN might need to be adjusted daily, depending on the phase of AKI, whether the patient is receiving dialysis, and whether dialysis is continuous or intermittent. Serum potassium and phosphate levels typically rise in patients with AKI until dialysis is initiated, at which time levels might drop, especially with the provision of PN. Potassium, phosphate, and magnesium levels need close monitoring and adjustment to correct imbalances. Acetate salts of potassium or sodium can be administered to help correct a metabolic acidosis.

Standard doses of the water-soluble vitamins and additional folic acid (1 mg/day total) and pyridoxine (vitamin B6) (10 mg/day) might need to be added to the solution for patients who are being dialyzed because these vitamins are lost from the body in the dialysate bath. Thiamine losses are increased with CRRT and repletion (100 mg/day) must be provided for patients receiving this therapy. The dose of vitamin C might need to be restricted to 100 mg/day to prevent oxalate deposits. However, additional vitamin C (250 mg/day) should be provided to patients receiving CRRT. The supplementation of fat-soluble vitamins is usually not required, especially in patients who also are eating, because excretion of fat-soluble vitamins is reduced in renal failure. For example, serum vitamin A levels may be elevated in AKI due to enhanced hepatic release of retinol and retinol-binding protein, decreased renal catabolism, and decreased degradation of vitamin A transport protein by the kidneys. Vitamin D levels may be decreased because of impaired activation of 1,25-dihydroxycholecalciferol in the kidneys. In anuric patients, trace elements may be withheld from the PN solution; however, for prolonged PN, trace elements and fat-soluble vitamins should be monitored and replaced accordingly.

Patients with chronic kidney disease (CKD) also have nutritional deficits due to anorexia, amino acid losses into the dialysate, concurrent illness, metabolic acidosis, and endocrine disorders. However, unlike those suffering from AKI, patients with CKD have normal energy requirements. Protein intake generally is restricted in predialysis patients to 0.6 g/kg/day or 0.75 g/kg/day if the patient is malnourished. Protein is required in higher amounts in patients on dialysis, depending on the type of dialysis: 1.2 g/kg/day for hemodialysis; 1.2 to 1.5 g/kg/day for peritoneal dialysis. Predialysis patients who become acutely ill should be given protein 1.2 to 1.5 g/kg/day even if this precipitates the need for dialysis. Starvation from insufficient calories or protein in the patient with renal dysfunction increases the risk of nutritionally related complications and should be avoided in the severely ill patient regardless of the potential need for dialysis.

Intradialytic PN is the provision of IV amino acids, carbohydrates, and fat directly into the venous drip chamber of the hemodialysis unit during treatment. It is a method of providing additional calories and protein in malnourished chronic hemodialysis patients. It is associated with significant increases

in body weight and serum albumin in patients with end stage renal disease. However, intradialytic PN is expensive and the benefits have not been fully elucidated. A typical solution contains about 1100 kcal and 50 g of protein, which is provided three times per week with hemodialysis. For example, in a dialysis patient who requires 2500 kcals and 70 g protein/day, intradialytic PN will provide approximately 20% of the weekly energy and approximately 30% of the weekly protein needs. Thus intradialytic PN is reserved for patients with end-stage renal disease on hemodialysis who cannot ingest sufficient nutrients by mouth and who are not candidates for nutritional support via EN or PN due to GI intolerance, venous access problems, or other reasons. Appropriate use of intradialytic PN should be limited to a very small fraction of people who are on hemodialysis.

### Hepatic Dysfunction and Liver Failure

Hepatic dysfunction is associated with a variety of abnormalities including metabolic abnormalities, malabsorption, maldigestion, anorexia, and early satiety due to ascites. Dietary restrictions also can contribute to malnutrition.

Protein intake in patients with stable chronic liver disease depends on the patient's nutritional status and protein tolerance. Nutritionally depleted patients can require as much protein as 1.5 g/kg estimated dry weight. In a minority of patients who have protein-sensitive hepatic encephalopathy, protein intake might need to be decreased to 0.5 to 0.7 g/kg/day and gradually increased to 1.0 to 1.5 g/kg/day, as tolerated. These patients have deranged plasma amino acid profiles, with increased concentrations of aromatic amino acids (phenylalanine, tyrosine, and tryptophan) and methionine and decreased branched-chain amino acids (leucine, isoleucine, and valine). Randomized, controlled trials that provided parenteral or enteral formulas enriched with branched-chain amino acids have been inconsistent with regard to improvements in encephalopathy, morbidity, and mortality. These specialty products should be reserved for patients with disabling encephalopathy who do not tolerate standard proteins and have not responded to other therapies, such as lactulose or neomycin administration.

Energy requirements are difficult to predict in patients with liver failure. Whereas most patients have a normal metabolic rate, up to one-third may be hypermetabolic. Although providing 25 to 30 kcal/kg/day is a guideline for providing energy needs, basing requirements on indirect calorimetry is often recommended.

Fluid restriction due to ascites and edema often necessitates increasing the dextrose concentration in the PN so as to maintain sufficient calories in a restricted volume. Sodium is reduced in the formula because liver-failure patients excrete nearly sodium-free urine. Vitamin and mineral deficiencies often occur as a result of suboptimal nutrient intake, decreased absorption, decreased storage, and in some cases alcohol use, which decreases thiamine (vitamin B1) and folate absorption. Copper and manganese may be contraindicated because a major route of excretion for these substances is the biliary system. Zinc deficiency is common in cirrhotic patients, and supplementation of this mineral may be necessary, especially if there are excessive GI losses.

### Acute Respiratory Distress Syndrome

Patients with protein-calorie malnutrition have an increased incidence of pneumonia, respiratory failure, and acute respiratory distress syndrome (ARDS). Nutritional support is indicated in patients with ARDS. Notably, underfeeding and overfeeding can be detrimental to pulmonary function.

Overfeeding calories, and particularly glucose, can lead to increased minute ventilation, increased dead space, and increased carbon dioxide production and ultimately to difficulty weaning from a ventilator. Hypercapnia from increased

carbon dioxide production is the result of glucose combustion causing more carbon dioxide production and excess calories triggering lipogenesis. A healthy person increases ventilation in response to increased calories and thus avoids hypercapnia. However, patients with compromised ventilatory status might not be able to compensate with increased ventilation and can develop respiratory distress, acute respiratory failure, and difficulty weaning from mechanical ventilation. Thus the use of indirect calorimetry measurements to determine energy expenditure is imperative in patients with ARDS.

### Critically Ill Patients With Obesity

Obesity is a growing problem worldwide, and management of critically ill patients with obesity poses many challenges. These patients are at risk for hyperglycemia, hyperlipidemia, and hypercapnia, all of which can be exacerbated by metabolic changes associated with critical illness. As with any critically ill patient, those with obesity will preferentially use protein and carbohydrate for energy and cannot effectively draw upon adipose tissue for energy. These patients require nutrition support to minimize loss of lean body mass.

The concept of "hypocaloric feeding" has emerged as the preferred way to feed critically ill patients with obesity. Energy delivery is restricted to approximately 60% to 70% of estimated energy requirements and protein delivery is high (typically >2 g/kg ideal body weight [IBW]). This is to avoid hyperglycemia, hyperlipidemia, and hypercapnia while providing the protein required to spare lean body mass and support recovery. Small-scale studies employing this feeding method have demonstrated that patients can achieve positive nitrogen balance. One study found decreased ICU length of stay, decreased antibiotic days, and a trend toward decreased mechanical ventilation days.

Energy and protein delivery for critically ill patients with obesity is guided by BMI. The ASPEN-SCCM guidelines recommend providing 11 to 14 kcal/kg of actual weight for patients with a BMI of 30 to 50 kg/m<sup>2</sup> or 22 to 25 kcal/kg IBW for patients with a BMI >50 kg/m<sup>2</sup>. For protein delivery, ASPEN and SCCM recommend protein provision of ≥2 g/kg IBW for patients with class I and class II obesity (BMI of 30–35 kg/m<sup>2</sup> and 35–40 kg/m<sup>2</sup>, respectively) and for patients with class III obesity (BMI >40 kg/m<sup>2</sup>) protein provision should be ≥2.5 g/kg IBW.

### Other Conditions and Nutritional Treatments

The catabolic response to major surgery, trauma, burn, and sepsis is characterized by a net breakdown of body protein stores to provide substrates for gluconeogenesis and acute-phase protein synthesis. Adequate nutrition can attenuate whole-body catabolism but rarely, if ever, prevents or reverses the loss of lean body mass during the acute phase of injury. Several strategies to prevent the loss of lean body mass have been investigated, including growth hormone, growth factors, and conditionally essential amino acids, such as glutamine.

Growth hormone is a potent anabolic agent, and administration to humans increases the rate of wound healing, decreases rates of wound infection, and decreases the catabolism and muscle wasting of critical illness. However, a large European trial found increased morbidity and mortality in patients with prolonged critical illness who received high doses of growth hormone. Thus the use of growth hormone in patients who are in the acute phase of critical illness is not recommended.

Alternative anabolic agents such as oxandrolone (Oxandrin)<sup>1</sup> and testosterone<sup>1</sup> are being pursued to induce positive nitrogen balance and enhance wound healing in critically ill patients. These anabolic steroid hormones increase protein synthesis

<sup>1</sup>Not FDA approved for this indication.

and can reduce the rate of protein breakdown. In a study of patients with alcoholic hepatitis, administration of oxandrolone was associated with lower mortality compared with patients receiving placebo. The patients receiving oxandrolone had improvements in the severity of their liver injury and the degree of malnutrition. Several studies have demonstrated a benefit of oxandrolone use in the burn patient population. Other anabolic steroid hormones, such as methandienone<sup>2</sup> and nandrolone decanoate (Deca Durabolin),<sup>2</sup> have been shown to increase protein anabolism and nitrogen balance in hospitalized patients.

Hormone treatment should be reserved for patients with major burns and documented impaired healing, patients who have large wounds or enterocutaneous fistulae who have impaired healing, patients with muscle wasting and weakness associated with AIDS or other failure to thrive conditions and, in general, patients who have not responded to aggressive nutritional support but whose underlying disease processes are controlled. Growth factors have not been shown to decrease length of time on a respirator in ICU patients. In fact, such factors can increase ventilator time and worsen outcome.

Glutamine-supplemented PN solutions administered to trauma or critically ill patients can improve overall nitrogen balance, enhance muscle protein synthesis, improve intestinal nutrient absorption, decrease gut permeability, improve immune function, and decrease hospital stays and costs in some patient populations. A review of 14 randomized trials in surgical and critically ill patients found that glutamine supplementation was associated with reduced mortality, lower rates of infectious complications, and a decreased hospital stay. The greatest benefit was in patients receiving high-dose (>0.29 g/kg/day) parenteral glutamine.

However, a recent randomized trial of glutamine and antioxidant micronutrient supplementation in critically ill patients showed a trend toward increased 28-day mortality and significant in-hospital and 6-month mortality in patients receiving glutamine supplementation. There were limitations in this study in that baseline glutamine levels were not checked for all patients; in a subset of 66 patients with plasma glutamine levels evaluated, all had normal levels at baseline. This suggests that glutamine supplementation may not be appropriate for all critically ill patients. In addition, patients received approximately 50% of goal energy requirements and approximately 45% of goal protein delivery from glutamine. The total amount of glutamine given in this study was significantly higher than the dose of glutamine usually recommended. This raises the possibility that there is an optimal “therapeutic window” for glutamine administration: Giving too little glutamine may not be efficacious and giving too much may be toxic. Further investigation is required before a definitive recommendation can be given based on this study alone.

Patients with intestinal dysfunction requiring PN, such as those with short-bowel syndrome or mucosal damage following chemotherapy and/or radiation therapy, might benefit from glutamine-containing PN. Glutamine-containing PN might also be beneficial in patients with immunodeficiency syndromes, including AIDS, immune-system dysfunction associated with critical illness, and bone marrow transplantation; patients with severe catabolic illness, such as major burns; patients with multiple trauma; and patients with other diseases associated with a prolonged ICU stay. Glutamine-supplemented solutions should not yet be considered routine care and should not be used in patients with significant renal insufficiency or in patients with significant hepatic failure. A recent ASPEN position paper summarizes recommendations for use of both enteral and IV glutamine.

## Common Complications and Management

### Catheter Sepsis

Catheter-related bloodstream infection (CRBSI) is an infection that originates from the catheter itself and is confirmed by culture. Central line-associated bloodstream infection (CLABSI) is a bloodstream infection without another identified focus of infection in a patient with a central line in place for at least 48 hours prior to the development of infection. Central venous CRBSIs range from 3% to 20% in hospitalized patients and is the most common complication of central venous catheters. Colonization of the skin, intraluminal contamination from manipulation of the catheter hub or IV connectors, and seeding of microorganisms from the bloodstream are common sources of infection. Common organisms associated with CRBSIs include *Staphylococcus epidermidis*, *Staphylococcus aureus*, *Enterococcus* spp., *Candida albicans*, *Escherichia coli*, *Klebsiella* spp., *Pseudomonas* spp., and *Enterobacter* spp. as well as resistant strains such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci.

Management of patients with catheter infection depends on their clinical condition. In extremely ill patients with high fevers who are hypotensive or who have local signs of infection around the catheter site, the catheter should be removed, its tip cultured, and peripheral and central venous blood cultures should be obtained. In CRBSI, the organisms that grow from the catheter tip are the same those identified in the peripheral blood culture, and typically more than 10<sup>3</sup> organisms are grown from cultures of the catheter tip.

Specific therapy should be initiated against the primary source in patients in whom a source of infection other than the catheter tip is present. Peripheral blood cultures should be obtained. Blood cultures should not be taken from the central venous catheter port dedicated for PN because this increases the risk of contaminating the line. If the infection resolves, central venous feedings can be continued, while making sure to maintain euglycemia. If a source is not identified and the symptoms persist, the catheter should be removed and its tip should be cultured. If the culture of the catheter tip returns positive or if the index of suspicion is high, empiric antibiotic therapy is initiated and later narrowed to target the specific microorganism once culture and susceptibility data become available. If removal of the catheter is indicated and is not possible due to lack of access sites or high risk of bleeding complications, then salvage therapy (systemic antibiotics plus antibiotic lock therapy) or, as a last resort, exchange of the catheter over a guidewire with systemic antibiotics and antibiotic lock therapy may be considered, with long-term ethanol lock therapy to prevent further infections. Central venous feedings may be continued during this interval if the patient is stable. It is important to note that changing the site of catheter, rather than salvage therapy or guidewire exchange, is preferred in patients in whom infection is suspected.

### Other Complications

Common complications, their etiologies, and treatments are outlined in Table 4. Prolonged administration of PN can result in altered hepatic function and can lead to liver failure. One to 2 weeks after initiating PN, transaminases may be elevated, but this often resolves without any change in the composition of PN or rate of administration. However, in patients receiving long-term PN (>20 days), prolonged elevations of alkaline phosphatase followed by elevated levels of serum transaminases can occur, even after therapy is discontinued.

Serum levels of alkaline phosphatase and bilirubin initially remain normal, but they rise in many patients who receive long-term PN. Patients who do not receive lipids in the PN solution have more frequent and severe hepatic abnormalities, most likely due to higher carbohydrate loads. Excess glucose increases insulin

<sup>2</sup>Not available in the United States.

**TABLE 4** Possible Etiologies and Treatment of Common Complications of Central Parenteral Nutrition

PROBLEM	POSSIBLE ETIOLOGY	TREATMENT
<b>Glucose</b>		
Hyperglycemia, glycosuria, hyperosmolar nonketotic dehydration, or coma	Excessive dose or rate of infusion, inadequate insulin production, concomitant steroid administration, infection	Decrease the amount of glucose given, increase insulin, administer a portion of calories as fat
Diabetic ketoacidosis	Inadequate endogenous insulin production and/or inadequate insulin therapy	Give insulin Decrease glucose intake
Rebound hypoglycemia	Persistent endogenous insulin production by islet cells after long-term high-carbohydrate infusion	Give 5%–10% glucose before parenteral infusion is discontinued
Hypercarbia	Carbohydrate load exceeds the ability to increase minute ventilation and excrete excess CO <sub>2</sub>	Limit glucose dose to 5 mg/kg/min Give greater percentage of total caloric needs as fat (up to 30%–40%)
<b>Fat</b>		
Hypertriglyceridemia	Rapid infusion	Decrease rate of PN infusion
	Decreased clearance	Allow clearance (~12 h) before testing blood
Essential fatty acid deficiency	Inadequate essential fatty acid administration	Administer essential fatty acids in doses of 4%–7% of total calories
<b>Amino Acids</b>		
Hyperchloremia metabolic acidosis	Excessive chloride content of amino acid solutions	Administer Na <sup>+</sup> and K <sup>+</sup> as acetate salts
Prerenal azotemia	Excessive amino acids with inadequate caloric supplementation	Reduce amino acids Increase the amount of glucose calories
<b>Miscellaneous</b>		
Hypophosphatemia	Inadequate phosphorus administration with redistribution into tissues	Give 15 mmol phosphate/1000 IV kcal Evaluate antacid and Ca <sup>2+</sup> administration
Hypomagnesemia	Inadequate administration relative to increased losses (diarrhea, diuresis, medications)	Administer Mg <sup>2+</sup> (15–20 mEq/1000 kcal)
Hypermagnesemia	Excessive administration; renal failure	Decrease Mg <sup>2+</sup> supplementation
Hypokalemia	Inadequate K <sup>+</sup> intake relative to increased needs for anabolism; diuresis	Increase K <sup>+</sup> supplementation
Hyperkalemia	Excessive K <sup>+</sup> administration, especially in metabolic acidosis; renal decompensation	Reduce or stop exogenous K <sup>+</sup> If ECG changes are present, treat with calcium gluconate, insulin, diuretics, and/or Kayexalate
Hypocalcemia	Inadequate Ca <sup>2+</sup> administration; reciprocal response to phosphorus repletion without simultaneous calcium infusion	Increase Ca <sup>2+</sup> dose
Hypercalcemia	Excessive Ca <sup>2+</sup> administration; excessive vitamin D administration	Decrease Ca <sup>2+</sup> and/or vitamin D administration
Elevated liver transaminases or serum alkaline phosphatase and bilirubin	Enzyme induction secondary to amino acid imbalances or overfeeding	Reevaluate nutritional prescription Cycle TPN Avoid overfeeding calories Consider change to a blended lipid rather than 100% soybean oil-lipid Consider administering carnitine

PN, Parenteral nutrition; TPN, total parenteral nutrition.

secretion, which stimulates hepatic lipogenesis and results in hepatic fat accumulation. Fatty infiltration is the initial histopathologic change; it is readily reversible and might not be accompanied by altered liver function tests.

Longer PN therapy may be associated with cholestasis, cholelithiasis, steatosis, and steatohepatitis and can progress to active chronic hepatitis, fibrosis, and eventual cirrhosis. The management of PN-related liver dysfunction is summarized in [Box 3](#).

Complications are minimized and nutritional therapy maximized when the care of patients who require specialized nutritional support is supervised by a nutrition support team. Ideally, the nutrition support team consists of a pharmacist, dietitian, nurse, and physician.

### BOX 3 Management of Parenteral Nutrition-Related Liver Dysfunction

- Have the patient eat, if possible.
- Avoid administering large amounts of glucose or protein calories.
- Supply IV fat emulsions (up to 30% of total calories).
- Consider addition of blended lipid emulsions with lower concentrations of soybean oil.
- Cycle the parenteral nutrition, infusing for 10 to 12 hours/day.
- Reevaluate energy needs; reduce energy delivery if liver dysfunction persists.

## PHEOCHROMOCYTOMA

Method of

Matthew A. Nazari, MD; Abhishek Jha, MD; and Karel Pacak, MD, PhD, DSc

### CURRENT DIAGNOSIS

- The most common clinical sign of a pheochromocytoma/paraganglioma (PPGL) is hypertension; when combined with the triad of headache, palpitations, and diaphoresis, the diagnosis should be suspected.
- A biochemical diagnosis of PPGL should be established with elevated plasma or urinary fractionated metanephrines and plasma methoxytyramine.
- Localize tumors with anatomic imaging (computed tomography [CT] or magnetic resonance), followed by specific functional imaging using positron emission tomography modalities.
- Following diagnosis, a thorough medical and family history should be obtained to assess for syndromic clinical presentations of PPGL. If available, all patients with confirmed PPGL should undergo genetic testing.
- If a causative mutation is identified, the patient's first-degree relatives should be appropriately tested. Positive individuals should be presymptomatically screened with plasma or urinary fractionated metanephrines and imaging as described, if appropriate.

### CURRENT THERAPY

- Prompt surgical excision remains the primary treatment for PPGL. If feasible, cortical sparing adrenalectomies should be attempted in patients with bilateral or hereditary PPGLs (except succinate dehydrogenase subunit B [*SDHB*]-related disease) to prevent lifelong corticosteroid supplementation.
- One to two weeks prior to the operation, regardless of biochemical activity, patients should be started on a preoperative  $\alpha$ - followed by  $\beta$ -adrenoceptor blockade to avoid unopposed  $\alpha$ -adrenoceptor stimulation leading to vasoconstriction and hypertensive crisis. At minimum, a normotensive patient should be maintained on low-dose calcium channel blockers.
- After surgery, scheduled clinical follow-up is necessary, particularly in cases of underlying genetic mutations or large tumors (>5 cm), which are more likely to metastasize.
- Management of metastatic PPGL requires a multidisciplinary approach involving surgical excision alongside pharmacologic, radio-, and chemotherapies.

The 2017 World Health Organization (WHO) Classification of Tumors of Endocrine Organs defines pheochromocytoma (PHEO)\* as a chromaffin cell tumor arising from the adrenal medulla. Paragangliomas (PGLs) are functionally similar tumors that originate along the extra-adrenal ganglia and are further classified as parasympathetic or sympathetic. Predominantly located in the head and neck, parasympathetic PGLs are locally invasive, rarely develop metastases, and secrete dopamine/methoxytyramine, with a minority (approximately 5% or less) producing and releasing norepinephrine/normetanephrine. In contrast to their parasympathetic counterparts, sympathetic PGLs are concentrated primarily in the abdomen and pelvis, with 2% found in the mediastinum and 1% in the neck. Abdominal PGLs often derive from the organ of Zuckerkandl, a collection of neural crest cells above the bifurcation of the aorta at the origin of the inferior mesenteric artery (Figure 1). Biochemically, PHEOs are characterized by the synthesis, metabolism, storage, and almost always the release of metanephrines/methoxytyramine (in approximately 98% of cases) and usually the release of catecholamines (in approximately 80% of cases).

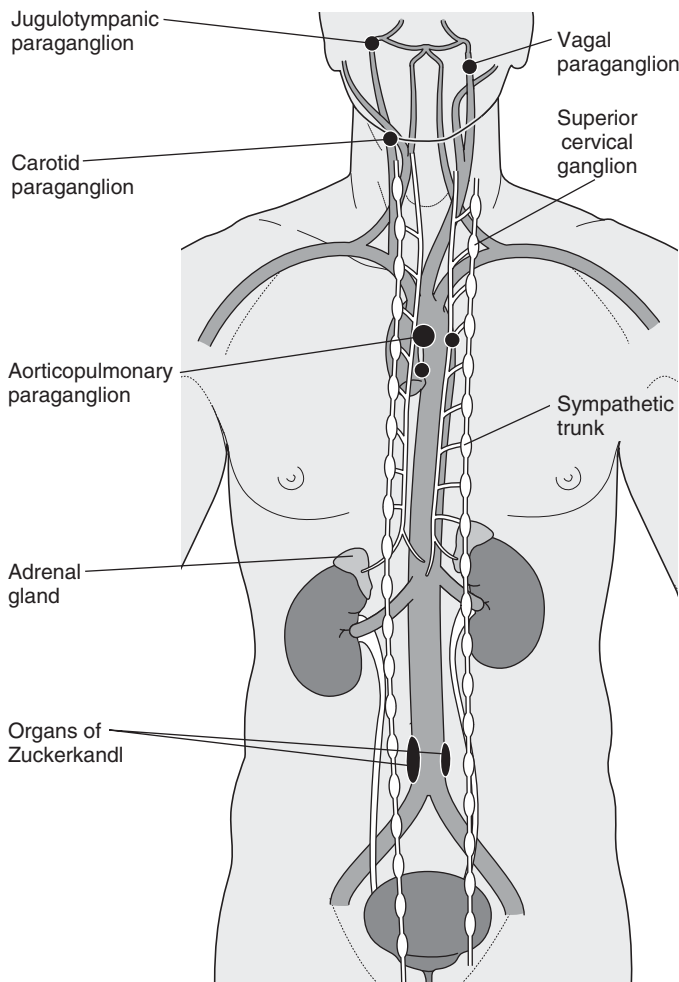

### Epidemiology

Previously, PHEOs were primarily diagnosed at autopsy. However, as the sensitivity of biochemical and imaging assays increased, the incidence of PHEO likewise swelled. A recent European analysis estimates that the age-standardized incidence rate increased from 0.29 to 0.46 from 1995 to 2015, respectively. While PHEO can occur at any age (including childhood, particularly when associated with germline genetic mutations), the average age of diagnosis is most commonly in the fifth decade. Although no consistent gender preference has been reported, in the Netherlands, a statistically significant number of PHEOs occurred in females (55%) compared to their male counterparts (45%). The PHEO to PGL ratio is approximately 0.80 to 0.20, respectively. Approximately 30% to 40% of patients with PHEO carry a germline or somatic mutation in one of the 25 known PHEO susceptibility genes (see "Genetics" below). The rate of malignancy varies from 0% to 71% depending on genetic background, with succinate dehydrogenase subunit B (*SDHB*)-related disease, the most clinically aggressive.

### Genetics

While complete consensus is lacking, 30% to 40% of PHEOs are hereditary, with a significant percentage (upwards of 20%) of apparently sporadic tumors carrying somatic mutations.

\*From this point forward, PHEO represents pheochromocytoma and paraganglioma unless otherwise specified.

**Figure 1** Important anatomic distribution of chromaffin tissue composing paraganglia.

Identification of a genetic alteration allows for appropriate treatment algorithms and management of subsequent endocrinopathies or syndromic neoplasias in the proband and at-risk relatives as well.

At present, at least 25 PHEO susceptibility genes have been discovered, which can broadly be categorized into major and minor contributors, with the major genes representing 85% to 90% of all hereditary tumors. Well-known hereditary genetic mutations include von Hippel-Lindau tumor suppressor (*VHL*), *RET* proto-oncogene resulting in multiple endocrine neoplasia (MEN) types 2A and 2B, neurofibromin 1 (*NF1*) tumor suppressor, and the succinate dehydrogenase (*SDHx*) subunits *SDHB* and *SDHD* genes. The minor susceptibility genes, representing 10% to 15% of hereditary tumors include *SDHA*, *SDHC*, succinate-CoA ligase GDP-forming subunit beta (*SUCLG2*), succinate dehydrogenase assembly factor 2 (*SDHAF2*), fumarate hydratase (*FH*), Myc-associated factor X (*MAX*), hypoxia-inducible factor 2 alpha (*HIF2A*), malate dehydrogenase 2 (*MDH2*), isocitrate dehydrogenase 1 (*IDH1*), isocitrate dehydrogenase 2 (*IDH2*), *H-RAS* and *K-RAS* proto-oncogenes, transmembrane protein 127 (*TMEM127*), cold-shock domain containing E1 (*CSDE1*), mastermind like transcriptional coactivator 3 (*MAML3*) fusion genes, prolyl hydroxylase 1 and 2 (*PHD1/2*), iron regulatory protein 1 (*IRP1*), *MDH2*, kinesin superfamily member (*KIF1B*), dihydrolipoamide S-succinyltransferase (*DLST*), and DNA methyltransferase 3 alpha (*DNMT3A*). Characteristics of the most important hereditary tumor syndromes are described in [Table 1](#).

Several well-established PHEO syndromes ([Box 1](#)) exhibit characteristic clinical features. Rare PGL-associated syndromes include Carney triad and Carney-Stratakis syndrome, which are

characterized by *SDHB* and *SDHD*-related gastrointestinal stromal tumors (GISTs). The novel recently described Pacak-Zhuang syndrome consists of *HIF2A*-associated PGLs in the setting of polycythemia, duodenal somatostatinomas, and marked, permanent choroidal thickening and tortuous dilated veins in the choroid and retina. Another rare, recently described PHEO syndrome is characterized by giant cell tumors associated with a postzygotic *H3F3A* mutation.

In conjunction with the United States Endocrine Society Clinical Practice Guidelines, recent publications have emphasized genetic counseling and subsequent testing in all patients diagnosed with PHEO, regardless of suggestive family history or age at presentation. Within the United States, several commercially available PHEO gene panels screen patients for the most prevalent hereditary genetic syndromes via DNA sequencing and deletion/duplication analysis. However, broad, comprehensive genetic panels covering 10 to 12 genes are expensive and may not be covered by insurance. In patients with a confirmed PHEO, an algorithm ([Figure 2](#)) based on family history, syndromic clinical features, and biochemical phenotype can be used to tailor genetic testing and reduce the financial burden. If genetic testing is positive for hereditary PHEO, all first-degree relatives should undergo genetic evaluation. Asymptomatic carriers should undergo annual biochemical evaluation with plasma metanephrines and whole-body magnetic resonance (MR) imaging every other year for surveillance. Genetic testing in children ([Box 2](#)) should be approached on an individual basis following discussion with parents/guardians, geneticists, and psychiatrists due to the ethical and legal ramifications. Children should only be screened if they will be offered regular surveillance.

### Clinical Manifestations

As a result of episodic catecholamine secretion on and stimulation of  $\alpha$ - and  $\beta$ -adrenoceptors, the clinical manifestations of PHEO are related to hemodynamic and metabolic instability. While the majority of primary clinical indicators ([Box 3](#)) for PHEO are nonspecific, when several symptoms are taken in conjunction, the diagnosis should be considered. Classically, patients experience paroxysmal hypertension accompanied with headaches, palpitations secondary to tachyarrhythmia, and diaphoresis. However, pallor, nausea, flushing, fatigue, and psychological symptoms—including anxiety, panic attacks, and nervousness—are common. Symptoms may occur spontaneously or as a result of direct tumor manipulation, anesthesia, or ingestion of tyramine-rich foods, which trigger catecholamine release and subsequent crisis. Unfortunately, patients may not exhibit any signs or symptoms of PHEO, thereby delaying a timely diagnosis. Therefore, if biochemistry or imaging suggests PHEO, the diagnosis may not be excluded based on the patient's asymptomatic state.

### Differential Diagnosis

Referred to as the “great mimic,” PHEO manifests with a myriad of signs and symptoms that are easily misconstrued for more common disorders, which often prevents a timely diagnosis. Consideration should be given to conditions that also result in sympathomedullary activation, including hyperadrenergic and renovascular hypertension, panic disorders, menopausal syndrome, temporal lobe epilepsy, and other neuroendocrine tumors that release vasoactive substances. Patients with a presumptive diagnosis of PHEO should be screened biochemically. If results are unequivocal, a normal response to the clonidine suppression test will effectively rule out PHEO.

### Biochemical Evaluation

PHEOs are capable of secreting all, none, or any combination of catecholamines—epinephrine, norepinephrine, and dopamine. Plasma metanephrines (the O-methylated metabolites of parent catecholamines) is the current gold-standard diagnostic criteria to detect and exclude a diagnosis of PHEO. Twenty-four-hour urinary metanephrines is a comparable alternative when plasma is not available. Definitive diagnosis is likely when biochemical evaluation is greater than two times the upper reference limit

**TABLE 1** Characteristics of Hereditary Pheochromocytoma Syndromes and Gene Mutations

SYNDROME	MUTATION	GENE	PROTEIN FUNCTION	PENETRANCE	BILATERAL	MALIGNANT	PHEO OR PGL	PEAK AGE (Y)	BIOCHEMICAL PHENOTYPE+
MEN2	10q11.2	<i>RET</i>	Receptor tyrosine kinase	50%	50–80%	Rare	PHEO	40	ADR

<sup>‡</sup>Observations at the National Institutes of Health report a much lower penetrance, almost zero percent

\*Probable paternal transmission only

(URL) (Figure 3). To reliably interpret test results, specific conditions (Box 4) should be ensured throughout the blood draw. Additionally, there are a variety of foods and medications (Table 2) that interact either directly or indirectly with catecholamine measurement and should therefore be avoided for 12 hours prior to collection. Patients with acute or chronic kidney disease, particularly those on dialysis, commonly have elevated plasma metanephrines (although likely less than three to four times the URL of normal). If necessary, liquid chromatography with tandem mass spectrometry is a quick and cost-effective means to detect and remove potentially interfering substances.

Confirmatory follow-up testing is necessary in almost all cases of PHEO given the high false-positive rate. Repeat plasma or urinary metanephrines and catecholamines, or the clonidine

suppression test, can be used in equivocal cases, as secondary validation or in patients in whom interfering drugs cannot be stopped. Prior to clonidine suppression testing, patients should undergo a complete medication review with consideration to hold antihypertensives given predilection for profound hypotension in response to clonidine. Additionally, diuretics, antidepressants, and  $\beta$ -adrenoceptor blockers have been reported to interfere with test results and should be held when appropriate. The patient should be fasting overnight and resting comfortably supine for 20 minutes prior to baseline blood draw. Clonidine (Catapres)<sup>1</sup> is administered at a dose of 0.3 milligrams (mg) per 70 kg, with appropriate dose adjustments as necessary (upwards of 0.5 mg based on weight), and subsequent repeat blood draw 3 hours after administration.

Adapted from Lenders JW, Eisenhofer G, Mannelli M, et al: Pheochromocytoma. *Lancet* 366:665–675, 2005.

With an increasing proportion of hereditary PHEO, it is important to distinguish their various catecholamine profiles, which can help guide genetic testing. In the last several years, the O-methylated metabolite of dopamine—methoxytyramine—has been used to confirm head and neck PGLs, which solely secrete dopamine and are therefore missed with standardized biochemical analysis. Furthermore, recent literature points to plasma methoxytyramine as a novel biomarker for metastatic PHEO,

which can be used in conjunction with large tumor size, germline genetic mutations (particularly *SDHx*), and the presence of extra-adrenal PGLs to indicate a higher likelihood of malignancy.

**Localization of Pheochromocytoma**

Imaging should only be pursued after clear biochemical evidence is confirmed. For optimal results, initial anatomic scans should consist of whole-body CT or MR imaging. T2-weighted MR imaging is preferred in patients in whom radiation exposure should be limited, those with a CT contrast allergy, and for the detection of skull-based lesions with the presence of known surgical clips. Ultrasound is not recommended for the localization of PHEO but may be utilized in children and during pregnancy if MR imaging is unavailable. Anatomic imaging is only sufficient for PHEO confirmation if the adrenal gland is the sole site of involvement (tumors <5 cm in size) and the metanephrine level is very high—all other patients should proceed with functional imaging, which is also useful in ruling out metastatic disease.

Currently, there are four primary nuclear imaging techniques used to confirm or detect metastatic PHEO (iodine-123 metaiodobenzylguanidine [<sup>123</sup>I-MIBG], gallium-68 DOTA coupled somatostatin analogs [<sup>68</sup>Ga-SSTa], fluorine-18-fluorodihydroxyphenylalanine [<sup>18</sup>F-FDOPA], and 18-fluorine-fluorodeoxyglucose [<sup>18</sup>F-FDG]). Several algorithms (Figure 4) have been proposed based on tumor location, genetic predisposition, and presence of metastatic disease. While <sup>18</sup>F-FDG was previously preferred for comprehensive localization of metastatic disease, recent systematic reviews have reported the superiority of <sup>68</sup>Ga-SSTa in apparently sporadic and *SDHx*-related metastatic PPGL. However, for other inherited PHEO (*NFI*, *VHL*, *RET*, *MAX*) or apparently sporadic PHEO, <sup>18</sup>F-FDOPA is the preferred positron emission tomography (PET) radiopharmaceutical. Given the relatively novel status of <sup>68</sup>Ga-SSTa and <sup>18</sup>F-FDOPA, these modalities may not be available at a particular institution. In this case, physicians should proceed with traditional <sup>18</sup>F-FDG. The use of <sup>123</sup>I-MIBG scintigraphy should be limited to patients with known metastatic PHEO in the evaluation and eligibility for targeted radionuclide therapy with <sup>131</sup>I-MIBG.

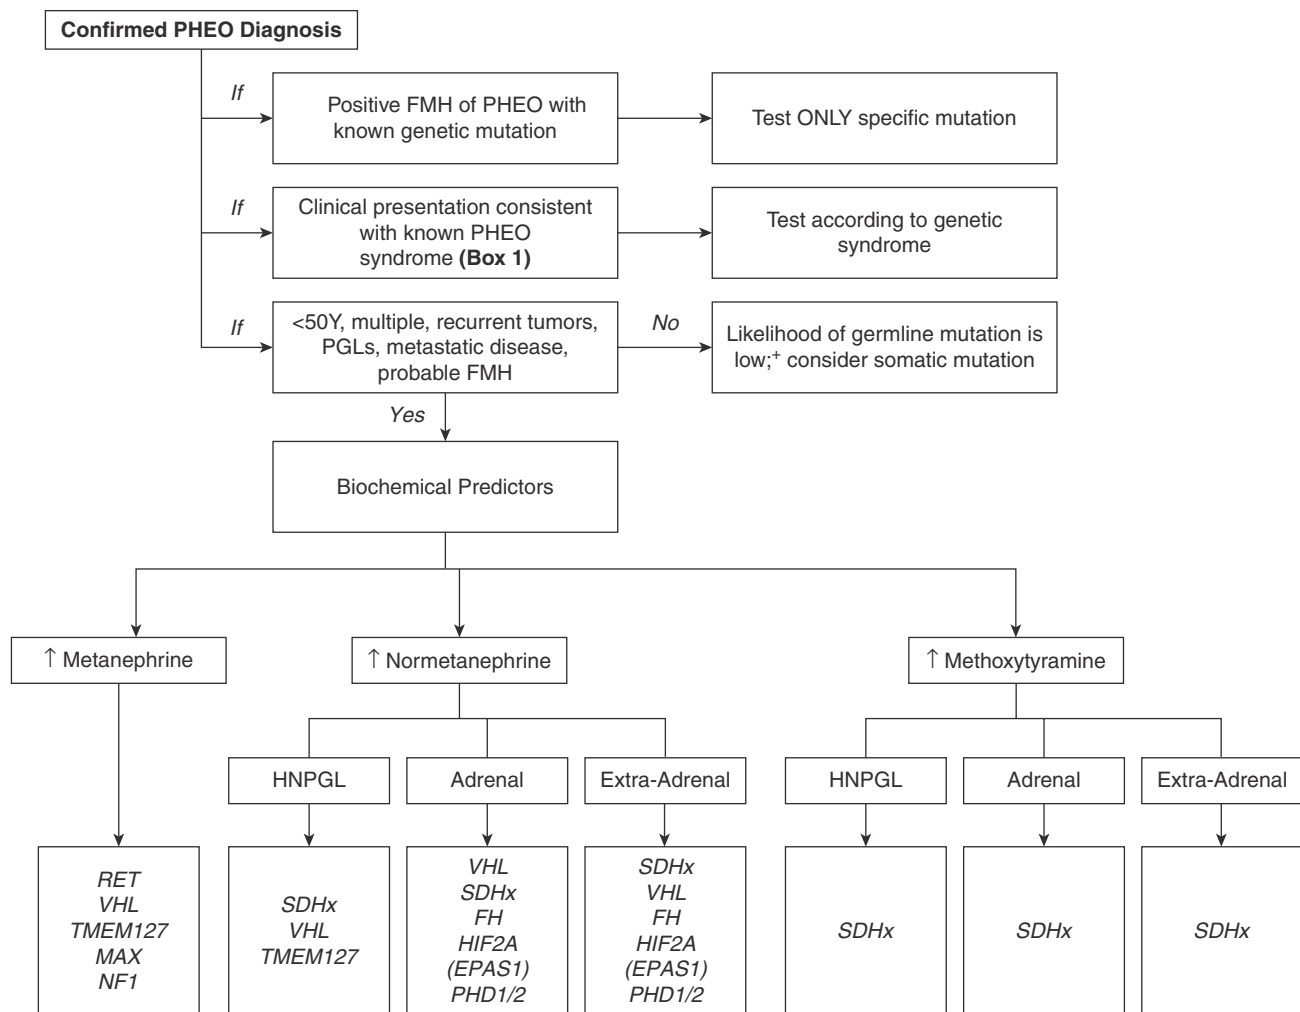

**Treatment**

The preferred, localized treatment for PHEO is surgical resection. Even in patients with metastatic disease or where complete excision is not feasible, debulking procedures are favorable to reduce hormonal secretion and prevent anatomic complications. To ensure patient safety throughout the perioperative period, a multidisciplinary team should include a medical internist/endocrinologist, anesthesiologist, and surgeon, preferably in an experienced center (see “Perioperative Management” for details). For metastatic, systemic treatment options, see “Metastatic Pheochromocytoma.”

**Preoperative Medical Preparation**

Surgical resection bears high perioperative risks and complications, which can be mitigated with an appropriate  $\alpha$ - and  $\beta$ -adrenoceptor blockade. Over the past decade, multiple case series have called into question the necessity of such medical management. However, the United States Endocrine Society Clinical Practices guideline continues to recommend an  $\alpha$ -adrenoceptor blockade to ensure the protection of patients, secondary to prolonged circulating catecholamines. While patients are most at risk for a catecholamine and subsequent hypertensive crisis during induction of anesthesia and direct tumor manipulation, daily psychological and physical stressors are just as likely to result in a sudden release of catecholamines. Therefore, it is imperative patients be adequately blocked even without a surgical plan.

At minimum, blood pressure should be treated preoperatively for 7–14 days barring extenuating circumstances (Figure 5). The most commonly used nonselective  $\alpha$ -adrenoceptor blocker is phenoxybenzamine (Dibenzylamine). However, this medication may be expensive, poorly covered by insurance, and is associated with nasal congestion, fatigue, and ejaculatory dysfunction—which may be rate limiting for patients. Selective  $\alpha$ 1-adrenoceptor

**Figure 2** Targeted algorithm for genetic analysis in patients with confirmed pheochromocytoma. If both normetanephrine and methoxytyramine are elevated, follow the algorithm for methoxytyramine. If both normetanephrine and metanephrine are elevated, follow the algorithm for metanephrine. *SDHAF2* mutation screening should be considered in patients who suffer exclusively from head and neck paragangliomas and who have familial antecedents, multiple tumors, or a very young age of onset and in whom *SDHB/C/D* gene mutations are negative. Only the most common genes are listed. *FMH*, Family medical history. (Adapted from Karasek D, Shah U, Frysak Z, et al: An update on the genetics of pheochromocytoma. *J Hum Hypertens* 27[3]:141–147, 2013.)

### BOX 2 Considerations for Pediatric Genetic Testing

- Parent/Guardian should meet with geneticist and/or psychiatrist in the absence of the child to discuss implications for genetic testing and subsequent screening recommendations if positive.
- Parent/Guardian should be given adequate time to reflect on their consultation and develop a plan to discuss why the child is undergoing the testing and the implications of the results.
- Medical providers should work with the family to avoid testing or revealing results close to or falling on birthdays, religious holidays, or important school activities, as this may negatively impact the memory of these events.
- If possible, avoid simultaneously testing multiple siblings given the potential impact of discordant results.
- If positive, genetic counselors should emphasize the importance of “at risk” vs. “being ill” and provide all parties with the appropriate space to express their immediate reactions, ask questions, and process their emotions.

Adapted from Lahlou-Laforet K, Consoli SM, Jeunemaitre X, et al: Presymptomatic genetic testing in minors at risk of paraganglioma and pheochromocytoma: our experience of oncogenetic multidisciplinary consultation. *Horm Metab Res* 44:354–358, 2012.

blockers include doxazosin (Cardura), prazosin (Minipress), and terazosin (Hytrin). Selective adrenoceptor blockers have a shorter duration of action and are more likely to result in first-dose orthostatic hypotension, while the long-acting phenoxybenzamine is associated with postoperative hypotension. In low-risk, normotensive patients, calcium channel blockers and metyrosine (Demser) can be utilized if available within the institution.

If tachycardia ensues, cardioselective  $\beta$ 1-adrenoceptor blockers, such as atenolol (Tenormin) or metoprolol (Lopressor), can be initiated 2 to 3 days after  $\alpha$ -adrenoceptor administration.  $\beta$ -Adrenoceptor blockers *cannot* be given prior to initiation of an  $\alpha$ -adrenoceptor blocker as unopposed antagonism can result in severe hypertensive crisis. In patients with persistent tachyarrhythmia, cardioselective calcium channel blockers diltiazem (Cardizem) or verapamil (Isoptin), ivabradine (Corlanor) can be used; however, it is not approved by the FDA for this indication.

### Perioperative Management

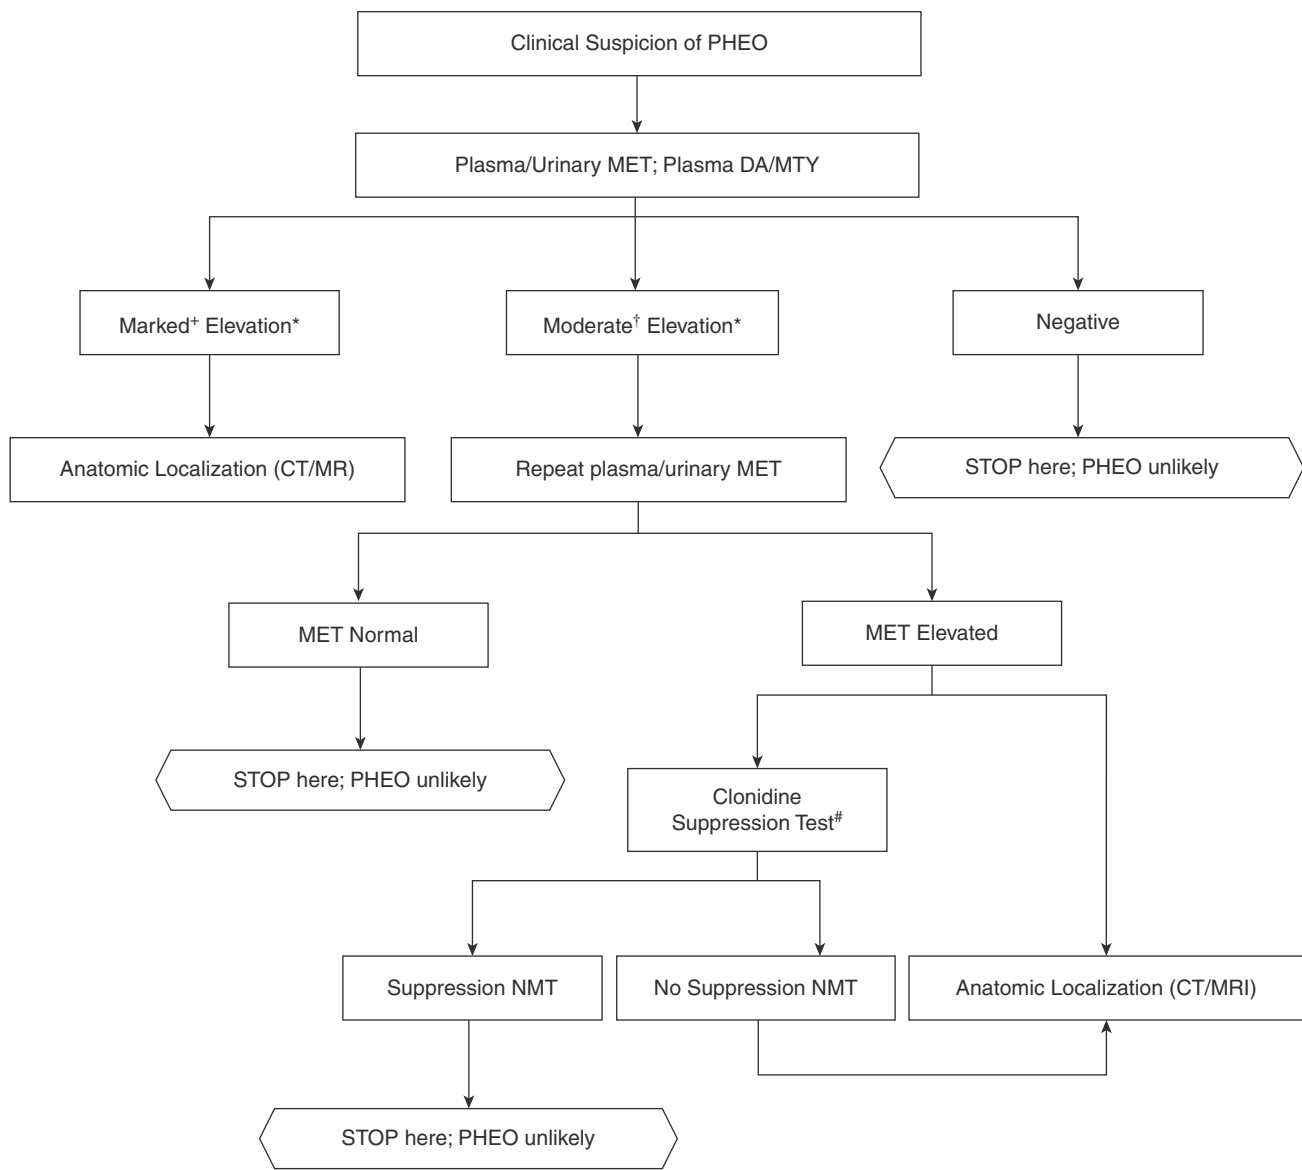

As stated previously, an appropriate preoperative blockade is a necessity to ensure 24 hours of systolic blood pressure less than 140 mm Hg prior to surgery. Orthostatic hypotension is tolerated, but not below 80/45 mm Hg. Immediately prior to surgical intervention patients should receive 1 to 1.5 L of intravenous crystalloid. Operative approach should be decided on an individual basis by the surgeon. When appropriate and feasible, small, nonmetastatic

**BOX 3****Clinical Indications to Screen for Pheochromocytoma**

- Patients with a known pheochromocytoma susceptibility gene mutation or a positive family history.
- Patients with triad of headaches, sweating, and tachycardia (regardless of blood pressure).
- Patients with recent onset of uncontrolled hypertension on greater than three to four standard oral therapies.
- Patients with previous history of hypertension, tachycardia, or arrhythmia following anesthesia, surgery, or ingestion of medications known to precipitate symptoms of pheochromocytoma.
- Patients with an incidental adrenal mass.

PHEOs and retroperitoneal PGLs should be surgically excised with a minimally invasive technique. Locoregional invasion is difficult to assess preoperatively; therefore, suspected cases should initially be explored by laparoscopy with conversion to an open procedure in the face of critical adhesions. In non-*SDHB*-related bilateral PHEO, an adrenocortical sparing procedure is recommended to avoid permanent glucocorticoid deficiency.

Intraoperatively, direct communication between the surgeon and anesthesiologist—particularly during tumor manipulation and excision—is imperative to minimize hemodynamic fluctuations secondary to massive catecholamine release. Careful and continued monitoring of postoperative hemodynamic stability is crucial. Common complications include hypertension, hypotension, arrhythmias, adrenocortical insufficiency, and hypoglycemia. Within the immediate (first 24 hours) postoperative period, transient hypertension is likely attributable to pain, volume overload, or autonomic instability, which should be treated symptomatically.

\*Marked: greater than 2x the URL of normal

†Moderate; less than 2x the URL of normal

\*First rule out any drug-related false elevation of MET/MTY (see Table 2) or renal failure

#If suspicion for PHEO is low or interfering drugs cannot be held

**Figure 3** Algorithm for biochemical diagnosis of pheochromocytoma.

**BOX 4** Optimal Conditions for Collection of Plasma Metanephrines/Catecholamines

- Patient should fast from midnight the previous evening
- Patient should abstain from nicotine, alcohol, and vigorous exercise for 12 hours prior to collection
- Establish intravenous access
- Patient should lie supine in quiet, dark room without distraction for 15–20 min prior to collection

However, persistent hypertension should be concerning for incomplete tumor resection, metastatic disease, excess fluid administration, or underlying essential hypertension. Recommended first-line management is with short-acting, easily titratable agents, such as nicardipine (Cardene) or labetalol (Trandate). Attempts to repeat plasma/urinary metanephrine levels to assess for residual disease burden should be delayed for five to seven days following surgery to ensure resolution of operative catecholamine spikes. In a postoperative hypotensive (SBP <90 mm Hg) patient, hemorrhage should be excluded before deliberating a differential. Alternative etiologies include prolonged  $\alpha$ -adrenoceptor blockade action, abrupt cessation of serum catecholamines, chronically low circulating plasma volume, or blood loss. The primary treatment modality is fluid resuscitation or blood transfusion, if needed. Vasopressors should be used sparingly, especially when metyrosine or long-acting  $\beta$ -adrenoceptor blockers were used preoperatively.

Postoperative tachyarrhythmias (>100 beats/min) are likely due to continued catecholamine secretion or the use of intraoperative inotropes, while bradyarrhythmias (<60 beats/min) are due to a variety of concerns. For persistent abnormal rhythms, expert evaluation is recommended. If adrenal insufficiency is expected postoperatively, patients should receive 50 to 100 mg hydrocortisone (Cortef) prior to induction, followed by 25 to 50 mg every 8 hours thereafter. Barring any postoperative complications, transition to an oral steroid regimen 24 to 48 hours after surgery (glucocorticoid and mineralocorticoid) and provide appropriate education on adrenal crisis, emergency bracelets, and dosage adjustments in times of sickness. In the absence of catecholamine excess, upregulated liver glycogenolysis and inhibition of insulin secretion may cease, leading to postoperative hypoglycemia. Importantly, the classic signs and symptoms may be masked in the immediate postoperative period and should be routinely monitored for the first 24 hours following surgery.

**Hypertensive Crisis**

The most dangerous PHEO-related complication, a hypertensive crisis, can manifest with a severe headache, visual disturbances, myocardial infarction, congestive heart failure, or a cerebrovascular accident. Immediate treatment with repetitive 5-mg intravenous boluses of phentolamine (Regitine)—a short-acting, reversible, nonselective  $\alpha$ -adrenoceptor agonist—should be repeated every 2 minutes until hypertension is adequately controlled (or initiate a continuous infusion). If unavailable, continuous infusions of sodium nitroprusside (Nitropress), labetalol (Trandate), or nicardipine (Cardene) are alternative options, with appropriate dose de-escalation upon the resolution of hypertension and subsequent symptoms related to the crisis.

**Metastatic Pheochromocytoma**

According to the 2017 WHO report, metastatic PHEO is only established by the presence of chromaffin cells where they are normally absent. PHEO metastasizes via a hematogenous or lymphatic route with the bones, lymph nodes, liver, and lungs being the most common sites of disease progression. Recent data suggest that almost half of patients with metastatic PHEO present within 1 year of initial diagnosis, while greater than 70% of patients will develop metastatic disease within 5 years of their primary diagnosis. At the time of primary tumor resection, over

75% of metastatic PHEO patients have a tumor larger than 5 centimeters (cm), with one study reporting a median tumor diameter of 7.0 cm. From a genetic perspective, around half of all patients with metastatic disease do not express a germline mutation and are apparently sporadic; however, of the remaining 50%, anywhere from 10% to 42% have been associated with *SDHB*-related disease. Biochemically, markedly elevated norepinephrine and/or dopamine methoxytyramine are associated with the presence of metastases, especially in patients with *SDHx*-related disease, and can be utilized to monitor disease progression. Current publications indicate that the 5-year overall survival ranges from 62% to 85%, while the median overall survival varied between 6 and 24 years. Location and type of tumor also indicate a higher likelihood of malignancy, with extra-adrenal PGLs the most worrisome for metastatic disease. Meanwhile, head and neck PGLs were associated with improved prognosis and very rarely reported cases of rapidly progressive disease.

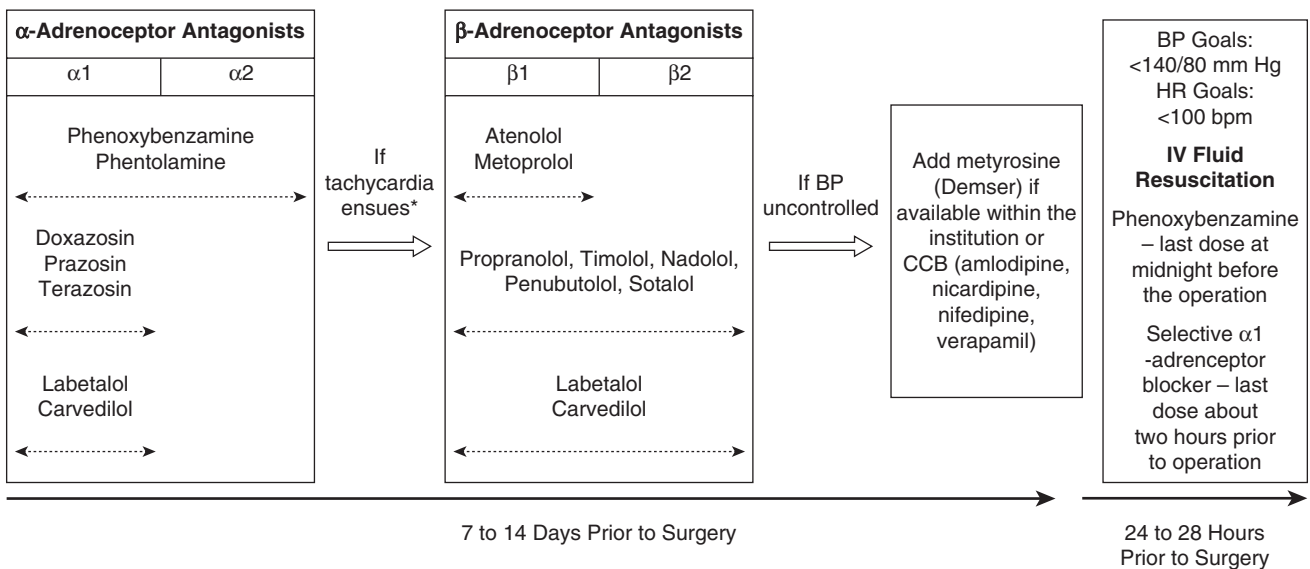

Management of metastatic PHEO (Figure 6) requires a multidisciplinary approach, consisting of targeted pharmacology, radiotherapy, chemotherapy, and surgery. Surgical debulking procedures continue to be the mainstay of palliative treatment. Delaying any procedures is positively correlated with rapidly progressive metastatic disease and should be avoided whenever possible. Chemotherapy with cyclophosphamide (Cytoxan)<sup>1</sup>, vincristine (Oncovin)<sup>1</sup>, and dacarbazine (DTIC-Dome)<sup>1</sup>, CVD, is the primary therapeutic modality in patients with rapidly progressive (within 3 to 6 months) PHEO. While only 30% of the metastatic PHEO population exhibits clinical benefit, the reported advantages in *SDHB*-related disease is as high as 80%. Temozolomide

<sup>1</sup>Not FDA approved for this indication.

We only live once: The dangers associated with neglecting a preoperative alpha adrenoceptor blockade in pheochromocytoma patients. *Endocr Pract*. 25[1]:106–108, 2019.)

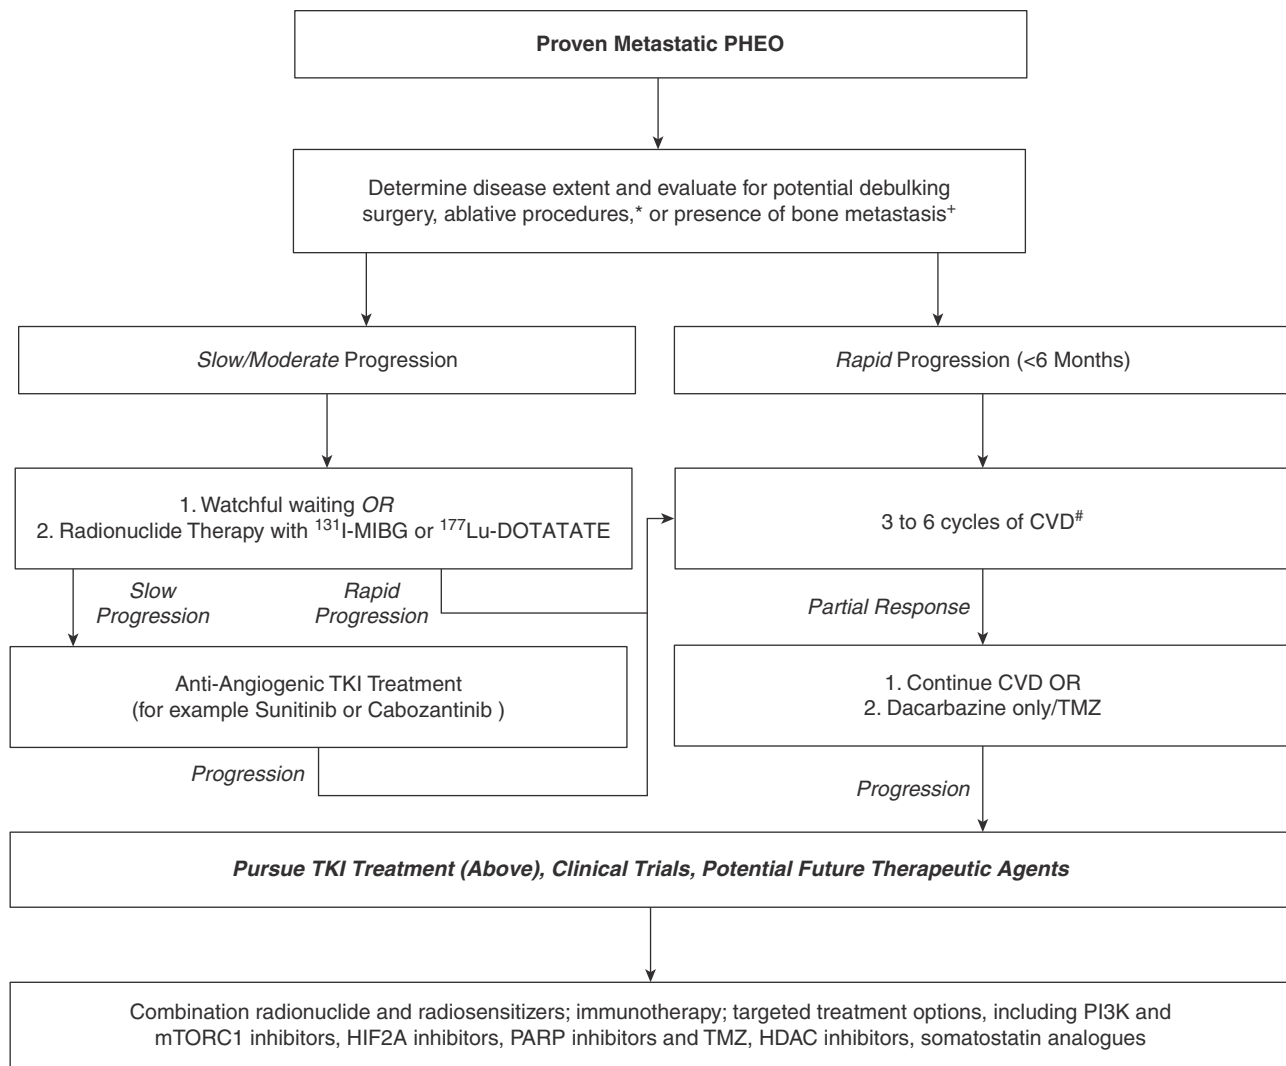

(TMZ [Temodar])<sup>1</sup> is the only other chemotherapeutic agent with significant experience in PHEO patients. Emerging targeted therapies include adjunctive olaparib (Lynparza)<sup>1</sup> in combination with TMZ, belzutifan (Welireg)<sup>1</sup> in patients with a causative HIF2A mutation, tyrosine kinase inhibitors (sunitinib [Sutent]<sup>1</sup> or cabozantinib [Cabometyx]<sup>1</sup>), and various immunotherapies (including chimeric antigen receptor expressing T cells or CAR-T-cell therapy).

For patients with slow to moderate progression, eligibility for targeted radiolabeled therapy should be considered with

<sup>131</sup>I-MIBG and peptide receptor radionuclide therapy (PRRT) if they have avid disease on <sup>123</sup>I-MIBG and <sup>68</sup>Ga-SSA, respectively. Targeted radiotherapy with high-specific activity <sup>131</sup>I-MIBG (Azedra) is the only FDA-approved treatment for metastatic or inoperable PPGL. In 68 PPGL patients receiving targeted radiotherapy with high-specific activity <sup>131</sup>I-MIBG (up to two cycles), 23% had a partial response (PR) and 69% had stable disease (SD) totaling 92% SD and PR as evaluated by the Response Evaluation Criteria in Solid Tumors (RECIST) 1.0. Furthermore, a reduction in baseline antihypertensive medication (lasting 6 months or longer) was achieved in 25% of patients, with 68% of patients showing a complete response (CR) or PR in serum

\*Arterial embolization, chemoembolization, selective radiotherapy, or radiofrequency ablation

+ Consider conventional radiotherapy, cyberknife procedures, denosumab, or bisphosphonates

#Averbuch: cyclophosphamide (750 mg/m<sup>2</sup>), vincristine (1.4 mg/m<sup>2</sup>), and dacarbazine (600 mg/m<sup>2</sup>) on Day 1, followed by dacarbazine (600 mg/m<sup>2</sup>) on Day 2 at 21-day intervals

**Figure 6** Treatment algorithm for metastatic pheochromocytoma/paraganglioma. (Adapted from Nolting S, Ullrich M, Pietzsch J, et al: Current management of pheochromocytoma/paraganglioma: A guide for the practicing clinician in the era of precision medicine. *Cancers* 11[10], 2019.)

chromogranin levels. The median overall survival (OS) achieved was 36.7 months from the first treatment. In the event Azedra is unavailable, low-specific activity <sup>131</sup>I-MIBG may be considered. PRRT with <sup>177</sup>Lutetium/<sup>90</sup>Yttrium-DOTATATE/DOTATOC has been used to treat patients with metastatic or inoperable PPGL. In a meta-analysis of 179 pooled patients treated with 1 to 11 cycles of PRRT using various dose regimens and radiopharmaceuticals, 90% of patients had achieved PR or SD. However, currently, lutetium-177 DOTATATE (Lutathera) is not approved by the FDA for metastatic PHEO in the United States; however, the recent National Comprehensive Cancer Network guidelines recommend <sup>177</sup>Lu-DOTATATE along with high-specific activity <sup>131</sup>I-MIBG for the treatment of metastatic PPGL, and a clinical trial (NCT03206060) with <sup>177</sup>Lu-DOTATATE is currently ongoing.

There are several up-and-coming novel therapeutic agents that will hopefully be approved for treatment of metastatic PHEO after further validation, including HIF-2 $\alpha$ , mTOR, and P13K inhibitors, as well as cold somatostatin analogs (octreotide<sup>1</sup> and lanreotide<sup>1</sup>) and immunotherapy.

<sup>1</sup>Not FDA approved for this indication.

## Prognosis and Monitoring

The long-term survival of patients after surgical excision of a benign, solitary PHEO is the same as age-adjusted normal subjects. A longitudinal follow-up study determined that recurrences are more likely in patients with extra-adrenal PGLs and those with germline mutations. Following treatment, 25% of patients continue to have well-controlled hypertension on oral medications. Periodic, lifelong biochemical and/or imaging surveillance is required for all patients, but especially for those with an underlying hereditary disorder. Frequency of follow-up depends on the surgical pathology, presentation at diagnosis, and biochemical profile. Patients with metastatic disease should have routine, scheduled observation with a specialist to ensure proper care.

## THYROID CANCER

Method of

Michael Holyoak, MD; and Rudruidee Karnchanasorn, MD

### CURRENT DIAGNOSIS

- Most thyroid cancer will present as incidentally discovered thyroid nodules.
- The vast majority of thyroid nodules are benign and risk of malignancy can be reliably estimated based on sonographic features.
- Thyroid function should always be assessed if a nodule is discovered. If thyroid stimulating hormone (TSH) is low, a thyroid uptake and scan should be obtained.
- The American Thyroid Association (ATA) and the American College of Radiology's (ACR's) Thyroid Imaging Reporting and Data System (TIRADS) uses ultrasound features to determine risk of malignancy and the need for fine needle aspiration (FNA).
- Approximately 90%–95% of thyroid nodules are benign and can be monitored with serial ultrasound. FNA is only indicated for nodules equal to or greater than 1 cm.
- Benign nodules can be monitored with ultrasound at intervals based on their risk of malignancy.
- The vast majority of thyroid cancer is classified as differentiated thyroid cancer (DTC). Medullary thyroid cancer (MTC) is less common and somewhat more aggressive. Anaplastic thyroid cancer (ATC) is a rare and very aggressive thyroid cancer that typically presents at a more advanced stage.

## CURRENT THERAPY

- Although thyroid cancer is relatively common, it is responsible for a very small portion of cancer-related mortality.
- Some experts have expressed concern about potentially unnecessary morbidity associated with overtreatment of very low risk DTCs, particularly micropapillary carcinoma.
- Most patients with thyroid cancer should be managed surgically. Smaller, lower-risk differentiated cancers can be treated with lobectomy. Larger or higher-risk tumors should be treated with total thyroidectomy and compartment neck dissections based on the presence of lymphadenopathy.
- Radioactive iodine (RAI) should be utilized based on the ATA risk stratification.
- Patients with DTC should be monitored longitudinally using serum thyroglobulin (Tg) levels and serial ultrasound.
- TSH suppression is indicated for many patients postoperatively, initially based on their ATA risk and later on their response to therapy.
- Patients with MTC should undergo surgery and be monitored with serial carcinoembryonic antigen (CEA) and calcitonin levels in addition to imaging studies.
- Patients with ATC typically require aggressive surgery, often including tracheostomy and management by a multidisciplinary team.

### Epidemiology

Thyroid nodules are highly prevalent. Data show that approximately 5% to 10% of patients will have palpable nodules and approximately 34% of patients will have nodules detectable by ultrasound. The prevalence of nodules increases significantly with age, and they are three to four times more common in women. Only a small portion of thyroid nodules are malignant, about 5% to 15%. In 2015, it was estimated that at least 62,000 cases of thyroid cancer were diagnosed in the United States, making it the most common form of endocrine cancer. The incidence of thyroid cancer has been increasing steadily for the past several decades. This is likely attributable to the increased utilization and sensitivity of diagnostic imaging. It is important to note that the climbing thyroid cancer incidence has not been accompanied by an increase in thyroid cancer deaths. Low-risk differentiated thyroid cancers (DTCs) such as micropapillary carcinomas are responsible for a large proportion of newly diagnosed thyroid cancers. There is significant concern that many individuals with low-risk DTCs may receive treatment associated with unnecessary risk and morbidity. Papillary thyroid carcinomas (PTCs) are particularly slow-growing cancers. In one study involving patients with low-risk DTCs who were monitored without surgery, only 10% were found to have disease progression at a median follow-up interval of 6 years.

### Risk Factors

The majority of thyroid cancer cannot be attributed to specific risk factors. Nutritional factors including iodine intake have been associated with an increased risk of thyroid nodularity. Childhood exposure to ionizing radiation is one particularly well-documented risk factor for thyroid cancer. In a large retrospective study, individuals treated with radiation for Hodgkin disease, were 27 times more likely to have thyroid nodules than those treated without radiation. An elevated thyroid stimulating hormone (TSH) level in the setting of thyroid nodularity has been associated with an increased risk of thyroid cancer. Cigarette smoking has actually been negatively correlated with risk of thyroid cancer.

### Pathophysiology

DTCs are derived from follicular cells and are responsible for more than 95% of cases of thyroid cancer (Table 1). DTC includes PTC and follicular thyroid carcinoma (FTC) as well as the follicular

variants including Hurthle cell cancer. Another related variant of thyroid tumor termed noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP) has an exceptionally low recurrence rate of less than 1% at 15 years. NIFTP is best described as a benign tumor and does not require completion thyroidectomy or radioactive iodine (RAI). PTC metastasizes via the lymphatic system, typically to cervical lymph nodes. FTC and its variants classically spread hematogenously, which contributes to a less favorable prognosis. The *BRAF* mutation is the most frequently encountered mutation in non-medullary thyroid cancer (MTC) and is present in 50% to 70% of patients with PTC. *TERT* mutations are frequently present in high-risk forms of PTC. Mutations in the *RAS* family of oncogenes are also commonly present in FTC.

Poorly differentiated thyroid carcinomas (PDTC) are high-risk cancers that classically spread hematogenously to lung and bone. These cancers are also derived from follicular cells.

MTC originates from parafollicular or calcitonin-producing C cells. Mutations of the *RET* proto-oncogene are thought to be responsible for the majority of cases. *RET* mutations are classically inherited in an autosomal dominant pattern; however, they can occur sporadically. All patients diagnosed with MTC should be screened for *RET* mutations. If such testing is positive, first-degree relatives should be screened as well. Specific *RET* mutations result in specific phenotypes with varying risks of MTC. Knowledge of the specific *RET* mutation guides the need and timing of prophylactic thyroidectomy; this is of particular importance in the pediatric setting. MTC is part of the classic presentation of patients with multiple endocrine neoplasia type 2 (MEN 2), which also includes a risk of pheochromocytoma and parathyroid adenomas.

Anaplastic thyroid cancer (ATC) is an uncommon (<1%) but aggressive form of cancer. Despite its rarity, ATC is responsible for as much as 50% of thyroid cancer-related mortality. Patients usually present with advanced disease, commonly with symptoms of hoarseness or dysphasia due to local invasion. Approximately 50% of ATCs arise from a known DTC, with the hypothesis of dedifferentiation changes from preexisting DTC to aggressive ATC.

### Clinical Manifestations

Most patients with thyroid cancer, particularly with DTCs, present asymptotically with incidentally discovered thyroid nodularity on imaging. More aggressive forms of thyroid cancer, including poorly differentiated cancers and ATC, can present with symptoms related to regional invasion, including dysphasia, hoarseness-related recurrent laryngeal nerve injury, and tracheal compression.

### Diagnosis

All patients suspected of having thyroid nodules should undergo ultrasound and measurement of serum their TSH levels. A TSH below normal should prompt a scintigraphic evaluation with thyroid uptake and scan to assess for functioning or “hot” nodules. Fine needle aspiration (FNA) is not generally indicated for hyperfunctioning nodules due to a low likelihood of malignancy. Thyroid scintigraphy is not needed when serum TSH is normal or elevated. Serum calcitonin measurement used as a screening test for MTC remains controversial due to its low specificity.

Ultrasound is a critical step in evaluating thyroid nodules. It is not only safe and cost effective but also reliably determines risk of malignancy and therefore need for FNA. Suspicious sonographic features of nodules associated with increased risk of malignancy include hypoechogenicity (darker than normal thyroid parenchyma), microcalcifications that are taller than wide on transverse view, and irregular or infiltrative nodule margins. Ultrasound of the central and lateral neck compartments is critical to screen for suspicious lymphadenopathy, which can influence the surgical approach. The American Thyroid Association (ATA) recommends FNA utilizing a risk stratification system based on size and sonographic patterns. FNA is recommended for nodules equal to

**TABLE 1** Overview of Thyroid Tumor Subtypes

SUBTYPE	ORIGIN CELL TYPE	% OF THYROID CANCER	5-YEAR SURVIVAL	COMMON MUTATIONS
PTC	Follicular	~80%	~99%	<i>BRAF, TKR</i>
FTC	Follicular	~15%	~98%	<i>RAS, PAX8-PPARG</i>
NIFTP	Follicular	0.4%–2.6%	N/A	<i>RAS</i>
PDTC	Follicular	~1%	~62%	<i>RAS, P53</i>
MTC	Parafollicular/C-cell	~3%	~90%	<i>RET</i>
ATC	Follicular	~1%	~7%	<i>BRAF, TERT, P53</i>

ATC, Anaplastic thyroid cancer; MTC, medullary thyroid cancer; NIFTP, neoplasm with papillary-like nuclear features; PDTC, poorly differentiated thyroid carcinomas.

or greater than 1 cm with intermediate (10% to 20% malignancy risk) or high suspicion patterns (>70% to 90% risk), 1.5 cm for low suspicion (5% to 10% risk) and 2 cm for very low suspicion (<3%). Purely cystic nodules are benign and do not need FNA.

The Thyroid Imaging Reporting and Data System (TIRADS) is another validated clinical tool produced by the American College of Radiology (ACR). It uses a points system based on sonographic features to stratify nodules into one of five TIRADS categories: TR1, benign; TR2, not suspicious; TR3, mildly suspicious; TR4, moderately suspicious; and TR5, highly suspicious, with malignancy risks of 0.3%, 1.5%, 4.8%, 9.1%, and 35%, respectively. TR1 and TR2 nodules do not require FNA. FNA is indicated for TR3 nodules starting at 2.5 cm, TR4 at 1.5 cm, and TR5 at 1 cm. Nodules less than 1 cm are too small for FNA based on both the ATA and ACR-TIRADS owing to the slow-growing nature of micropapillary thyroid cancer. Other considerations governing the need for FNA include specific risk factors of thyroid cancer or syndromes associated with thyroid cancer, such as MEN, Cowden syndrome, familial adenomatous polyposis, and Carney complex. In addition, fluorodeoxyglucose-avid nodules are associated with a malignancy rate of about 35%. However, the recommended FNA size of these nodules remains at least 1 cm or greater.

The 2017 Bethesda system has been the standard method of cytology diagnosis of thyroid nodules, consisting of six categories. Category I, nondiagnostic (ND) or unsatisfactory, represents a 5% to 10% malignancy risk; in such cases repeat FNA is required unless the lesion is mostly cystic or ultrasound features of very low suspicion. Category II, benign, represents approximately 70% of specimens and a less than 3% risk of malignancy. Both category III, atypia of undetermined significance/follicular lesion of undetermined significance (AUS/FLUS), and category IV, follicular neoplasm or suspicious for follicular neoplasm (FN/SFN), are associated with a slightly higher malignancy risk, 10% to 30% in AUS/FLUS and 25% to 40% in FN/SFN. The management of both categories III and IV is not straightforward, and various molecular assessments can be utilized to help with decision making. Currently available molecular tests—including the Afirma GSC, RNA seq panel, and ThyroSeq3 112-gene panel—have high sensitivity and specificity, functioning as rule-out and rule-in tests to decrease the number of unnecessary thyroid surgeries. Category V (suspicious for malignancy [SFN]) and category VI (malignant), carry high rates of malignancy (60% to 75% and 97% to 99%, respectively) and should prompt referral for operative management.

Nodules that do not meet the initial threshold for cytologic assessment require continued sonographic surveillance, the recommended interval of which ranges from 6 to 24 months based on sonographic features. FNA should be performed if there is a 50% increase in the tumor volume calculated with three-dimensional measurement or once nodules reach the threshold size. A nodule with two negative biopsies should be considered benign.

## Therapy

Papillary thyroid microcarcinoma (PTMC) is defined as a small PTC equal to or less than 10 mm in size. PTMCs generally grow very slowly and carry an excellent prognosis. Although many individuals are asymptomatic and do not require treatment,

an increased rate of detection has likely resulted in overtreatment. It has been shown that PTMCs in young patients are more likely to progress more than those in elderly patients. Active surveillance for most PTMCs has been shown to be safe, and FNA is not recommended for thyroid nodules smaller than 1 cm. Active surveillance should not be considered in the presence of high-risk features such as nodal metastasis or distant metastasis, vocal cord paralysis due to invasion of the recurrent laryngeal nerve, high-grade malignancy on cytology, or in the case of PTMCs attached to the trachea or located along the path of the recurrent laryngeal nerve. Ultrasound-guided percutaneous ethanol ablation (UPEA) by experienced specialists has been shown to be a safe and well-tolerated definitive minimally invasive alternative for PTMC patients who do not wish to have surgery and are uncomfortable with active surveillance, although UPEA is currently available at only a limited number of centers.

Treatment of thyroid cancer is mainly based on individualized risk stratification, accounting for both mortality based on TNM (tumor, node, and metastases) staging, the risk of disease recurrence, and the persistence of structural disease.

Although DTC carries a very low risk of mortality as compared with other cancers, the TNM staging system remains an accurate predictor of mortality. Recent changes to the system recommend that patients younger than 55 years of age at the time of diagnosis receive only stage I (no distant metastases) or stage II (distant metastases present) classification. Ten-year disease-specific survival rates for stages I to IV were 99.5%, 94.7%, 94.1%, and 67.6%, respectively.

In addition to TNM staging, an individualized risk stratification outlined by the ATA 2015 guidelines is an important milestone for the assessment of risk of thyroid cancer recurrence and persistence of structural disease. The ATA system utilizes variables such as histology, extent of the first surgery, and postoperative thyroglobulin (Tg) to guide initial postoperative therapy and treatment in follow-up. Patients with tumor sizes less than 4 cm without clinical lymph node metastases or micrometastases measuring less than 2 mm in five or fewer lymph nodes can be classified as ATA low risk. Intermediate-risk disease is defined as DTC with minimal extrathyroidal extension or aggressive histology. High-risk disease includes patients with gross extension, distant metastases, any lymph node metastases greater than 3 cm, as well as FTC with greater than 4 foci of vascular invasion. In contrast, minimally invasive FTC is considered low risk.

The ATA recommends either total thyroidectomy or lobectomy for low-risk patients with DTC. The decision to proceed with total thyroidectomy or lobectomy primarily depends on tumor size and patient preference. Low-risk patients are not routinely treated with RAI.

Use of RAI is based on individualized risk stratification accounting for extent of tumor, histology type, age, and presence of distant metastases. Radioiodine is typically delayed several months after surgery to allow for complete recovery and assessment of the biochemical response with Tg. Serum Tg reaches its nadir approximately 4 to 6 weeks postoperatively, and measurement at this point is perhaps the most accurate method of appraising the quality of surgery and probability of cure.

RAI remnant ablation uses a low dose of radioiodine-131 (131-I), around 30 mCi, to destroy any residual thyroid tissue postoperatively. Remnant ablation thus facilitates the interpretation of subsequent serum Tg levels and follow-up RAI whole-body scans to detect any residual or recurrence disease or metastatic foci. Remnant ablation is not routinely recommended in ATA low-risk DTC patients.

Adjuvant treatment utilizes a higher dose of 131-I (75 to 150 mCi) postoperatively to destroy microscopic thyroid cancer and/or suspected residual disease to potentially decrease recurrence and mortality. RAI adjuvant treatment should be considered in ATA intermediate-risk DTC patients.

Primary treatment with RAI uses 100 to 200 mCi of 131-I to destroy known locoregional and/or distant metastasis with a goal of cure, reduced recurrence and mortality, and/or palliation among high-risk DTC patients.

Serum TSH should be elevated prior to proceeding with RAI, as TSH potentiates RAI uptake by iodine-avid tissues including normal thyroid tissue and most thyroid cancers. This has historically been accomplished by withdrawing thyroid hormone replacement for approximately 2 weeks until TSH increases to 30 or more. During this time patients should be instructed to consume a low-iodine diet. The use of recombinant human TSH (Thyrogen) is also a safe and effective alternative to thyroid hormone withdrawal in the detection of recurrent/residual thyroid cancer and facilitation of RAI ablation.

Localized treatments with external beam radiation are sometimes needed for gross residual disease or bone metastases. Surgery may be necessary when bone metastases threaten a limb's function.

Systemic treatments for advanced DTC and MTC include tyrosine kinase inhibitors (TKIs). These agents are reserved for patients with progressive or unresectable disease or tumor that is threatening vital structures. TKI-associated adverse effects are common and include hypertension, hand-foot skin reactions, diarrhea, rash, fatigue, and weight loss. The dose of TKI often needs to be titrated based on tolerability.

Most patients with MTC have advanced disease at the time of diagnosis, leading to an unfavorable prognosis. Cure is much more probable if all disease is intrathyroidal at the time of diagnosis. Early identification and complete surgical resection are ideal for the definite treatment of MTC. Calcitonin is a specific serum marker and its doubling time is the most important prognostic factor for survival and disease progression. Serum carcinoembryonic antigen (CEA) is usually elevated in advanced cases and is often used as a tumor marker in conjunction with calcitonin. The risk of recurrence is low when postoperative calcitonin is undetectable. Patients with low but detectable calcitonin level less than 150 pg/mL likely have persistent or recurrent disease confined to neck lymph nodes and can be followed every 6 to 12 months with physical examination, neck ultrasound, and serial measurement of calcitonin and CEA. If postoperative calcitonin is greater than 150 pg or has a rapid doubling time, additional imaging studies are required to evaluate for distant metastases. If there is concern for disease progression, systemic therapy with vandetanib (Caprelsa) or cabozantinib (Cometriq) should be considered. Before starting this, the possibility of using a local treatment should be evaluated to delay systemic therapy, along with a multidisciplinary team approach.

Patients with ATC usually present with a rapidly enlarging neck mass that can cause compressive neck symptoms and invasion of the adjacent recurrent laryngeal nerve, leading to dysphonia, or compression of the trachea, causing airway obstruction. Ultrasound remains the primary imaging study for ATC, but additional studies including computed tomography (CT) with contrast of neck, abdomen, and pelvis; positron emission tomography CT (PET-CT) if available, and brain magnetic resonance imaging (MRI) can be used. Due to the risk of acute airway compromise, an expeditious diagnosis and management plan by a multidisciplinary team is crucial. Ideally a care team would include a pathologist, head and neck surgeon, medical oncologist, radiation oncologist, and endocrinologist. A palliative care physician should also be involved, given ATC's extremely poor prognosis.

Patients with ATC and their families should take part in an in-depth discussion about the natural history of the disease, goals of treatment, treatment toxicities, and expected outcomes. Most untreated patients will die of asphyxiation; therefore treatment addressing the primary neck disease, even with a goal of only palliation, is a priority. Hospice care could be the best option for patients who do not wish to pursue aggressive therapy. Tracheostomy to prevent airway obstruction as a part of palliative care is controversial but may be appropriate for patients with impending airway compromise. In contrast, patients with limited disease should initially be treated with surgery followed by chemoradiotherapy (intensity-modulated radiotherapy [IMRT] plus taxane-based chemotherapy) as a standard of care when feasible, unless hospice is alternatively elected. Patients with widely metastatic or stage IVC disease should instead be treated with palliative systemic therapy or best supportive care.

Recent studies have indicated improvements in overall survival in early multimodality therapy, especially with recent advancements in systemic therapy including targeted and immunotherapies such as the *BRAF* inhibitor dabrafenib (Tafinlar) and the *MEK* inhibitor trametinib (Mekinist), anti-PD1 monoclonal antibody spartalizumab,<sup>5</sup> and newer agents such as the peroxisome proliferator-activated receptor (PPAR)- $\gamma$  agonist efatutazone,<sup>5</sup> and mammalian target of rapamycin (mTOR) inhibitors, which seem to provide a more efficacious treatment in advanced ATC.

### Monitoring

Regardless of the initial risk assessment, patients with DTC should be monitored longitudinally and classified as having either an excellent, indeterminate, or incomplete response, both biochemically and structurally, to therapy. An excellent response (1% to 4% recurrence rate) is defined as no clinical, biochemical, or structural evidence of disease. Serum Tg should be less than 0.2 ng/mL with a suppressed TSH, or less than 1 ng/mL if TSH is stimulated. Patients with an indeterminate response (15% to 20% recurrence rate) will have nonspecific biochemical or structural findings. A biochemical incomplete response (20% recurrence rate) reflects abnormally elevated Tg or Tg antibody levels (Serum Tg >1 ng/mL basal or >10 ng/mL if TSH is stimulated or increasing Tg antibodies) in the absence of disease. A structural incomplete response (50% to 85% recurrence rate) includes persistent or newly identified locoregional or distant metastasis with or without abnormal Tg or Tg antibodies.

TSH suppression therapy (TST) requires supraphysiologic doses of exogenous thyroid hormone, with the goal of lowering serum TSH. TSH has trophic effects on thyroid tissue, and a subnormal serum TSH may minimize tumor growth and reduce the risk of progression of advanced thyroid cancer. Aggressive TST is not recommended for low-risk patients but may improve survival outcome for those at high risk. Serum TSH levels that were consistently maintained in the subnormal to normal ranges have led to better outcomes in patients at all stages of disease compared with subjects whose serum TSH levels were in the normal to elevated ranges.

### Management of Complications

Immediate surgical complications following thyroidectomy are adversely correlated with low-volume surgeons. High-volume surgeons are also associated with an increased risk of postoperative complications; however, this is likely attributable to overall greater case complexity. Potential complications include injury of the recurrent laryngeal nerve leading to temporary or permanent hoarseness, airway difficulty due to bilateral vocal cord paralysis, and need for tracheostomy. Total thyroidectomy can lead to transient or permanent hypoparathyroidism with resultant hypocalcemia. Adequate preoperative vitamin D replacement can help to maintain normocalcemia. Postoperatively the parathyroid hormone (PTH) level should be checked; calcitriol (Rocaltrol) may be needed in addition

<sup>5</sup>Investigational drug in the United States.

to calcium supplementation if the PTH level is low or undetectable. Serum calcium levels should be obtained following discharge.

Long-term TST can result in adverse outcomes such as osteoporosis, fracture, and cardiovascular disease, including atrial fibrillation. In general, daily levothyroxine (Levoxyl, Synthroid) doses of 1.6 to 1.8 µg/kg are the initial treatment following thyroidectomy, whereas doses of 2.0 to 2.2 µg/kg are needed to suppress the serum TSH. The dosage requirements of individual patients are highly variable and depend on multiple factors, including body mass index, the concomitant use of other medications, and patient adherence. The ATA recommends maintaining serum TSH levels between 0.5 and 2 mU/L in low-risk and intermediate-risk patients with an excellent response to treatment. Mild TSH suppression (TSH 0.1 to 0.5 mU/L) should be used for high-risk patients who have had an excellent response (negative imaging and undetectable suppressed Tg). Mild TSH suppression is also recommended in patients with a biochemically incomplete response. More significant TSH suppression (i.e., serum TSH <0.1) is recommended in patients with residual structural disease or a biochemically incomplete response if they are young or at low risk for complications from iatrogenic hyperthyroidism.

Adverse effects of RAI—including radiation thyroiditis, sialadenitis, and tumor hemorrhage or edema—occur in 10% to 30% of patients. The possibility of adverse effects is dose dependent. Long-term risk of secondary malignancies has been reported; however, the risk is considerably lower when the total dose is less than 100 mCi. Immediately after patients have been treated with RAI, an appropriate isolation protocol is required to protect household members from radiation exposure, especially women who are pregnant as well as infants. The required duration of isolation is predominantly based on RAI dose and rate of clearance.

## Conclusion

Thyroid nodules are very common and are often discovered incidentally. The vast majority of nodules, approximately 90% to 95%, are benign. Thyroid sonography should be obtained for all nodules, as this reliably predicts the risk of malignancy and need for FNA. DTCs are indolent; FNA is not indicated for nodules less than 1 cm in size. Thyroid function should be assessed prior to proceeding with FNA. Patients with a TSH below normal should undergo thyroid uptake and scan to investigate for an autonomously functioning nodule or nodules. Most nodules can be monitored with ultrasound alone. Guidelines produced by either the ATA or ACR can reliably determine the need for FNA. PTC is the most common type of DTC and typically has a very favorable prognosis. Lower-risk patients with DTC can be managed with lobectomy. Patients with larger tumors (>4 cm), extrathyroidal extension, or higher-risk cytology should be treated with total thyroidectomy and central neck dissection. Lateral compartment neck dissections should be completed if there is FNA-positive disease.

Low-risk patients with DTC do not need treatment with RAI, whereas intermediate- and high- risk cases should receive RAI. All patients should be monitored longitudinally after initial therapy, both radiographically and biochemically, utilizing serum Tg. The ATA categorizes patient response as excellent, indeterminate, or incomplete. Patients should receive appropriate levels of TSH suppression, initially based on their ATA risk and subsequently on their response to therapy. TSH suppression poses multiple risks if continued long-term.

MTC should be considered of higher risk than DTC and is managed surgically. MTC is often detected later and is usually more advanced than DTC. Calcitonin and CEA levels can be monitored longitudinally. Calcitonin doubling time is a particularly important prognostic factor for following these patients.

ATC is a rare but extraordinarily aggressive and rapidly growing form of thyroid cancer. Patients should be managed by a multidisciplinary team with consideration for tracheostomy due to risk of asphyxiation in the setting of rapid tumor growth. Aggressive resection as well as prompt chemotherapy are appropriate treatment options in appropriately selected patients with less advanced disease.

## THYROIDITIS

Method of

Leigh M. Eck, MD

### CURRENT DIAGNOSIS

- Thyroiditis is a term used to describe a diverse group of disorders associated with thyroid inflammation.
- Thyroiditis can be associated with a euthyroid state, thyrotoxicosis, or hypothyroidism.
- The clinical presentation of thyroiditis will direct the evaluation with useful testing to include measurement of thyroid hormone levels, thyroid antibody testing, white blood cell count, erythrocyte sedimentation rate, thyroid scintigraphy, and thyroid ultrasound.

### CURRENT THERAPY

- Abnormalities of thyroid hormone levels resulting from thyroiditis may be transient and require no or only short-term therapy.
- If symptomatic thyrotoxicosis is present, beta-blocker therapy should be initiated.
- Thyroiditis associated with persistent hypothyroidism is managed with synthetic thyroxine (T4, Levoxyl, Synthroid).
- Thyroid pain associated with subacute thyroiditis is managed with a nonsteroidal antiinflammatory drug or, if ineffective, glucocorticoid therapy.
- Acute suppurative thyroiditis requires immediate parenteral antibiotic therapy as well as surgical drainage, if indicated.

*Thyroiditis* is a term used to describe a diverse group of disorders characterized by inflammation of the thyroid gland (Table 1). Presentation of thyroiditis is variable depending on the etiology. The most common thyroid disorder in the United States, Hashimoto's thyroiditis, most often presents with hypothyroidism. Other forms of thyroiditis may present with thyrotoxicosis because of inflammation in the thyroid gland resulting in the release of stored hormone. Painful thyroiditis is seen with subacute, suppurative and radiation-induced thyroiditis, while other variants are most often painless.

### Epidemiology

The most common cause of hypothyroidism in iodine-sufficient areas of the world is *Hashimoto's thyroiditis*, also known as *chronic autoimmune thyroiditis*. Elevated serum antithyroid peroxidase antibody concentrations are found in ~ 5% of adults and ~ 15% of older women; overt hypothyroidism is seen in up to 2% of the population. A variant of chronic autoimmune thyroiditis, *postpartum thyroiditis*, is a destructive thyroiditis induced by an autoimmune mechanism that occurs within 1 year of parturition. Postpartum thyroiditis occurs in up to 10% of women in the United States. *Silent thyroiditis* is indistinguishable from postpartum thyroiditis, with the exception of lack of temporal relationship to pregnancy. Silent thyroiditis may account for about 1% of all cases of thyrotoxicosis. Many medications are associated with an alteration in thyroid function testing; however, only a few are known to provoke an autoimmune or destructive inflammatory thyroiditis, including amiodarone (Cordarone), lithium, interferon alfa, interleukin-2, tyrosine kinase inhibitors, and checkpoint inhibitor immunotherapy. *Riedel's thyroiditis* is a progressive fibrosis of the thyroid gland with a prevalence of only 0.05% among patients with thyroid disease requiring surgery. *Subacute thyroiditis* is the most common cause of thyroid pain. It occurs in up to 5% of patients with clinical thyroid disease. *Suppurative thyroiditis*, most commonly caused by bacterial infection, is rare because of the thyroid gland's encapsulation, high iodine content, rich blood supply, and extensive lymphatic drainage. *Radiation-induced thyroiditis* occurs in approximately 1% of patients who receive radioactive iodine therapy for hyperthyroidism.

### Risk Factors

Hashimoto's thyroiditis is more common in women, particularly older women. Hashimoto's thyroiditis is associated with several gene polymorphisms, suggesting a role for genetic susceptibility. Subacute thyroiditis frequently follows an upper respiratory tract infection, with its incidence highest in summer. Suppurative thyroiditis is most likely to occur in patients with preexisting thyroid disease, those with congenital anomalies such as pyriform sinus fistula, and those who are immunosuppressed.

### Pathophysiology

Hashimoto's thyroiditis, postpartum thyroiditis, and silent thyroiditis all have an autoimmune basis. The antithyroid immune response begins with activation of thyroid antigen-specific helper T cells. Once helper T cells are activated, they induce B cells to secrete thyroid antibodies; thyroid antibodies most frequently measured are those

directed against thyroid peroxidase and against thyroglobulin. The mechanism for autoimmune destruction of the thyroid likely involves both cellular immunity and humoral immunity. Riedel's thyroiditis is the local involvement of the thyroid in a systemic disease, multifocal fibrosclerosis; the etiology of Riedel's thyroiditis is not known. Although a viral cause of subacute thyroiditis has been proposed, clear evidence for this proposed etiology is lacking. Suppurative thyroiditis is most often associated with a bacterial pathogen; however, fungal, mycobacterial, or parasitic infections may also be the cause. Although rare, radiation-induced thyroiditis may occur following the treatment of hyperthyroidism with radioactive iodine because of radiation-induced injury and necrosis of thyroid follicular cells and associated inflammation.

### Clinical Manifestations

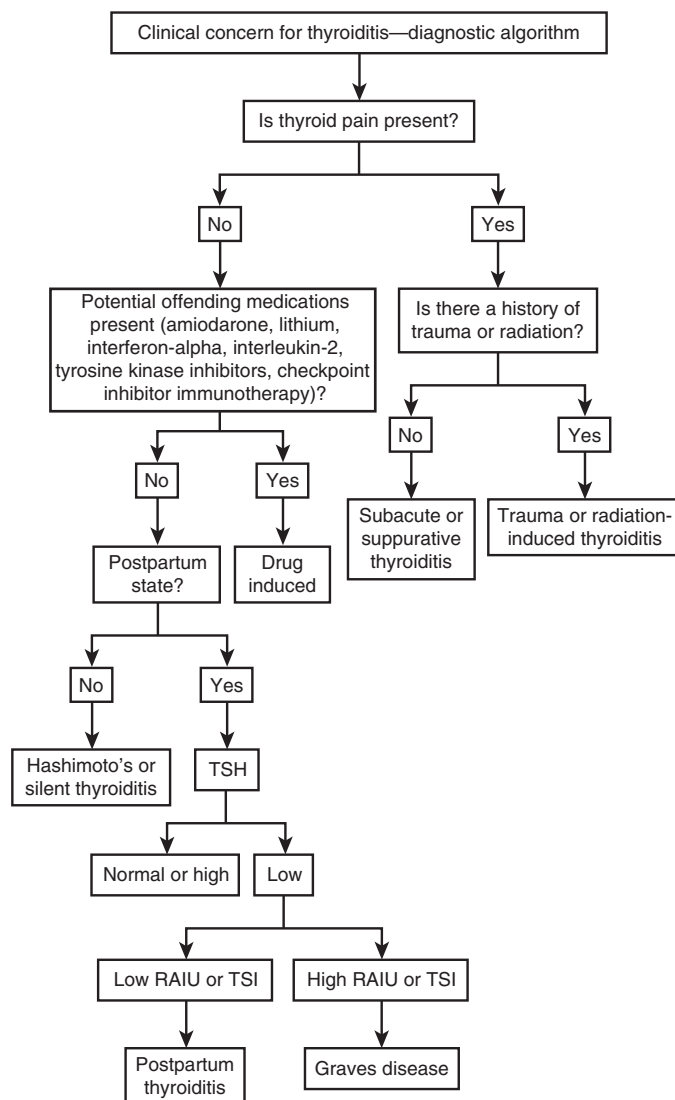

A symmetrical, painless goiter is frequently the initial finding in Hashimoto's thyroiditis. The usual course of Hashimoto's thyroiditis is gradual loss of thyroid function. Among patients with this disorder who have subclinical hypothyroidism, overt hypothyroidism occurs at a rate of about 5% per year. The classic presentation of postpartum thyroiditis occurs in only approximately 30% of afflicted women, with the characteristic sequence of hyperthyroidism, followed by hypothyroidism, and then recovery. Persistent hypothyroidism is seen in up to 30% of women following an episode of postpartum thyroiditis. Silent thyroiditis is marked by a similar characteristic sequence of thyroid hormone dysfunction. However, it is not temporally associated with pregnancy; 20% will have residual hypothyroidism. *Medication-induced thyroiditis* is variable in its presentation. Amiodarone (Cordarone), rich in iodine, is associated with hypothyroidism and hyperthyroidism; type 2 amiodarone-induced thyrotoxicosis is due to a destructive thyroiditis process. Lithium is more commonly associated with hypothyroidism. Interferon-alfa and interleukin-2 can cause both permanent and transient hypothyroidism likely related to the ability of these substances to induce or exacerbate thyroid autoimmune disease. Riedel's thyroiditis presents with neck discomfort or tightness, dysphagia, hoarseness, and a diffuse goiter that is hard, fixed, and often not clearly separable from the adjacent tissues. Generally, patients are euthyroid, and their antithyroid antibody concentrations are often high. Subacute thyroiditis manifests with a prodrome of myalgias, pharyngitis, low-grade fever, and fatigue with subsequent fever and neck pain, and up to 50% of patients have symptoms of thyrotoxicosis. Patients with suppurative thyroiditis are usually acutely ill with fever, dysphagia, dysphonia, anterior neck pain with erythema, and a tender thyroid mass. Radiation-induced thyroiditis presents 5 to 10 days following radioactive iodine treatment with neck pain and tenderness. In addition, there can be a transient exacerbation of hyperthyroidism.

### Diagnosis and Differential Diagnosis

Figure 1

**TABLE 1** Causes of Thyroiditis

Autoimmune thyroiditis: Hashimoto's thyroiditis, postpartum thyroiditis, silent thyroiditis
Subacute thyroiditis, also known as de Quervain's thyroiditis or subacute granulomatous thyroiditis
Suppurative thyroiditis, also known as infectious thyroiditis or pyrogenic thyroiditis
Riedel's thyroiditis, also known as fibrous thyroiditis
Therapy induced thyroiditis: amiodarone (Cordarone), interferon-alpha, interleukin-2, lithium, tyrosine kinase inhibitors, radioactive iodine, checkpoint inhibitor immunotherapy

**Figure 1** Clinical concern for thyroiditis—diagnostic algorithm. *Abbreviations:* RAIU = radioactive iodine uptake; TSI = thyroid-stimulating immunoglobulins.

## Treatment

Once overt hypothyroidism is present in the patient with Hashimoto's thyroiditis, treatment with synthetic L-thyroxine (Levoxyl, Synthroid) therapy is indicated. The average replacement dose of thyroxine in adults is approximately 1.6 mcg/kg body weight per day. Adjustment of dosage is undertaken every 6 weeks until a euthyroid status is achieved. The majority of women with postpartum thyroiditis will not need treatment during either the hyperthyroid or hypothyroid phase. If symptomatic hyperthyroidism is present, beta-blocker therapy can be used; antithyroid medications have no utility in the management of postpartum thyroiditis. Women with symptomatic hypothyroidism should be treated with synthetic thyroxine therapy; in asymptomatic women, initiation of thyroxine therapy should be considered if TSH is  $>10$  mU/L. Management of silent thyroiditis is the same as that for postpartum thyroiditis. Symptoms associated with Riedel's thyroiditis may be relieved with prednisone; a small case series associated improvement and even

resolution of the process with tamoxifen (Nolvadex)<sup>1</sup> therapy. Surgery is indicated in Riedel's thyroiditis if compressive symptoms are present. The goal of therapy in subacute thyroiditis is to provide symptom relief. Nonsteroidal antiinflammatory medications are often adequate to control pain; if insufficient, glucocorticoid therapy should be initiated. Beta-blockade therapy can ameliorate symptoms of thyrotoxicosis if indicated. Suppurative thyroiditis is managed with appropriate antibiotics and drainage of any abscess; the disease may prove fatal if diagnosis and treatment are delayed. Pain associated with radiation-induced thyroiditis can be managed with nonsteroidal antiinflammatory therapy or, if ineffective, a short course of glucocorticoid therapy. Radiation-induced thyroiditis is a self-limited process and will resolve spontaneously within days to weeks.

## Monitoring

In the patient with Hashimoto's thyroiditis with a euthyroid state, routine TSH testing should be undertaken given the risk of development of overt hypothyroidism at 5% per year. Any woman who has had postpartum thyroiditis should be monitored very closely for thyroid dysfunction with future pregnancies, as reoccurrence is likely. For women who have fully recovered from postpartum thyroiditis, yearly TSH measurements should be considered because of underlying chronic autoimmune thyroiditis and risk for overt

<sup>1</sup>Not FDA approved for this indication.

hypothyroidism. Although overall recurrence rates for silent thyroiditis have not been well established, a similar monitoring plan is warranted for this variant of chronic autoimmune thyroiditis. Subacute thyroiditis recurs in only about 2% of patients. Routine monitoring following resolution of process has not been defined.

## ACUTE LEUKEMIA IN ADULTS

Method of

Anthony Hunter, MD; and William Blum, MD

### CURRENT DIAGNOSIS

- Diagnosis of acute leukemia is made based on the presence of myeloid (acute myeloid leukemia [AML]) or lymphoid (T- or B-cell acute lymphoblastic leukemia [ALL]) blasts in blood and/or bone marrow. Acute leukemia may uncommonly have an ambiguous lineage or mixed phenotype.
- Medical history taking should identify risk factors such as prior exposure to chemotherapy for other malignancies (or nonmalignant disorders), antecedent hematologic disorders, familial hematologic disorders, or other inherited genetic disorders (e.g., Down syndrome, others).
- Clinical examination should identify extramedullary sites of involvement such as meninges/central nervous system (CNS), active infection, hemorrhage, or disseminated intravascular coagulation (DIC).
- AML requires the presence of at least 20% blasts in blood or marrow except in selected subsets of disease with specific cytogenetic aberrations associated with more favorable clinical outcomes, which do not require at least 20% blasts. These favorable subsets are  $t(8;21)(q22;q22)$ ,  $inv(16)(p13q22)$  or  $t(16;16)(p13;q22)$ , and  $t(15;17)(q22;q12)$ . Testing for additional cytogenetic and molecular aberrations is critical for diagnosis, prognosis, and therapy.
- Acute promyelocytic leukemia (APL) with *PML-RARA* gene fusion, detected by genetic methods or cytogenetics showing  $t(15;17)$ , is a unique entity requiring different therapy; APL has a favorable prognosis.
- ALL is subcategorized based on B- or T-lymphocyte lineage and requires at least 20% blasts in blood or marrow. Less than 20% blasts constitutes lymphoblastic lymphoma, which is treated similarly.
- For B-ALL (also in mixed-phenotype acute leukemia), identification of the Philadelphia chromosome  $t(9;22)(q34.1;q11.2)$  or its *BCR-ABL1* gene fusion is essential for proper diagnosis and treatment. As with AML, testing for an established group of other specific chromosomal and molecular aberrations is standard.

### CURRENT THERAPY

- AML is typically treated with intensive initial therapy (induction) followed by repetitive cycles of intensive postremission therapy (consolidation). Induction chemotherapy most commonly consists of anthracycline plus cytarabine (Cytosar).

Several acceptable postremission approaches are used; often, these are repetitive high-dose cytarabine-based regimens.

- APL is uniquely treated with all-*trans*-retinoic acid (tretinoin [Vesanoïd]) and arsenic trioxide (Trisenox), instead of chemotherapy, although cases with high presenting white blood cell (WBC) counts may also require chemotherapy or the antibody-drug conjugate gemtuzumab ozogamicin (Mylotarg)<sup>1</sup> for cytoreduction.
- ALL is treated with multidrug regimens for induction and postremission therapies. Postremission therapies include further intensification cycles and prolonged lower-dose maintenance therapy. CNS-directed therapy is a critical component of treatment, even in patients without clear involvement. Most acute leukemias of ambiguous lineage are treated with ALL-type regimens, although clinical outcomes are poor.
- The use of pediatric ALL regimens for adolescents and young adults has improved outcomes.
- Older patients or those with medical infirmities may require less intensive treatment regimens; because of more resistant disease and also higher toxicities, such patients fare worse than younger patients. Novel treatment approaches, such as the combination of a hypomethylating agent and venetoclax (Venclexta) in AML, have led to improved outcomes.
- Because of high relapse risks, allogeneic hematopoietic stem cell transplantation (alloHCT) in first remission is an important consideration for all eligible patients with AML except those with favorable-risk disease. High-risk older adult patients with ALL are also offered early transplantation. All patients who relapse should be considered for transplantation if remission is again achieved.
- Several subsets of acute leukemia can be treated by effective therapies that target specific aberrant signaling or enzymatic activities or that are directed to unique biologic targets of disease. Most important among these are the tyrosine kinase inhibitors (TKIs), which are used in treating acute leukemia (typically ALL) with *BCR-ABL1*.
- Advances in immunology have rapidly and dramatically improved the options for treatment, especially for those with relapsed B-ALL. Novel antibody constructs and genetically engineered autologous cellular products directed to eliminate B-lymphocytes can induce durable remissions in B-ALL.

<sup>1</sup>Not FDA approved for this indication.

### Epidemiology

According to data from the National Institutes of Health, the incidence of AML in the United States is 4.1 per 100,000 per year, with an estimate of 20,050 new cases for 2022. According to the American Cancer Society, AML accounts for about 1.0% of all new cancer cases and 33% of all new leukemia cases (but nearly one-half of leukemia deaths). AML is far more common than ALL in adults. Although AML affects all age groups, the incidence increases with advancing age, presenting at a median age of 68 years of age. ALL is estimated to occur in 6660 cases in the United States for 2022 and has a bimodal distribution across ages, with a peak in early childhood and a smaller second peak around 70 years of age.

## Risk Factors

Most cases of acute leukemia in adults have no established cause. Genetic predisposition, drugs, and radiation have been associated with the development of acute leukemia, particularly AML. Several rare genetic syndromes—including Down syndrome, Fanconi anemia, Bloom syndrome, neurofibromatosis type I, short telomere syndromes, Shwachman-Diamond syndrome, and ataxia telangiectasia—are associated with an increased risk for developing acute leukemia. AML with germline predisposition represents an uncommon but important subset of disease. Germline mutations associated with increased risk of developing a myeloid neoplasm include *CEBPA*, *DDX41*, *RUNX1*, *ANKRD26*, *ETV6*, and *GATA2*. Down syndrome–associated AML and ALL pose an increased risk of toxicity with standard chemotherapy and require dose adjustment (and expert management).

Anticancer drugs are the leading cause of therapy-associated AML. Alkylating agent–associated leukemias typically occur 4 to 6 years after exposure; affected individuals often have multilineage dysplasia and monosomy/aberrations in chromosomes 5 and 7. Topoisomerase II inhibitor–associated leukemias typically occur with shorter latency, 1 to 3 years after exposure; affected individuals often have AML with monocytic features and aberrations involving chromosome 11q23.

## Pathophysiology

Acute leukemias are hematologic malignancies arising from hematopoietic progenitor (stem) cells in the bone marrow. Clonal immature cells accumulate in the blood, bone marrow, and occasionally in the extramedullary tissues. These malignant cells divide and proliferate, but they do not differentiate into functional cells (i.e., neutrophils, lymphocytes, or others). Patients with acute leukemia are immunocompromised and have impaired oxygen-carrying capacity (anemia) and bleeding diathesis (because of thrombocytopenia or disrupted coagulation).

Patients experience complications directly from the accumulation of abnormal immature blasts or indirectly from the reduction in functional hematopoietic cells in the marrow and blood. Leukemic involvement of the bone marrow often results in pancytopenia; patients may present with cytopenias in all hematopoietic cell lineages. Patients with acute leukemias typically have evidence of circulating leukemic blasts in the peripheral blood (sometimes with high WBC counts consisting entirely of blasts), or they may have pancytopenia with no circulating blasts at all. Patients typically require transfusions of red blood cells and platelets and are at risk of life-threatening infectious complications caused by neutropenia. Most patients with acute leukemia die from infection or, less frequently, hemorrhage.

Patients with morphologically similar acute leukemias may experience vastly different clinical outcomes. Increasingly, this is explained by karyotyping or genetic sequencing studies that demonstrate marked heterogeneity in the cytogenetic and mutational profiles among patients with acute leukemia. It is clear that morphology and cytochemical staining alone to establish diagnosis does little to explain the pathophysiology and clinical behavior of these varied hematologic cancers. Genetic sequencing studies demonstrate common dysregulation of several critical cellular pathways but also a myriad of genetic alterations that occur only in small (or very small/unique) subsets. In adults, most cases of AML ultimately arise against the backdrop of a limited number of mutations that accumulate with advancing age. As noted earlier, cases with a clear cause, such as germline predisposition or drug exposure, are rare. The Cancer Genome Atlas ([cancergenome.nih.gov](http://cancergenome.nih.gov)) and other databases have shown that 5% to 10% of healthy individuals older than 70 years of age have blood cells with potentially “pre-malignant” mutations that are associated with clonal expansion, referred to as *clonal hematopoiesis of indeterminate potential* (CHIP). There appear to be a variety of “final insults” that transform these expanded clones to AML, but how these genetic aberrations contribute to leukemic transformation remains incompletely understood. Although the

number of mutations per cell in AML is relatively small (median of 13 mutations) compared with other cancers (e.g., melanoma and non–small cell lung cancer may have several hundred mutations per cell), great heterogeneity exists in the mutations identified between individual patients with AML. The same can be said of ALL. Indeed, dramatic differences in mutations/genetic signatures have been observed among patients with childhood, adolescent, young adult, and older adult ALL, respectively, and contribute to dramatic differences in prognosis among these groups.

Great heterogeneity exists not just among patients with different types of acute leukemia but within each individual patient. Each patient may have several leukemic clones and subclones with slightly different mutational profiles. The presence of genetically different clones and subclones helps explain why a patient may achieve remission but then experience relapse with more resistant disease because sensitive clones are eliminated by chemotherapy, whereas surviving clones are more resistant to subsequent treatment. Furthermore, clones that persist after treatment may emerge with additional novel mutations.

## Clinical Manifestations

Patients with any type of acute leukemia present with similar symptoms. Most have vague symptoms that are consequences of pancytopenia. Typically, the onset of illness is no more than 3 months before diagnosis unless the leukemia is associated with an antecedent hematologic disorder. Fatigue is common, as are anorexia and weight loss. Fever or infection is also common but not universal at presentation. Patients may have evidence of abnormal hemostasis (bleeding, easy bruising). Bone pain, lymphadenopathy, nonspecific cough, headache, and diaphoresis (excessive sweating) may also occur. Bone pain, typically vaguely localized to the pelvis or back, is frequent. Patients with ALL (as compared with AML) are more likely to have lymphadenopathy, splenomegaly, or extramedullary involvement at other sites, such as the testicles or CNS. However, involvement at any of these sites is not exclusive to ALL and can also be observed in AML patients, particularly in cases with monocytic differentiation. Rarely, patients present with primary symptoms caused by extramedullary leukemia. Extramedullary disease in AML is known as a *myeloid sarcoma* (also called a *granulocytic sarcoma* or *chloroma*). This is a tumor mass consisting of myeloid blasts and is most commonly seen in the skin, lymph nodes, gastrointestinal tract, soft tissue, or testis. Patients who present with isolated myeloid sarcoma typically develop blood or marrow involvement quickly thereafter; such patients thus require systemic treatment akin to that used in patients with systemic disease (not solely surgical resection or local radiation). CNS involvement at initial presentation (headache, cranial nerve palsies) is uncommon. Patients with ALL, however, have an increased risk of CNS disease and should thus be given intrathecal chemotherapy as prophylaxis even without such symptoms (or detectable CNS involvement).

Severe hemorrhagic complications are relatively infrequent at presentation but are most commonly encountered in acute promyelocytic leukemia (APL). Recognition of this risk at the time of initial presentation is critical, as replacement of fibrinogen or plasma may be lifesaving. Patients with APL often present with DIC-associated hemorrhage and may have intracranial hemorrhage or bleeding at other sites. Appropriate therapy for APL such as all-*trans*-retinoic-acid (tretinoin [Vesanoid]) should be initiated upon suspicion and not withheld pending genetic confirmation of the classic *t*(15;17) rearrangement. Thrombosis is a less frequent but well-recognized feature of APL. Bleeding associated with coagulopathy may also occur in monocytic AML and with extreme degrees of leukocytosis or thrombocytopenia in other acute leukemias. Retinal hemorrhage caused by thrombocytopenia, and extreme leukocytosis is detected in approximately 15% of patients.

Laboratory parameters are quite variable with any type of acute leukemia. The presenting WBC count may be elevated, normal, or

low for patients with acute leukemia. A minority of patients present with leukocytosis and high levels of circulating blasts, with hyperleukocytosis defined as WBC count  $>100,000/\mu\text{L}$ . Patients with AML and hyperleukocytosis are at increased risk of developing leukostasis, which manifests with CNS and pulmonary symptoms and requires prompt recognition and management. Alternatively, many patients present with low WBC count or even with no circulating blasts. Typically though, review of the peripheral blood smear identifies the classic blast—fine, lacy chromatin with one or more nucleoli and a high nucleus-to-cytoplasm ratio, which is characteristic of immature cells. The presence in blasts of abnormal rod-shaped granules called *Auer rods* on light microscopy indicates a diagnosis of AML.

Anemia is observed at diagnosis in nearly all patients but may not be severe. Decreased erythropoiesis often results in a reduced reticulocyte (immature red blood cell) count; red blood cell survival may be shortened by accelerated destruction. Most patients also present with at least mild thrombocytopenia (below the normal lower limit value of  $150,000/\mu\text{L}$ ); severe thrombocytopenia ( $<10,000/\mu\text{L}$ ) can be life threatening and requires immediate platelet transfusion.

### Diagnosis

When acute leukemia is clinically suspected, in addition to morphologic and flow-cytometric analyses, cytogenetic and genetic tests are mandatory to aid rapid diagnosis, assess prognosis, and inform the best approach to treatment. That said, clinical features also remain important. These include a history of antecedent hematologic disorder or prior chemotherapy, advanced age, and a strong family history of acute leukemia or related hematologic disorder (all favoring AML); all of these have an adverse prognosis. In ALL, a high WBC count at presentation ( $>100,000/\mu\text{L}$  for B-ALL and  $>30,000/\mu\text{L}$  for T-ALL) and T-cell phenotype have an adverse prognosis.

Initial assessments should evaluate cardiovascular, pulmonary, hepatic, and renal systems; patients should also be evaluated and treated for infection, tumor lysis syndrome, leukostasis, or DIC. Preparation for transfusion of blood or platelets requires blood type and crossmatch to be determined, and human leukocyte antigen (HLA) testing is required early in the treatment course (before chemotherapy) in consideration of future alloHCT. Cytogenetic analysis typically requires bone marrow. Genetic testing (from blood or marrow) continues to evolve and is critical for successful diagnosis, prognosis, and therapy.

The diagnosis of AML is based on a finding of at least 20% myeloid blasts by histology, cytochemistry, or flow cytometry in the blood or bone marrow. However, this 20% threshold is not required for the diagnosis in cases of myeloid sarcoma or if any of the following recurrent cytogenetic abnormalities is present:  $t(15;17)$ ,  $t(8;21)$ ,  $inv(16)$ , or  $t(16;16)$ . Myeloid blasts stain positive for myeloperoxidase; by flow cytometry, myeloid blasts are typically positive for CD13 and CD33. A prognostic schema developed by the European LeukemiaNet assigns prognostic risk based on cytogenetic and genetic features of disease (Table 1). Some morphologic features are associated with specific cytogenetic or molecular findings such as  $t(15;17)$  and APL, or dysplastic eosinophils and  $inv(16)$  or  $t(16;16)$ . The expression of B-cell markers (CD19, PAX5, cytoplasmic CD79a) is not infrequent in  $t(8;21)$ .

The diagnosis of ALL likewise requires at least 20% lymphoid blasts. Cases with primarily nodal or extranodal involvement and  $<20\%$  blasts in the blood and marrow are classified as lymphoblastic lymphoma (LBL). By immunohistochemical methods, lymphoid blasts stain positive for terminal deoxynucleotidyl transferase (TdT); by flow, lymphoid blasts are typically positive for CD10, CD19, CD22, and CD20 (variable) for B-ALL and CD3, CD4, CD7, and CD8 for T-ALL.

Patients may uncommonly present with acute leukemia of ambiguous lineage; this classification includes acute undifferentiated leukemias, which express no lineage-defining antigens, and

**TABLE 1** 2017 European LeukemiaNet Risk Stratification by Genetics for Acute Myeloid Leukemia\*

RISK CATEGORY <sup>†</sup>	GENETIC ABNORMALITY
Favorable	$t(8;21)(q22;q22)$ ; <i>RUNX1-RUNX1T1</i> <i>inv(16)(p13.1q22)</i> or $t(16;16)(p13.1;q22)$ ; <i>CBFB-MYH11</i> Mutated <i>NPM1</i> without <i>FLT3-ITD</i> or with <i>FLT3-ITD</i> <sup>low‡</sup> Biallelic mutated <i>CEBPA</i>
Intermediate	Mutated <i>NPM1</i> and <i>FLT3-ITD</i> <sup>high‡</sup> Wild type <i>NPM1</i> without <i>FLT3-ITD</i> or with <i>FLT3-ITD</i> <sup>low‡</sup> (without adverse- risk genetic lesions) $t(9;11)(p21.3;q23.3)$ ; <i>MLL3-KMT2A</i> <sup>§</sup> Cytogenetic abnormalities not classified as favorable or adverse
Adverse	$t(6;9)(p23;q34.1)$ ; <i>DEK-NUP214</i> $t(v;11q23.3)$ ; <i>KMT2A</i> rearranged $t(9;22)(q34.1;q11.2)$ ; <i>BCR-ABL1</i> <i>inv(3)(q21.3q26.2)</i> or $t(3;3)(q21.3;q26.2)$ ; <i>GATA2</i> , <i>MECOM(EV11)</i> $-5$ or $del(5q)$ ; $-7$ ; $-17/abn(17p)$ Complex karyotype, <sup>¶</sup> monosomal karyotype <sup>¶¶</sup> Wild-type <i>NPM1</i> and <i>FLT3-ITD</i> <sup>high‡</sup> Mutated <i>RUNX1</i> <sup>**</sup> Mutated <i>ASXL1</i> <sup>**</sup> Mutated <i>TP53</i> <sup>††</sup>

\*This table excludes acute promyelocytic leukemia. Frequencies, response rates, and outcome measures should be reported by risk category and, if sufficient numbers are available, by specific genetic lesions indicated.

<sup>†</sup>Prognostic impact of a marker is treatment-dependent and may change with new therapies.

<sup>‡</sup>Low, low allelic ratio ( $<0.5$ ); high, high allelic ratio ( $>0.5$ ); semiquantitative assessment of *FLT3-ITD* allelic ratio (using DNA fragment analysis) is determined as ratio of the area under the curve (AUC) “*FLT3-ITD*” divided by AUC “*FLT3-wild type*”; recent studies indicate that acute myeloid leukemia with *NPM1* mutation and *FLT3-ITD* low allelic ratio may also have a more favorable prognosis and patients should not routinely be assigned to allogeneic hematopoietic-cell transplantation.

<sup>§</sup>The presence of  $t(9;11)(p21.3;q23.3)$  takes precedence over rare, concurrent adverse-risk gene mutations.

<sup>¶</sup>Three or more unrelated chromosome abnormalities in the absence of one of the World Health Organization–designated recurring translocations or inversions, i.e.,  $t(8;21)$ ,  $inv(16)$  or  $t(16;16)$ ,  $t(9;11)$ ,  $t(v;11)(v;q23.3)$ ,  $t(6;9)$ ,  $inv(3)$  or  $t(3;3)$ ; AML with *BCR-ABL1*.

<sup>¶¶</sup>Defined by the presence of one single monosomy (excluding loss of X or Y) in association with at least one additional monosomy or structural chromosome abnormality (excluding core-binding factor AML).

<sup>\*\*</sup>These markers should not be used as an adverse prognostic marker if they occur with favorable-risk AML subtypes.

<sup>††</sup>*TP53* mutations are significantly associated with AML with complex and monosomal karyotype.

Modified from Döhner H, Estey E, Grimwade D, et al. Diagnosis and management of AML in adults: 2017 ELN recommendations from an international expert panel. *Blood*. 2017;129(4):424–447.

mixed-phenotype acute leukemias, which express antigens defining more than one lineage. However, more common are AML cases that express an aberrant B-cell or T-cell marker (e.g., CD7 on myeloid blasts); this is called an *aberrant immunophenotype*. Likewise, B-ALL may aberrantly express CD13 or CD33.

Molecular testing is an important component of diagnosis. For AML, molecular testing is performed by next-generation sequencing (NGS) and/or polymerase chain reaction (PCR) assays and should, at minimum, include assessment of *FLT3* (with allelic ratio), *NPM1*, *CEBPA* (biallelic), *IDH1*, *IDH2*, *RUNX1*, *ASXL1*, and *TP53*. For ALL, testing is equally complex but is still evolving in terms of commercial availability for important molecular analyses. Critical to the initial assessment of ALL is testing for the *BCR-ABL1* fusion by molecular methods that are widely available; TKIs targeting this lesion are an integral part of treatment. Likewise, testing by interphase fluorescence in situ hybridization

for the major recurrent cytogenetic abnormalities seen in ALL—including *ETV6-RUNX1*, *TCF3-PBX1*, and *KMT2A* rearrangements, among others—is mandatory. Although not yet widely available, testing in B-ALL for the “*BCR-ABL1*-like” genetic signature identifies a subset of patients with adverse prognosis but potential responsiveness to TKI therapies. *BCR-ABL1*-like disease as a subset has several common genetic features including disruption of B-lymphoid transcription factors including *IKZF1*, *CRLF2*, *JAK2*, and others. Diagnostic testing guidelines for both AML and ALL are delineated and annually updated by the National Comprehensive Cancer Network ([NCCN.org](http://NCCN.org)).

Cytogenetic analysis should be performed on the bone marrow aspirate taken at diagnosis in any patient suspected to have acute leukemia. Prognosis is determined by molecular testing along with the presence of structural or numeric chromosomal abnormalities. Broadly speaking, patients with AML with *t(15;17)*, known as APL as described earlier, have an excellent prognosis, with 80% to 90% cured. Patients with *t(8;21)* or *inv(16)* also have a favorable prognosis. Patients with no cytogenetic abnormalities (cytogenetically normal AML; CN-AML) have an intermediate prognosis (classification further dependent on molecular testing, discussed later), while patients with adverse-risk cytogenetic abnormalities (see [Table 1](#)) have a poor prognosis with few cures, particularly in older adult patients. Genetic testing provides valuable additional information, especially in CN-AML. Favorable genetic risk is observed in those with *NPM1* mutations without a high allelic ratio of *FLT3* internal tandem duplication (*FLT3-ITD*) and also in those with biallelic *CEBPA* mutations. Conversely, mutations in *TP53* (often but not exclusively observed in the setting of complex karyotype), *RUNX1*, and *ASXL1* are associated with adverse risk, with *TP53*-mutated patients demonstrating particularly dismal outcomes. Mutations in genes encoding isocitrate dehydrogenase (IDH) enzymes may contribute to prognostication but, more importantly, identify patients who are likely to respond to novel therapies that target these aberrant pathways.

Cytogenetic testing for ALL enables classification into several groups, including, for example, *BCR-ABL1* fusion disease. This fusion, known cytogenetically as *t(9;22)* and colloquially referred to as the *Philadelphia (Ph) chromosome* (based on the city where it was originally identified) has a poor prognosis. However, the incorporation into multiagent regimens of TKIs that target the aberrantly active kinase has improved clinical outcomes. Other important ALL subsets include *KMT2A* (formerly *MLL*) rearrangements at chromosome 11q23 (with various translocation partners but often chromosome 4 in B-ALL). Both *BCR-ABL1* and *KMT2A* aberrant ALLs are associated with an unfavorable prognosis. Many other subsets of ALL exist in the World Health Organization (WHO) classification. Favorable risk is seen in patients with B-ALL with hyperdiploidy (51 to 65 chromosomes) and *t(12;21)(p13.2;q22.1)*, the *ETV6-RUNX1* fusion. T-ALL is characterized by activating mutations in *NOTCH1* (present in about 60% of cases) and deregulation of a number of transcription factors; immunophenotyping showing an early T-cell precursor (ETP) phenotype (low expression of CD1a, CD8, CD5) has been associated with an adverse prognosis.

Historically, the diagnosis and classification of acute leukemia was based on the French-American-British morphologic and cytochemical criteria, which assigned patients with AML to one of eight groups designated M0 to M7. Likewise, ALL was classified into L1, L2, and L3 groups. These categories, although still in the vernacular on the clinical wards, are practically obsolete. Diagnosis and classification are based instead on the complex morphologic, flow, cytogenetic, and molecular characterization schemas outlined by the WHO for myeloid neoplasms and acute leukemia.

### Differential Diagnosis

The differential diagnosis for acute leukemia includes many bone marrow disorders that present with pancytopenia. However, the presence of excess blasts in the blood or marrow limits the diagnosis to AML, ALL, or acute leukemia of ambiguous lineage. For patients without circulating blasts in the blood, highest in the differential diagnosis of pancytopenia are other hematologic cancers

with marrow infiltration or bone marrow failure syndromes such as aplastic anemia. Advanced myeloproliferative disorders with bone marrow fibrosis and myelodysplastic syndromes can also present similarly, occasionally with rare circulating blasts. Rarely, the pancytopenia caused by the displacement of hemopoietic bone marrow tissue by fibrosis, tumor, or granuloma (called *myelophthisis*) mimics acute leukemia (but without blasts). Examples include solid organ cancers with extensive marrow involvement and granulomatous disease such as tuberculosis. However, essentially only acute leukemia is the appropriate diagnosis in patients with high-level circulating blasts visualized on light microscopy.

### Treatment of Acute Myeloid Leukemia

Treatment of the newly diagnosed adult patient with AML is usually divided into two phases: (1) induction and (2) consolidation (i.e., postremission management). The aim of induction chemotherapy is complete remission (CR), defined as fewer than 5% blasts on a bone marrow aspirate, with recovery of blood counts (absolute neutrophil count >1000/ $\mu$ L and platelet count >100,000/ $\mu$ L). Additional defining criteria of CR include absent circulating blasts and no detectable extramedullary disease. Achievement of CR (or failure to do so) is the best predictor of long-term clinical outcome. The definition of CR is further refined based on the detection of measurable residual disease (MRD) by cytogenetics, flow cytometry, and/or molecular testing. Marrow response *without* full blood count recovery meets lesser response definitions (often termed CR with incomplete count recovery, or CRI); patients with such responses have outcomes inferior to those with CR. Blood count recovery occurs approximately 4 weeks after the initiation of intensive induction chemotherapy. CR is achieved in 60% to 90% of younger patients (depending on molecular risk) and in approximately 2% to 60% of older adult patients (>60 years). Notably, for older adult patients, this estimate is from the subset limited to those who are actually offered intensive therapy; many older patients are not treated intensively (or at all) because of medical comorbidities. Such patients would likely fare even worse than the estimates provided if offered intensive treatment. Long-term survival estimates are approximately 60% for younger patients with favorable-risk disease (see [Table 1](#)), 40% for intermediate-risk disease, and 20% for adverse-risk disease. Older adult patients do poorly in each group; indeed, there are very few long-term survivors among older patients with adverse-risk disease.

Induction and consolidation therapies are chosen based on the patient's age, overall fitness, and cytogenetic/molecular risk. Intensive induction therapy is the norm in younger patients (<60 years). In older patients, the benefit of intensive therapy is more controversial in all but those with a favorable-risk profile; novel approaches for selecting patients predicted to be responsive to treatment and new therapies remain under investigation. Notably, large datasets have demonstrated that even more infirm older patients with AML benefit from treatment as compared with only palliative care.

Standard induction therapy for AML consists of cytarabine (cytosine arabinoside, AraC; Cytosar), 100 to 200 mg/m<sup>2</sup> per day administered as a continuous infusion for 7 days, and daunorubicin (Cerubidine), 60 to 90 mg/m<sup>2</sup>/day for 3 days, commonly known as the 7 + 3 *schedule*. Idarubicin (Idamycin; 12 mg/m<sup>2</sup>/day) is equivalent to daunorubicin. Resistant disease is more frequent in older adult patients and those with prior hematologic disorders, therapy-related AML, or cytogenetic and genetic abnormalities that adversely affect clinical outcome (which are more frequent in older patients). In older adult patients, the long-term outcome is generally poor because of the higher frequency of resistant disease in this group plus an increased rate of treatment-related mortality. As an alternative to intensive induction, unfit or adverse-risk older patients may instead receive lower-intensity therapy with a hypomethylating agent (such as decitabine [Dacogen]<sup>1</sup> or azacitidine [Vidaza]<sup>1</sup>). For patients older than 75 years of age or those who are not candidates

<sup>1</sup>Not FDA approved for this indication.

for intensive therapy, the U.S. Food and Drug Administration (FDA) recently approved the Bcl-2 inhibitor venetoclax (Venclexta) in combination with hypomethylating agent therapy. A randomized trial demonstrated improved survival and higher remission rates with azacitidine in combination with venetoclax compared with azacitidine alone. All older adult patients should be considered for clinical trials, but those in adverse-risk groups should ideally be offered investigational approaches whenever available.

Induction of first complete remission (CR1) is critical to long-term survival in AML. However, without further therapy, virtually all patients in CR will eventually relapse. Patients are estimated to have  $10^{12}$  leukemic cells at diagnosis, which intensive induction chemotherapy reduces by four to five orders of magnitude. Although this reduces the disease burden by 99.9%, approximately  $10^8$  residual leukemic cells still remain after successful induction therapy. These residual cells may not be measurable at all or may be measurable only by sensitive techniques such as multiparameter flow cytometry or quantitative reverse transcriptase polymerase chain reaction (RT-PCR). They cannot be detected by morphology alone. Thus, postremission therapy is designed to eradicate residual (typically undetectable) leukemic cells to prevent relapse and prolong survival. As for induction, the type of postremission therapy in AML is selected for each individual patient based on age, fitness, and cytogenetic/molecular risk.

Postremission treatment options include chemotherapy and/or transplantation. The choice between consolidation with chemotherapy or transplantation is complex and based on age, risk, and practical considerations. In younger patients receiving chemotherapy, postremission therapy with intermediate/high-dose cytarabine for two to four cycles is standard practice. It is clear that alloHCT is the best relapse-prevention strategy currently available for AML. However, the benefit of alloHCT in reducing relapse risk is offset somewhat by increased morbidity and mortality from complications including graft-versus-host disease. Given that relapsed AML is typically resistant to chemotherapy, alloHCT in CR1 is a favored strategy for patients at high risk for relapse. Transplantation is generally recommended for physically fit patients younger than 75 years of age who do not have favorable-risk disease (see Table 1) and have a suitable donor. Donors are typically HLA-matched (related or unrelated) or, increasingly, haploidentical (half-matched sibling, parent, or child). Prognostic factors help in selecting the appropriate postremission therapy in patients in CR1. Generally speaking, patients with favorable-risk AML in CR1 are treated with chemotherapy alone; patients with adverse-risk disease should proceed to alloHCT at CR1 if possible. The decision for alloHCT versus chemotherapy in CR1 for intermediate-risk patients remains in debate, but transplant is typically favored for young, fit patients.

Recent years have seen FDA approval for several targeted drugs. For AML patients with *FLT3* mutation, midostaurin (Rydapt, in combination with induction chemotherapy) and gilteritinib (Xospata, as monotherapy for relapsed AML), respectively, have improved outcomes compared with chemotherapy alone. Likewise, agents targeting mutated IDH enzymes 1 or 2 (in AML patients with *IDH1* or *IDH2* mutations) have been shown effective in both relapsed and initial therapy settings. Another nontargeted drug, CPX-351 (Vyxeos, a liposomal combination of daunorubicin [an anthracycline] and cytarabine), has demonstrated superiority to initial standard chemotherapy in patients with therapy-related AML or AML with myelodysplasia-related changes (including patients with antecedent hematologic disorder). All of these drugs, as well as venetoclax and many other novel agents, are currently in additional clinical trials.

APL is uniquely treated with all-*trans*-retinoic acid (tretinoin [Vesanoid]) and arsenic trioxide (ATO, Trisenox) rather than chemotherapy, although cases with high presenting WBC counts ( $>10,000/\mu\text{L}$ ) may require the addition of chemotherapy or the antibody-drug conjugate gemtuzumab ozogamicin (Mylotarg)<sup>1</sup> for cytoreduction. Cases with high WBC counts are at increased

risk for fatal hemorrhage and other complications. Low-risk patients (WBC  $<10,000/\mu\text{L}$ ) have a virtually nonexistent frequency of resistant disease when treated with all-*trans*-retinoic acid (tretinoin [Vesanoid]) and arsenic trioxide (Trisenox). Patients with APL require expert management to address complications of DIC and hemorrhage and the so-called *APL syndrome* (formerly known as *differentiation syndrome* and *retinoic acid syndrome*). APL syndrome is marked by an increasing WBC count, fever, hypoxia, shortness of breath, and fluid accumulation; it occurs up to 3 weeks after treatment initiation. It is common, especially in presentations with higher WBCs, and requires urgent therapy consisting of steroids, diuresis, and possibly cytoreduction.

### Treatment of Acute Lymphoblastic Leukemia

Standard chemotherapy treatment of ALL is of much more extended duration and regimen complexity than that of AML. However, the same general principles apply; achievement of CR1 with initial therapy is the critical first step for long-term survival. Postremission therapy in ALL is broken into different segments of various intensity, including consolidation, interim maintenance, delayed intensification, and prolonged (24 to 36 months) maintenance. CNS-directed therapy (systemic chemotherapy with intrathecal chemotherapy, or cranial radiotherapy) is an important and mandatory feature of ALL treatment because of high rates of CNS relapse in patients who do not receive such therapy. Generally, treatment approaches include variations on a five-drug induction combination of cyclophosphamide (Cytoxan), prednisone<sup>1</sup> or dexamethasone (Decadron),<sup>1</sup> anthracycline (doxorubicin [Adriamycin]; or daunorubicin [Cerubidine]), PEGylated asparaginase (Oncaspar), and vincristine (Oncovin). The principle of therapy for ALL is continuous exposure to multiple chemotherapy agents with nonoverlapping resistance mechanisms; all regimens use alternating chemotherapy regimens given over an extended period. Additional agents include methotrexate, cytarabine, 6-mercaptopurine (Purinethol), and others. Examples of common treatment strategies are the Berlin-Frankfurt-Munster (BFM) approach and the hyper-CVAD (hyperfractionated cyclophosphamide, vincristine, adriamycin, dexamethasone) regimen. Although data are sparse, patients with mixed-phenotype acute leukemias appear to fare better with ALL-like treatment approaches compared with those used in AML.

Unfortunately, although children with B-ALL have favorable long-term survival in the 80% to 90% range, adults fare far worse. Estimated long-term survival rates for adults with ALL are only 30% to 40%. Encouraging data have come from recent cooperative group studies: adolescents and young adults (16 to 40 years of age) treated with “pediatric-inspired” regimens have significantly more favorable outcomes than those treated with “adult” regimens. Pediatric regimens have a greater focus on less myelotoxic therapies such as PEGylated asparaginase, vincristine, and steroids. Unfortunately, older adults ( $>40$  years of age) have difficulty tolerating such approaches. The addition of nelarabine (Arranon) to first-line therapy has improved outcomes in T-ALL.

As noted previously, the identification of the Ph chromosome (*t(9;22)*) or the *BCR-ABL1* fusion is critical in the initial diagnosis of B-ALL or mixed-phenotype acute leukemia. The introduction of TKIs for Ph-positive patients into multiagent induction and postremission treatment has dramatically improved outcomes and is now standard. Whether Ph-positive B-ALL should have mandatory alloHCT in CR1 is now controversial. Imatinib (Gleevec) is a standard TKI; second- or third-generation TKIs such as dasatinib (Sprycel), nilotinib (Tasigna),<sup>1</sup> or ponatinib (Iclusig) are also commonly used for the treatment of Ph-positive acute leukemia.

Additional advances to traditional approaches include the use of CD20 monoclonal antibodies (rituximab [Rituxan]<sup>1</sup>) for patients with B-ALL whose lymphoid blasts express this surface marker

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

and nelarabine in T-ALL. Nelarabine is a purine analogue with increased activity in T-lymphoid blasts and 30% response rates in the relapsed setting; it is being incorporated into front-line multi-agent trials. AlloHCT in adult ALL is more controversial than in AML, although most trials offer alloHCT in CR1 for high-risk disease. MRD status at completion of induction therapy is also increasingly being utilized to identify patients likely to benefit from alloHCT. The addition of the bispecific antibody blinatumomab (Blinicyto, see later) for patients who remain MRD positive after intensive chemotherapy has improved clinical outcomes.

### Immune-Based Therapies in Acute Leukemia

Beyond the use of alloHCT, recent years have seen remarkable progress in immunologic therapies for acute leukemia. The US Food and Drug Administration recently approved exciting engineered cellular therapies for relapsed malignancies of B-lymphocytes: chimeric antigen receptor (CAR) T cells that target CD19 (in B-ALL and non-Hodgkin lymphoma). Tisagenlecleucel (Kymriah) is approved for relapsed or refractory B-ALL in patients 25 years or younger, and brexucabtagene autoleucel (Tecartus) was recently approved for all adult patients. In these cases, autologous B cells are collected by apheresis from the patient, genetically engineered *ex vivo* to target CD19, and then infused back into the patient to treat CD19+ malignancy (typically after some type of lymphodepleting therapy). In the process, CD19+ normal B cells are also eliminated. High response rates and long-term remissions have been reported in patients with ALL with highly refractory disease using CAR T-cell therapy; complete response rates in the range of 70% to 90% have been observed in CD19+ cancers: ALL, chronic lymphocytic leukemia, diffuse large B-cell lymphoma, and mantle cell lymphoma (Figure 1). Challenges of CAR T cells include issues with uncontrolled immune cell activation (termed *cytokine release syndrome*), neurotoxicity, killing of normal CD19+ B cells, and resistance caused by loss of CD19 expression on leukemic cells (e.g., CD19– relapse). CAR retargeting to other hematologic targets beyond CD19 remains an area of active investigation; CAR T cells targeting the BCMA antigen have recently been approved in multiple myeloma, while products targeting CD22 and CD123, among others, appear promising.

Several novel antibodies have also recently been approved. Inotuzumab ozogamicin (Besponsa; targeting CD22 in B-ALL) and gemtuzumab ozogamicin (Mylotarg; targeting CD33 in AML) are antibody-drug conjugates that deliver the toxin calicheamicin to lymphoid or myeloid blasts, respectively. Both agents have activity as a monotherapy and may also be incorporated into chemotherapy regimens. Blinatumomab (Blinicyto) is a CD3-CD19 bispecific

antibody; this class of agents functions by linking immune cells to malignant cells resulting in cytotoxicity. Bispecific agents targeting CD33, CD123, and CD20 are in ongoing clinical trials.

### Monitoring

Measurement of residual disease is an important component of management in ALL. It is not surprising that initial responsiveness to chemotherapy is a useful predictor for long-term outcome. Lack of early clearance of blasts (by days 7 to 14) has adverse prognostic value (especially in ALL). Persistence of abnormal karyotype after induction among patients in CR is also associated with poor clinical outcomes. For patients in morphologic CR, measurement of MRD is an emerging standard (ALL) and intensive research area (AML). More sensitive methods of MRD measurement beyond light microscopy and cytogenetics are increasingly used to aid decision making. Examples of sensitive MRD assessment include immunophenotyping by multiparameter flow cytometry to detect minute populations of blasts or quantitative RT-PCR and other molecular methods to detect leukemia-associated molecular abnormalities. Particularly in B-ALL, early clearance of MRD is favorable. In ALL and in APL, MRD assessment is a very useful and reliable tool to assess prognosis, detect early relapse, and direct the initiation of additional therapy. In AML, MRD identifies high-risk patients, but how to utilize these data to mitigate risk is not yet established in most cases. Specifically, quantitative measurement of mutated *NPM1* transcript levels during first remission provides important and potentially actionable information in that subset of AML.

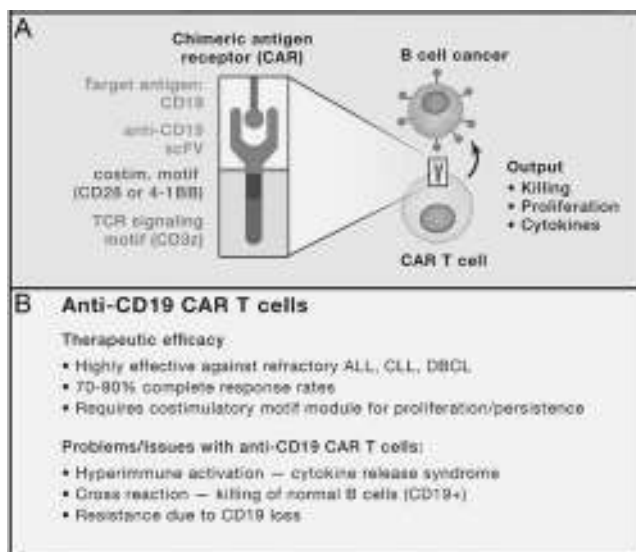

### Management of Complications

The treatment of acute leukemia involves repeated cycles of myelotoxic or immunosuppressive chemotherapy, requiring intensive supportive care. The emergence of infections with multidrug-resistant organisms is a growing concern. In addition, invasive fungal infections are associated with early death. Standard infection precautions include reverse isolation, air filtration, and prophylactic antimicrobials. Recommendations on the latter are best tailored based on institutional antibiograms; in AML patients undergoing induction therapy, antifungal prophylaxis using agents with broad mold coverage is generally recommended.

Transfusion of red blood cells and platelets is a common and necessary part of treatment. Blood products should ideally be leukodepleted (done by the American Red Cross in the United States) to reduce the risk of febrile transfusion reaction and allo-immunization. Particularly in the multicourse induction and postremission therapies in ALL, it is clear that the management of complications while still proceeding with the on-time administration of subsequent therapies whenever possible improves outcomes.

## BLOOD COMPONENT THERAPY AND TRANSFUSION REACTIONS

Method of

Theresa Nester, MD

### CURRENT DIAGNOSIS

- Fever greater than 1°C rise during or within 4 hours after transfusion should prompt evaluation of the patient and consideration of a transfusion reaction.
- Fever and pain are the most common manifestations of an acute hemolytic transfusion reaction.
- The point of the transfusion reaction laboratory investigation is to evaluate for hemolysis, either intravascular or extravascular. The majority of reactions are negative for hemolysis.
- The differential diagnosis of a transfusion reaction with respiratory symptoms includes febrile nonhemolytic and circulatory overload (common), allergic or anaphylactic reaction, transfusion-related acute lung injury, acute hemolytic reaction, and bacterial contamination (rare).

### CURRENT THERAPY

- The decision to transfuse red blood cells to a patient should depend more on the clinical state of the patient than on an absolute trigger for hemoglobin or hematocrit.
- A transfusion trigger of less than 7 g/dL is recommended for hospitalized adult patients who are hemodynamically stable, including critically ill patients. A transfusion trigger of 8 g/dL is recommended for patients undergoing orthopedic or cardiac surgery, as well as those with preexisting cardiovascular disease.
- For severe autoimmune hemolytic anemia, maintenance of hemoglobin at greater than 4 g/dL in younger patients and greater than 6 g/dL in older patients or patients with cardiovascular disease is appropriate.
- Platelets are not typically indicated in thrombotic thrombocytopenic purpura, autoimmune thrombocytopenic purpura (ITP), and heparin-induced thrombocytopenia (HIT) unless the patient has significant bleeding.
- Currently available coagulation tests are not very useful for predicting bleeding in patients with end-stage liver disease. These patients establish a new equilibrium between coagulation, anticoagulation, and fibrinolysis that results in relatively less bleeding than predicted by the international normalized ratio.
- The goal during massive transfusion scenarios should be to prevent marked acidosis, hypothermia, and coagulopathy. The latter is often achieved with replacement of coagulation factors using plasma or cryoprecipitate within the first hour of the resuscitation.
- Cryoprecipitate is useful as a source of concentrated fibrinogen. In a patient who is actively bleeding and has a fibrinogen less than 100 mg/dL, cryoprecipitate is indicated.

### Therapeutic Use of Blood Components

The community blood supply depends on two types of donors: whole blood donors and apheresis donors. Units of whole blood are centrifuged and then separated into components within a closed system. Using apheresis techniques, individual components of whole blood can be collected. Citrate is used to keep blood components from clotting.

The decision to transfuse blood to a patient should always include a consideration of the risks versus the benefits. Risks of transfusion-transmitted diseases are small with current testing standards. Transfusion reactions do occur; the most common ones are not life-threatening unless the patient cannot tolerate tachycardia or hypertension. Rarely, a patient experiences a life-threatening reaction. Thus it is important to ensure that the need for the blood component outweighs the risks. Additionally, in a bleeding patient, it is important to check coagulation parameters (platelet count, prothrombin time [PT], international normalized ratio [INR], activated partial thromboplastin time [aPTT], fibrinogen) in addition to hematocrit (Hct) to ensure that the component that will best address the bleeding is being used.

### Red Blood Cells

#### Indications

Red blood cells should be given to increase oxygen-carrying capacity. The hemoglobin (Hb) and Hct levels alone should not be used to determine the need for transfusion; instead, the patient's clinical picture should drive the decision to transfuse. The patient's intravascular volume status, cardiopulmonary function, and baseline vital signs in the presence of anemia should all be considered. When anemia has persisted over weeks and months, large volume transfusion is often not indicated because compensatory mechanisms have had time to work.

#### Transfusion Triggers

The most recent clinical practice guideline from AABB (formerly known as the American Association of Blood Banks) has the following recommendations: in hospitalized adult patients who are hemodynamically stable, including critically ill patients, a transfusion threshold of 7 g/dL is acceptable. In patients undergoing orthopedic or cardiac surgery, and those with preexisting cardiovascular disease, a transfusion threshold of 8 g/dL is recommended. The recommendations do not apply to patients with acute coronary syndrome, severe thrombocytopenia, or chronic transfusion dependent anemia, because of insufficient evidence.

#### Dosage

One unit of packed red blood cells will increase the hemoglobin by 1 g/dL and hematocrit by 3% in the patient who is not bleeding or experiencing hemolysis (Table 1).

### Autoimmune Hemolytic Anemia

#### Special Situation

When the autoantibody responsible for autoimmune hemolytic anemia reacts at body temperature, all red blood cell units can appear incompatible. This is because the antibody binds to an epitope common to all red blood cells, such as the band 3 protein. The clinician needs to decide when to transfuse the (apparently) incompatible units. In a patient who has never received a transfusion or been pregnant, there is little possibility of red blood cell alloantibodies in circulation, and the chance of hemolysis (beyond that being caused by the autoantibody) is low. For the patient who has received a transfusion or who has been pregnant in the past, the risk that a circulating red blood cell alloantibody is present and is being masked by the autoantibody is higher; special studies are available to reduce the risk of an alloantibody being overlooked. The transfusion trigger depends on whether the anemia is acute or chronic. For acute severe anemia, maintenance of hemoglobin at greater than 4 g/dL in younger patients and greater than 6 g/dL in older patients or patients with cardiovascular disease is appropriate.

### Platelets

Platelets are required as part of normal clotting. The first stage of clot formation is development of a platelet plug over the site of endothelial injury.

**TABLE 1** Component Therapy: Dosage and Expected Increment

COMPONENT	DOSE	EXPECTED INCREMENT	AVERAGE VOLUME
Red blood cells	1 unit	Hct 3%, Hb 1 g/dL	250 mL
Whole blood platelets	1 unit	Platelet count increased by 5000–10,000/ $\mu$ L	50 mL/unit (1 pool of 6 = 300 mL)
Apheresis platelet	1 unit	Platelet count increased by 20,000–60,000/ $\mu$ L	300 mL/unit
Plasma	10 mL/kg	Factor levels increased by 20%	300 mL/unit
Cryoprecipitate	1 unit	Fibrinogen increased by 5 mg/dL	15 mL/unit
Prepooled cryoprecipitate	1 6-unit pool	Fibrinogen increased by 45 mg/dL	120 mL/pool

Abbreviations: Hb = hemoglobin; Hct = hematocrit.

### Indications

The indications for platelet transfusion may be divided into prevention of bleeding and treatment of bleeding in the setting of thrombocytopenia or platelet dysfunction.

### Transfusion Triggers

**Prevention of Bleeding.** In a stable patient with normal platelet function, transfusion is appropriate if the platelet count is less than 10,000/ $\mu$ L. One randomized, controlled trial has shown that transfusion at platelet counts of 5000/ $\mu$ L to 10,000/ $\mu$ L prevents bleeding in the stable patient. In a stable patient with other hemostatic abnormalities (e.g., on anticoagulation), transfusion is appropriate with a platelet count less than 50,000/ $\mu$ L.

Before a planned invasive procedure such as open lung biopsy, transfusion is appropriate with a platelet count of <50,000/ $\mu$ L. For lumbar puncture, consensus guidelines suggest that a platelet count of 50,000/ $\mu$ L is appropriate, although there are a few large studies suggesting that counts between 20,000 and 50,000/ $\mu$ L may be adequate. A patient undergoing major surgery should receive platelets if the count is less than 50,000 to 100,000/ $\mu$ L. The transfusion should take place as close to the procedure as possible so the platelets remain in circulation while the procedure is occurring.

**Treatment of Bleeding.** Platelets may be transfused with a major hemorrhage (e.g., gastrointestinal or genitourinary) and a platelet count less than 30,000 to 50,000/ $\mu$ L. For bleeding with major surgery or trauma, transfusion is appropriate for counts less than 80,000/ $\mu$ L. For bleeding into critical areas (e.g., central nervous system bleeding or diffuse alveolar hemorrhage), platelets may be given for counts less than 100,000/ $\mu$ L.

### Dosage

Dosage is determined on the basis of the baseline platelet count, desired platelet count, and estimated blood volume. For a 70-kg patient,  $3 \times 10^{11}$  platelets (four to six units of pooled whole blood platelets or one unit of apheresis platelets) increases platelet count by approximately 30,000 to 50,000/ $\mu$ L in the absence of alloimmunization or excessive consumption. For prophylactic therapy, lower dosages have been shown to be as effective as higher dosages in the prevention of bleeding.

### Out of ABO Group Platelet Transfusion

Because platelets can only be stored for a maximum of 7 days following collection, and the community platelet supply is collected from

**TABLE 2** ABO Compatibility\*

PATIENT'S ABO	ANTIBODIES IN CIRCULATION	COMPATIBLE PACKED RED BLOOD CELLS	COMPATIBLE PLASMA
O	anti-A, anti-B	O	O, A, B, AB
A	anti-B	O or A	A or AB
B	anti-A	O or B	B or AB
AB	None	O, A, B, AB	AB

\*For platelet compatibility, see text.

### BOX 1 Rh(D) compatibility

Rh(D) negative patients should receive Rh negative red blood cells and platelet units.\*†

Rh(D) positive patients can receive Rh positive or Rh negative red blood cells and platelet units.

Rh compatibility does not apply to acellular components (plasma and cryoprecipitate).

Only 15% of blood donors are Rh negative.

\* In times of shortage, it becomes necessary to preserve the Rh(D) negative red blood cell inventory for females of childbearing potential (< 50 years old).

† Platelet components contain very few red blood cells; Rho(D) immune globulin (RhoGAM) may be administered if prevention of anti-D formation is deemed appropriate. Consult with a transfusion medicine physician if further discussion is needed.

volunteer donors, a platelet product that is identical to the patient's ABO type might not be available (Table 2 and Box 1). Thus it may be necessary to infuse a small volume of incompatible plasma (suspending the platelets) to the patient. There is therefore a small risk of hemolysis of the patient's red blood cells if the isoagglutinin (anti-A or anti-B) titer in the donated plasma is high. Studies of healthy blood donors indicate that these antibody titers are typically low and do not precipitate hemolysis. Transfusion services often have policies that limit the amount of incompatible plasma a patient has received with platelet transfusion. Alternatively, some centers measure the antibody titer in the donated product and give high-titer products only to patients whose red blood cells lack the corresponding ABO antigen.

### Unresponsiveness to Platelet Transfusion

A number of clinical factors can result in a patient's less-than-optimal response to platelet transfusion. In addition to consumption, some of these factors include splenomegaly, fever, and antifungal therapy. Patients who have been sensitized to foreign human leukocyte antigens through prior pregnancy or transfusion can also have a poor response to platelet transfusion. Transfusion medicine consultation regarding the evaluation of refractoriness to platelet transfusion may be indicated.

### Special Situations

**Uremia.** Patients who are dialysis dependent might have an acquired platelet defect as a result of the uremic environment. Transfusion of platelets into this environment will render the transfused platelets dysfunctional. Thus if optimal platelet function is desired, dialysis should be performed frequently. Consider performing dialysis without heparin if the patient is actively bleeding.

**Purpura and Thrombocytopenia.** In patients with autoimmune thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP), or heparin-induced thrombocytopenia (HIT), platelet transfusion is not indicated unless the patient has significant bleeding. Other therapies, such as steroid administration for ITP and plasma exchange for TTP, should be initiated to address the condition.

## Plasma

Plasma contains all of the coagulation proteins needed for clot formation, as well as all of the fibrinolytic proteins that prevent systemic thrombosis. There are currently several kinds of plasma, such as fresh frozen, FP24, thawed, and liquid. All contain hemostatic levels of coagulation factors as long as they are stored appropriately. The effect of plasma transfusion on the PT and INR is 4 to 6 hours, owing to the short half-life of coagulation factor VII. Thus other, longer-lasting means of restoring coagulation factors, such as vitamin K administration, should be undertaken if a more durable response is desired.

When replacing coagulation factors with plasma, it is not necessary to have 100% factor replacement as the goal. Hemostasis is typically able to occur if circulating coagulation factor levels are between 40% and 50%. It is important to understand that the relationship between the INR and the percentage factor level is a logarithmic, rather than a linear, relationship (Figure 1). Thus whether the INR is 9 or 1.8, the initial dosage of plasma should be 10 to 20 mL/kg, with recheck of the laboratory values a few minutes after infusion. The more prolonged the INR, the more significant the impact of the dose on the INR.

### Transfusion Triggers

For bleeding or imminent surgery that cannot be corrected in a timely manner by vitamin K administration, use plasma to correct an INR greater than 1.8 to 2.0. The exception is patients with end-stage liver disease (see later).

### Dosage

At a dosage of 10 mL/kg, each unit has an average of 300 mL (3–5 units in a 70-kg adult). This dosage should increase circulating coagulation factors by 20% immediately after infusion.

### Special Situations

**Liver Disease.** The INR is a less useful test in patients with end-stage liver disease. The destruction of liver tissue leads to decreased production of coagulation and fibrinolytic proteins such that a new balance is established. Patients with end-stage liver disease have been shown to have normal levels of circulating thrombin and reduced levels of certain anticoagulant proteins (e.g., protein C), which could explain why they do not bleed as often as predicted with the elevation in INR. Thus the prophylactic use of plasma to correct a mildly prolonged laboratory value in the absence of bleeding is not indicated. It will lead to unnecessary plasma infusion, and the risk of volume overload and transfusion reactions outweighs the benefit in these patients.

**Massive Transfusion.** In trauma patients, patients with ruptured aortic aneurysms, and patients with other arterial bleeding,

**Figure 1** American Association of Blood Banks international normalized ratio (INR) compared with percentage factor levels. Reprinted with permission from Nester T, AuBuchon J: Hemotherapy decisions and their outcomes. In Roback JD (ed): AAB Technical Manual, 17th ed. Bethesda, MD, American Association of Blood Banks, 2011, p 592.

massive transfusion may be necessary. The basic principles of such a scenario include taking steps early into the resuscitation to prevent the patient from becoming too cold, acidotic, or coagulopathic to reverse the situation. Some plasma (and cryoprecipitate, if the fibrinogen is very low) should be infused early into the resuscitation to help prevent coagulopathy. Red blood cells and plasma should be infused through a blood warmer, if possible.

**Isolated Prolonged aPTT.** Other than a deficiency in coagulation factor XI, bear in mind that the differential of an isolated prolonged aPTT includes entities that do not typically require plasma (refer to Figure 2). Hemophilia A, hemophilia B, and von Willebrand disease are no longer treated by plasma but can require factor concentrates to prevent bleeding. Systemic administration of heparin must be reversed by protamine, if fast reversal is desired. Note that plasma transfusion will not reverse the effect of heparin. One of the most common causes of a prolonged aPTT is a lupus anticoagulant; this is an antibody directed against phospholipids that typically leads to thrombosis rather than hemorrhage.

**Intracranial Hemorrhage or Life-Threatening Bleeding.** Reversal of anticoagulation in the setting of intracranial hemorrhage or life-threatening bleeding depends on the anticoagulant. For patients taking warfarin (Coumadin), refer to Box 2.

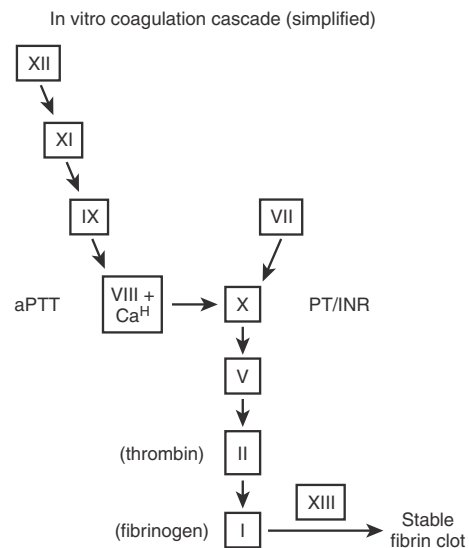

Prothrombin complex concentrates (PCCs) may be used to replenish factors II, VII, IX, and X rapidly. For reversal of dabigatran (Pradaxa), a direct oral anticoagulant (DOAC), idarucizumab (Praxbind) is approved by the Food and Drug Administration (FDA) as a reversal agent. KCentra is a 4-factor PCC that has been FDA approved to treat life-threatening hemorrhage in adult patients on warfarin. For reversal of apixaban (Eliquis) and rivaroxaban (Xarelto) in life-threatening bleeding, andexanet alfa (Andexxa) is available.

### Cryoprecipitate

Cryoprecipitate contains fibrinogen, coagulation factors VIII and XIII, and von Willebrand factor. The most common current use is as a source of concentrated fibrinogen. It may also be used to treat hemorrhage in the rare patient with factor XIII deficiency.

### Indications

Clinical scenarios that increase probability for low fibrinogen include any clinical situation where disseminated intravascular coagulation (DIC) may be present. These include obstetric bleeding, trauma involving head injury or crush injury, and sepsis. Clinical events that can lead to an isolated decrease in serum fibrinogen concentration include administration of L-asparaginase

**Figure 2** Coagulation cascade.

**INR Higher than Therapeutic but <5, No Significant Bleeding**

Lower anticoagulant dosage.

Temporarily discontinue drug, if necessary.

**INR >5 but <9, No Significant Bleeding**

Omit 1 or 2 doses, monitor INR, resume when INR is in therapeutic range.

Alternative if patient is at increased risk of hemorrhage:

- Omit 1 dose
- Give 1–2.5 mg vitamin K orally.

For rapid reversal before urgent surgery:

- Give 2–4 mg vitamin K orally.
- Give 1–2 mg at 24 hours if INR remains elevated.

**INR >9, No Significant Bleeding**

Omit warfarin; give 2.5–5.0 mg vitamin K orally.

Closely monitor INR; give additional vitamin K, if necessary.

Resume warfarin at lower dose when INR is within therapeutic range.

**Serious Bleeding at Any Elevation of INR**

Omit warfarin.

Give 10 mg vitamin K by slow IV infusion.

Supplement with plasma or prothrombin complex concentrate depending on urgency of correction.

Vitamin K infusions may be repeated every 12 hours.

**Life-Threatening Hemorrhage**

Omit warfarin.

Give prothrombin complex concentrate with 10 mg vitamin K by slow IV infusion.

Repeat as necessary, depending on INR.

Abbreviation: INR = international normalized ratio.

From Nester T, AuBuchon J: Hemotherapy decisions and their outcomes. In Roback JD (ed): AAB Technical Manual, 17th ed. Bethesda, MD, American Association of Blood Banks, 2011, p 571–616.

(Elspar) and surgeries that disrupt bladder or salivary gland endothelium. Fibrinogen concentrates are available for patients who will not accept cryoprecipitate.

**Transfusion Triggers**

Transfusion is appropriate in patients with low serum fibrinogen, typically less than 100 mg/dL. In cases of massive transfusion, a trigger of 150 mg/dL is considered practical, so that the patient becomes less coagulopathic in the time that it takes to draw and review new laboratory values. New evidence indicates that a fibrinogen level of less than 300 mg/dL predicts severe postpartum hemorrhage, as a normal postpartum fibrinogen level is in the 600 mg/dL range. Because component therapy aims to replete coagulation factors to hemostatic (rather than completely normal) levels, consensus guidelines suggest maintaining a fibrinogen level greater than 200 mg/dL during a postpartum hemorrhage.

**Dosage**

Dosage depends on the type of cryoprecipitate available. If the product requires resuspension in saline before pooling, then one unit (average 15 mL volume) will increase fibrinogen by 5 mg/dL. If the product has been pooled in plasma before freezing, then one unit will increase fibrinogen by 7 to 8 mg/dL; a six-unit pool will increase fibrinogen by 45 mg/dL. Check with the transfusion service laboratory regarding which product is available and the expected increment.

**Special Situation**

DIC is a state where fibrinogen is consumed at a faster rate than other circulating coagulation factors. This is because DIC is

typically a thrombin-generating process (thrombin cleaves fibrinogen into fibrin for clot formation). Thus, although all coagulation factors are being consumed in DIC, timely repletion of fibrinogen by use of cryoprecipitate can result in more-timely cessation of bleeding in a patient with active DIC. The target value is fibrinogen at least 100 mg/dL. If the PT and INR are still prolonged with fibrinogen greater than 100 mg/dL, administration of plasma will replete other coagulation factors being consumed.

**Transfusion Reactions**

Reactions to transfusion are relatively common; life-threatening reactions are rare (Tables 3 and 4).

Because fever is a feature of both common and dangerous reactions, a transfusion reaction evaluation should be initiated with fever greater than 1°C above patient's baseline temperature at the start of the transfusion. The infusion of product should cease, at least until the laboratory results are known and the patient has responded to treatment. The main point of the laboratory investigation is to evaluate the plasma for abnormal (usually red) color in an effort to detect intravascular hemolysis as quickly as possible. If the clerical check and hemolysis direct antiglobulin tests are negative, one might consider restarting the transfusion with careful surveillance of the patient. A direct antiglobulin test is performed to detect the presence of antibody coating red blood cells in circulation; a positive result could indicate extravascular hemolysis, which is not as dangerous as intravascular hemolysis.

**Most-Common Reactions****Febrile Nonhemolytic Reaction**

**Presentation.** A febrile nonhemolytic transfusion reaction manifests as fever greater than a 1°C rise above the patient's baseline, often accompanied by rigors. Hypertension, tachypnea, and transient decrease in oxygen saturation can also occur until the symptoms are treated. Evidence of hemolysis will be absent on laboratory evaluation. These reactions can manifest during or 2 to 3 hours after the transfusion.

**Pathophysiology.** Cytokines produced by white blood cells present in cellular blood components (red blood cell and platelet units) are responsible for the clinical presentation. Platelets also secrete cytokines; thus leukoreduction of platelet units might not be successful in preventing the reaction.

**Acute Management.** Administration of an antipyretic is the routine treatment; meperidine (Demerol)<sup>1</sup> may be required to address severe rigors. Slow IV push of 25 mg as a first dose is recommended; an additional 25-mg dose can be given 10 to 15 minutes later if rigors persist.

**Prevention with Future Transfusion.** Antipyretic may be administered prior to transfusion. Ordering leukoreduced red blood cells and platelets (if the hospital inventory is not entirely composed of leukoreduced components) is also a preventive measure. For recurring reactions with platelets, volume reduction of the component can reduce the incidence.

**Allergic Reaction of Mild Severity**

**Presentation.** Urticaria or flushing occurs during a transfusion. Evidence of hemolysis is absent on laboratory evaluation.

**Pathophysiology.** Allergic reactions are immunoglobulin (Ig) E-mediated reactions against some allergen in the donor plasma. Because all blood components have some amount of plasma, it is possible to experience an allergic reaction with any blood product.

**Acute Management.** Slowing the infusion rate may be all that is required to alleviate the reaction. Antihistamine administration also addresses the symptoms.

**Prevention with Future Transfusion.** A reaction of this type may be a one-time event. For patients with recurrent reactions, transfusing the blood product more slowly (maximum of transfusion

<sup>1</sup>Not FDA approved for this indication.

over 4 hours), or premedication with antihistamines will reduce the incidence.

**Transfusion Associated Circulatory Overload (TACO)**

**Presentation.** The patient has respiratory distress, typically during the transfusion, and increase in blood pressure unless cardiac decompensation occurs. Tachycardia, tachypnea, and decrease in oxygen saturation are often present. Jugular venous distension may be seen. Radiographic findings include

pleural effusions, perihilar edema, and increased vascular pedicle width.

**Pathophysiology.** The reaction results in cardiogenic pulmonary edema.

**Acute Management.** Diuretic should be administered. Supplemental oxygen may be required temporarily to improve oxygen saturation.

**Prevention with Future Transfusion.** Slowing the infusion rate with a maximum time of transfusion over 4 hours can prevent the reaction. Diuretic administration may be necessary in patients with poor heart function.

**TABLE 3** Transfusion Reactions

MOST-COMMON REACTIONS	INCIDENCE
Allergic reaction of mild severity	1:33 to 1:100
Febrile nonhemolytic reaction	1:100 to 1:1000 with leukocyte reduction
Transfusion-related circulatory overload	< 1:100
MOST DANGEROUS REACTIONS	INCIDENCE
Acute hemolytic reaction	1:38,000 to 1:70,000
Anaphylactic reaction	1:20,000 to 1:50,000
Transfusion-related acute lung injury	1:1200 to 1:190,000
Bacterial contamination of red cell unit with gram-negative organisms	1:1,000,000

**Most-Dangerous Reactions**

**Acute Hemolytic Transfusion Reaction (AHTR)**

**Presentation.** The most common signs include fever with or without rigors and pain. The more commonly reported sites of pain include flank, back, chest, or abdomen. Nausea and vomiting and dyspnea can also occur. In more severe presentations, hemodynamic instability is present, accompanied by oozing from line sites or petechial hemorrhage if DIC is occurring. Red or cola-colored urine is another manifestation of an acute hemolytic transfusion reaction and represents overwhelming of the renal capacity to recirculate free heme.

**Pathophysiology.** Red blood cells have proteins and carbohydrates on the cell surface that are antigenic. These epitopes are categorized into blood groups based on structure and sharing of a parent protein. A patient who lacks particular epitopes can develop antibodies through pregnancy or transfusion. Such red blood cell alloantibodies then lyse transfused red blood cells that possess the cognate antigen. When time allows for pretransfusion testing, the antibodies are identified, and antigen-negative units are provided. The ABO blood group system is unusual in that almost all patients older than 4 months have naturally occurring antibodies to the A and B antigens that they did not inherit. These antibodies are capable

**TABLE 4** Transfusion Reactions with Respiratory Symptoms

REACTION	CLASSIC SIGNS	RELATIVE FREQUENCY	ACUTE MANAGEMENT (TRANSFUSION STOPPED IN ALL CASES)
Febrile nonhemolytic reaction	Transient tachypnea in the presence of rigors and fever	Common	Antipyretic ± meperidine (Demerol) <sup>1</sup>
Circulatory overload	Hypoxia Crackles in lower lung fields Increased BP Chest radiograph consistent with volume overload	Common	Diuresis
Allergic reaction of moderate severity	Wheezes Possible perioral or periorbital edema Possible hives	Uncommon	IV antihistamines and possibly epinephrine (Adrenalin)
Allergic reaction of marked severity	Wheezes, swollen lips, tongue, uvula Stridor or other signs of airway compromise Very decreased BP	Rare	Epinephrine IV fluids and airway management Bronchodilators and glucagon (GlucaGen) <sup>1</sup> for patient on β-blockers
Transfusion-related acute lung injury	Tachypnea and hypoxia during or within 6 of transfusion Persisting for several hours Chest radiograph consistent with bilateral white out	Rare	Respiratory support of noncardiogenic pulmonary edema
Acute hemolytic reaction	Red urine and red serum Hypotension and diffuse oozing may be present Tachypnea (10% of patients)	Rare	Supportive (possibly ICU) care Administration of crystalloid solution Blood component therapy if DIC is present
Bacterial contamination with Gram-negative organism	Very decreased BP Fever Nausea, vomiting Possible tachypnea	Rare	Intensive care for support of Gram-negative sepsis

Abbreviations: BP = blood pressure; DIC = disseminated intravascular coagulation; ICU = intensive care unit.  
1Not FDA approved for this indication.

of activating complement and causing intravascular lysis when bound to their cognate antigen. Thus it is of utmost importance to avoid transfusing red blood cells against the ABO antibody in circulation. Refer to the ABO compatibility table (see Table 1).

**Acute Management.** Management is largely supportive. The end result of intravascular hemolysis and activation of the complement cascade can be shock, uncontrolled bleeding secondary to DIC, and renal failure. Therefore prompt infusion of intravenous crystalloid solutions are indicated to maintain blood pressure and renal perfusion. The goal for urine flow rate should be more than 1 mL/kg per hour. Coagulation laboratory values should be obtained to determine whether DIC is present; if so, component therapy to reverse the DIC is indicated. If the reaction is severe, intensive care is appropriate, because cardiac monitoring and mechanical ventilation may be necessary to support the patient.

**Prevention with Future Transfusion.** An acute hemolytic reaction is one of the most feared complications of transfusion. It is also often one of the most preventable. Great care should be given to the pretransfusion blood sample draw, comparing the label to the patient's unique identifiers, and labeling the tube at the patient's bedside as soon as the blood is in the tube. Just before transfusion, the unit label attached to the blood product should be compared with the patient's armband to ensure that the product is intended for this particular patient. To prevent intravascular hemolysis from antibodies directed against non-ABO antigens, pretransfusion testing (antibody screen or crossmatch) should be done in advance of the need for red cell transfusion for any patient whose clinical situation indicates a likelihood of needing blood. The exception is a patient who is hemodynamically unstable because of acute red blood cell loss, where uncrossmatched red blood cells are indicated. If the patient's identity is known, a call to the hospital transfusion service in this situation is warranted; explain that the patient needs uncrossmatched red blood cells and ask if there are transfusion records that indicate a need for antigen-negative units.

#### **Allergic Reaction of Marked Severity (Anaphylaxis)**

**Presentation.** Significant drop in blood pressure occurs, typically early into the transfusion. Wheezes, difficulty breathing, and stridor may be present. Tongue or facial edema and hives may be observed.

**Pathophysiology.** Anaphylaxis is an IgE-mediated reaction against an allergen in the donor plasma. In a patient with absolute IgA deficiency, naturally occurring anti-IgA can precipitate this reaction on binding IgA in the plasma. Anti-haptoglobin antibodies can also induce a severe reaction.

**Acute Management.** Airway and blood pressure support should be provided with the patient recumbent and the lower extremities elevated. The treatment of choice is epinephrine (Adrenalin) 1 mg/mL, also labeled as 1:1000 or 0.1%, using an adult dosage of 0.3 to 0.5 mg per single dose, typically administered intramuscularly to the mid-quadriceps area. If symptoms persist, the dose may be repeated every 5 to 15 minutes for a maximum of three times, unless palpitations, tremors, or extreme anxiousness occurs. Supplemental oxygen should be administered and the airway maintained. Intravenous fluid administration is also recommended. Bronchodilators such as albuterol can be given as adjunctive treatment for bronchospasm that does not appear to respond to epinephrine. For patients on  $\beta$ -blockers, the addition of intravenous glucagon<sup>1</sup> (GlucaGen) 1 to 5 mg administered over 5 minutes, followed by infusion of 5 to 15  $\mu$ g/minute, may be required. The addition of glucocorticoids can help prevent the biphasic reaction that occurs in some patients.

**Prevention with Future Transfusion.** Slow administration with careful observation of any transfusion is required. Premedication with intravenous antihistamines is appropriate. Steroids may be administered, although their effectiveness has not been confirmed through controlled trials. Epinephrine should be available at the bedside. For severe allergic reactions, a discussion with the transfusion service physician regarding washed components is appropriate.

#### **Transfusion-Related Acute Lung Injury**

**Presentation.** The signs of transfusion-related acute lung injury (TRALI) are difficulty breathing, tachypnea, and hypoxia during or within 6 hours of a transfusion of any blood component. Ideally, signs of underlying lung disease or circulatory overload are absent. Chest radiograph may show diffuse bilateral opacities (white-out). Diuretic administration does not result in improvement. The hypoxemia can progress to the point that the patient requires mechanical ventilation, and thus the patient should be closely monitored while the reaction is occurring.

**Pathophysiology.** The factors that result in TRALI are not entirely known. In a portion of cases, antibodies against white blood cell antigens are present in donor plasma. These antibodies are believed to bind the cognate antigens on the patient's white blood cells, leading to degranulation and a capillary leak syndrome involving the lungs. Other theories regarding the pathophysiology of TRALI exist. One such theory implicates biologically active substances such as lipids and cytokines in the stored blood products. These substances are believed to prime the patient's granulocytes and activate pulmonary endothelium, setting the stage for an additional trigger to cause acute lung injury. Regardless of the cause of TRALI, the end result is an increase in pulmonary vascular permeability and noncardiogenic pulmonary edema. The estimated mortality rate from TRALI is 5% to 8%.

**Acute Management.** Management consists of supportive care, with particular regard to respiratory support. With adequate supportive care, the process most often reverses over 48 to 96 hours.

**Prevention with Future Transfusion.** Marked respiratory compromise is occasionally due to white blood cell antibodies in the patient, which bind cognate antigens in the donated red blood cells or platelet unit ("reverse TRALI"). In these cases, leukoreduction of cellular blood products may reduce the severity of subsequent transfusions, although solid evidence to support this is lacking. For TRALI caused by white blood cell antibodies in the donated product, there are no preventive measures for the clinician to take. The majority of US blood suppliers provide plasma from only male donors, in an effort to reduce the incidence of TRALI caused by multiparous women with white blood cell antibodies.

#### **Bacterial Contamination of a Blood Component**

**Presentation.** The most-common presentation includes fever and rigors, nausea and vomiting, and possible onset of moderate hypotension during or after a platelet transfusion. Rarely, presentation includes signs of overt septic shock, including marked hypotension, typically early into the transfusion of a red blood cell or platelet component. Bacterial contamination of plasma or cryoprecipitate is extremely rare.

**Pathophysiology.** The most-common organisms to contaminate a platelet product are gram-positive organisms such as *Staphylococcus epidermidis*. These organisms are thought to be introduced into the collection bag via a skin plug that results from phlebotomy using a large-gauge needle when sterilization of the phlebotomy site has been ineffective.

The most common organisms to contaminate a red blood cell unit are gram-negative, endotoxin-producing organisms such as *Yersinia enterocolitica*. This organism is introduced into the blood product as a result of asymptomatic bacteremia in the donor, from sources such as the gastrointestinal tract. The donor-screening questionnaire and vital sign assessment at the time of donation help to make collection from such a donor a very rare event. Transfusion of a bacterially contaminated red blood cell unit is most often a fatal event. It is important to remember that platelets can also be contaminated by the same gram-negative, endotoxin-producing organisms; in this case, signs of septic shock may be manifest.

**Acute Management.** Blood cultures from the patient should be drawn, and then prompt intravenous antibiotic administration should begin. Supportive care including inotropic agents and close nursing attention may be required.

**Prevention with Future Transfusion.** Bacterial contamination is associated with a donor product, and thus preventive measures

<sup>1</sup>Not FDA approved for this indication.

for the patient do not apply. Blood suppliers perform bacterial detection tests on platelet components, and transfusion services have strict policies related to visual inspection of all blood products before they are issued to a patient-care area. However, these measures are not completely effective. The FDA recently approved pathogen inactivation technology for platelets, which may further lower the risk.

### Other Reactions

#### *Delayed Hemolytic Transfusion Reaction*

**Presentation.** The main finding with a delayed hemolytic transfusion reaction is usually an unexplained decrease in hematocrit within 2 to 7 days after transfusion. The patient often remains symptom free unless the decline in hemoglobin is poorly tolerated. Jaundice can occur, and laboratory values consistent with hemolysis may be positive (elevated indirect bilirubin, elevated lactate dehydrogenase, decreased haptoglobin). Rarely, signs of intravascular hemolysis can occur.

**Pathophysiology.** The most common source of this reaction is a red blood cell alloantibody that the patient developed with prior transfusion or pregnancy; the antibody titer wanes over time such that pretransfusion testing does not detect the antibody. A unit of red blood cells positive for the cognate antigen is then transfused, and within a few days the patient's memory B cell response produces the antibody again. Transfused cells are then cleared, most often by an extravascular mechanism.

**Acute Management.** Most transfusion services have a policy to notify the clinician that a serologic delayed hemolytic transfusion reaction is present on testing a new plasma sample from the patient. If the patient's hematocrit has declined, it may be useful to determine a clinical correlation by obtaining the laboratory values just described. This is of particular importance when the distinction between hemolysis and bleeding will lead to different management strategies for the patient. Although extravascular clearance of hemoglobin is fairly well tolerated by the kidneys, the conservative approach is to increase renal perfusion with intravenous crystalloid solutions if possible.

**Prevention with Future Transfusion.** For a patient who routinely receives care through one hospital system, the transfusion service will keep a record of the red blood cell alloantibody and provide antigen-negative cells for transfusion. The prevention, then, is to plan ahead for transfusion when possible, so that fully compatible units can be provided. Uncrossmatched red blood cells may be positive for the cognate antigen.

#### *Allergic Reaction of Moderate Severity*

**Presentation.** The patient has labile blood pressure, either hypotension, accompanied by at least one of the following: throat scratchiness, respiratory wheezes, or perioral or periorbital edema. Hives may be present. Gastrointestinal symptoms such as crampy abdominal pain may also be present.

**Pathophysiology.** This is an IgE-mediated reaction against an allergen in the plasma of the donated product.

**Acute Management.** Treatment is administration of intravenous antihistamines. If the respiratory component does not resolve, consider epinephrine administration and treat similarly to anaphylaxis (see previous section).

**Prevention with Future Transfusion.** Slower infusion of blood products can reduce further episodes of this type of reaction. If the patient is atopic, intravenous antihistamines may be administered as a premedication. If the patient requires chronic transfusion and experiences this type of reaction on a repeated basis, discussion with the transfusion service regarding washed components may be warranted.

#### *Hypotensive Transfusion Reaction*

**Presentation.** The patient has isolated hypotension (drop in systolic BP greater than 30 but less than 80 mm Hg) that responds quickly to cessation of the transfusion. The reaction classically occurs within the first 15 minutes of infusion of the blood product.

**Pathophysiology.** Pathophysiology is unclear. Some research indicates that the patient may have slower ability to metabolize bradykinin compared to other individuals.

**Acute Management.** Stop the transfusion.

**Prevention with Future Transfusion.** Prevention is unclear. In the author's experience, rate of infusion has a role. Slower infusion may help to prevent this type of reaction.

#### *Transfusion Associated Dyspnea*

**Presentation.** Acute respiratory distress that occurs within 24 hours of cessation of transfusion.

**Pathophysiology.** Pathophysiology is unclear.

**Acute Management and Prevention with future transfusion.** Management is supportive and prevention is unclear.

## CHRONIC LEUKEMIAS

Method of

Jatin Rana, MD; and Daniel Isaac, DO

### CURRENT DIAGNOSIS

#### Chronic Myelogenous Leukemia

- Clinical symptoms
  - Constitutional symptoms
  - Splenomegaly (abdominal discomfort, early satiety)
- Laboratory parameters
  - Elevated white blood cell count, ~100,000/ $\mu$ L, with differential consisting of various stages of granulocyte maturation from myeloblasts to mature neutrophils
  - Absolute basophilia
- Genetic parameters
  - Presence of *bcr-abl1* by cytogenetics, fluorescence in situ hybridization, or reverse transcriptase polymerase chain reaction

#### Chronic Lymphocytic Leukemia

- Clinical symptoms
  - B symptoms (fevers, night sweats, weight loss)
  - Lymphadenopathy and/or organomegaly
  - Recurrent infections
- Laboratory parameters
  - Absolute lymphocytosis
  - Anemia
  - Thrombocytopenia
- Immunophenotypic analysis by flow cytometry
  - Monoclonal population of light-chain-restricted mature B cells that express CD19, CD20(dim), and CD23 and coexpress CD5

## CURRENT THERAPY

### Chronic Myelogenous Leukemia: Chronic Phase

- First-line therapy
  - Imatinib mesylate (Gleevec) 400 mg daily
  - Dasatinib (Sprycel) 100 mg daily
  - Nilotinib (Tasigna) 300 mg twice daily
  - Bosutinib (Bosulif) 400 mg daily
- Later-line therapy
  - Imatinib mesylate (Gleevec)
  - Dasatinib (Sprycel)
  - Nilotinib (Tasigna)
  - Bosutinib (Bosulif)
  - Ponatinib (Iclusig)
  - Omacetaxine mepesuccinate (Synribo)
  - Asciminib (Scemblix)
- High risk for failure
  - Allogeneic stem cell transplantation

### Chronic Lymphocytic Leukemia

- Chemotherapy
  - Fludarabine (Fludara)
  - Cyclophosphamide (Cytoxan)
  - Chlorambucil (Leukeran)
  - Bendamustine (Treanda)
- Immunotherapy (monoclonal antibodies)
  - Rituximab (Rituxan)
  - Ofatumumab (Arzerra)
  - Obinutuzumab (Gazyva)
  - Alemtuzumab (Campath)
- Targeted therapy
  - Idelalisib (Zydelig)
  - Duvalisib (Copiktra)
  - Ibrutinib (Imbruvica)
  - Venetoclax (Venclexta)
  - Acalabrutinib (Calquence)

## Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) is a myeloproliferative disorder with malignant clonal expansion and pathogenic leukemogenesis. It is defined by a translocation of chromosomes 9 and 22 (the Philadelphia [Ph] chromosome) with the resultant formation of a fusion gene product *bcr-abl* (Figure 1). In 2001, management of the disease changed dramatically with the approval and clinical use of imatinib mesylate (Gleevec), the first tyrosine kinase inhibitor (TKI) targeting the BCR-ABL1 oncoprotein.

### Epidemiology and Risk Factors

The worldwide incidence of CML is 1 to 2 cases per 100,000 adults. In the United States, the disorder accounts for approximately 11% to 15% of all new adult cases of leukemia annually. CML is predominately a disorder of adults with a median age at diagnosis of 55 to 60 years. The disease has a slight predominance to males, with a male-to-female ratio of 1.4 to 1.0. The number of patients living with CML is expected to continually increase as a result of successful management of the disorder with TKI therapy. Other than prior radiation exposure, little is known regarding potential risk factors. No specific genetic or familial predisposition to the pathogenesis of CML has been identified.

### Pathogenesis

The reciprocal translocation between chromosomes 9 and 22 giving rise to the Ph chromosome is key to the pathogenesis of CML. There is an exchange of genetic material with a portion of the Abelson murine leukemia (*abl1*) gene on the long arm of chromosome 9 relocating next to the breakpoint cluster region (*bcr*) on the long arm of chromosome 22. The presence of the newly formed Ph chromosome (t(9;22)(q34;q11.2) is a characteristic

rearrangement seen in approximately 95% of CML cases. This leads to the creation of a hybrid oncogene *bcr-abl1*, which in turn translates into a BCR-ABL1 protein. There are three distinct breakpoint regions in the *BCR* gene, and each one is associated with a unique disease phenotype. The transcript from the most common breakpoint region (major breakpoint cluster region [M-BCR]) is translated into the p210BCR-ABL1 oncoprotein with the molecular consequence of constitutive tyrosine kinase activity. This leads to activation of signal-transduction proteins and upregulation of several key signaling pathways (RAS, JAK/STAT, and PI-3-kinase) with consequential alterations in cellular proliferation, differentiation, adhesion, and survival.

The clinical course of CML can be divided into three distinct phases of the disorder: the chronic phase, in which the vast majority (90% to 95%) of patients are diagnosed, or the more aggressive accelerated and blast phases. The malignant clone acquires additional mutations with time with subsequent progression to the advanced phases of CML. The aberrations most commonly seen at the chromosomal level include trisomy 8, amplification of t(9,22), abnormalities in chromosome 17, trisomy 19, trisomy 21, and monosomy 7, which if present at diagnosis may have a negative prognostic impact on survival. Changes at the molecular level (e.g., *bcr-abl1* kinase domain mutations) are associated with clinical resistance to TKI therapy.

### Clinical and Laboratory Characteristics

The malignant disorder of hematopoietic stem cells produces marked myeloid hyperplasia in the bone marrow and resultant uncontrolled proliferation of myeloid cells, erythroid cells, and platelets in the peripheral blood. Up to 50% of CML patients in the United States are asymptomatic at diagnosis and have abnormalities only noted on routine physical examination or with the presence of abnormalities on a complete blood count (CBC). Clinical manifestations seen at presentation include fatigue, weight loss, splenomegaly leading to abdominal fullness and early satiety, malaise, and acute gouty arthritis. Laboratory findings include a markedly elevated white blood cell count (~100,000/ $\mu$ L) with a differential consisting of various stages of granulocyte maturation from myeloblasts to mature neutrophils. There is presence of absolute basophilia and often associated absolute eosinophilia. The findings of an elevated platelet count and anemia can be seen at presentation in approximately 20% to 30% and 50% of patients, respectively. High levels of lactate dehydrogenase (LDH) and uric acid can be seen as a result of increased cellular turnover associated with the disorder.

Without therapy, a patient in the chronic phase of CML will eventually progress to the more aggressive phases in 3 to 5 years. A consensus is lacking on the definition of accelerated phase; however, common features include an increase in the number of peripheral blood myeloblasts and basophils, development of low platelet counts, or discovery of additional clonal cytogenetic abnormalities. The definition of *blast phase* by the International Bone Marrow Transplant Registry (IBMTR) uses criteria of at least 30% blasts in the peripheral blood or bone marrow, or the presence of extramedullary infiltrates of the clonal leukemic cells. The blast phase of CML presents clinically like acute leukemia (30% having a lymphoid morphology, 60% as acute myeloblastic leukemia, and the remainder as megakaryocytic or undifferentiated) with worsening constitutional symptoms, anemia, and bleeding tendencies.

### Diagnosis

Clinical suspicion of a CML diagnosis is made from a patient presenting with the typical laboratory abnormalities with or without any physical manifestations (see the Current Diagnosis box earlier in this chapter). Examination of a peripheral blood smear reveals increased neutrophils and immature circulating myeloid cells, increased basophils and eosinophils, a normal to increased number of platelets, and possible normocytic anemia. Obtaining a bone marrow examination with aspirate is essential in the initial workup of a CML patient to appropriately stage the

**Figure 1** Schematic of the formation of Philadelphia chromosome (the new chromosome 22) and its physiological consequences. (From Chen, et al. *Protein Kinase Inhibitors as Sensitizing Agents for Chemotherapy*, Fig. 2.1. Elsevier, 2019.)

disorder and to assess for the presence of the Ph chromosome by cytogenetics. The routine cytogenetic study is valuable to evaluate for clonal evolution denoted by the presence of additional karyotypic changes, which may poorly affect prognosis. Utilizing fluorescence in situ hybridization (FISH) or reverse transcriptase polymerase chain reaction (RT-PCR) amplification studies for the detection of the *bcr-abl1* hybrid gene or its transcripts is important both as a baseline confirmatory test for CML and its continued monitoring. FISH analysis has the ability to detect the *bcr-abl1* molecular anomaly using specific probes targeting the chimeric oncogene among interphase nuclei in the peripheral blood. Qualitative RT-PCR can reveal the presence of *bcr-abl1* transcripts, whereas continued monitoring of CML patients for the amount of residual disease can be assessed by obtaining quantitative RT-PCR levels. The techniques involving FISH analysis and RT-PCR have both demonstrated high concordance in simultaneous sampling of peripheral blood and bone marrow specimens.

#### Differential Diagnosis

At presentation, CML can be routinely differentiated from leukemoid reactions, which typically have lower white blood cell counts, absence of basophilia, and presence of Döhle bodies and toxic vacuolation of granulocytes. Temporary extreme neutrophilia and associated left shift can be present after corticosteroid use. The detection of *bcr-abl1* can aid in differentiating CML from other myeloproliferative disorders (essential thrombocytosis, polycythemia vera), chronic neutrophilia leukemia, chronic myelomonocytic leukemia, chronic eosinophilia leukemia, chronic basophilic leukemia, or myelodysplastic syndromes. Rarely, patients can have *bcr-abl1*-negative or atypical CML in which additional mutations (*CSF3R*, *KRAS/NRAS*, *SETBP1*) may be present and are associated with a poor outcome.

#### Prognosis

The introduction of imatinib mesylate and additional TKIs in the 2000s has changed a dismal prognosis of CML into a manageable chronic disorder with a near-normal lifespan. Before the current TKI-based era, the median survival for patients with CML was 5 to 7 years. Oral chemotherapeutics (hydroxyurea [Hydrea] and busulfan [Busulfex, Myleran]) and injectable interferon alfa (interferon alfa-2b [Intron A]<sup>1</sup> and peginterferon alfa-2a [Pegasys]<sup>1</sup>) were important in achieving hematologic remissions, reducing thrombotic complications, and increasing median survival. Allogeneic stem cell transplantation (allo-SCT) remains a vital option for patients with advanced phases of CML or following failure of multiple TKIs.

CML prognostic scoring systems (Sokal, Euro) have traditionally used basic hematologic data, spleen size, and age to stratify patients into risk groups. Compared with the prior conventional cytotoxic-based scoring systems (Sokal), the new EUTOS Long Term Survival (ELTS) score considers the current TKI treatment era, and age does not hold such a negative impact in the scoring.

The mainstay of managing CML is continuation of long-term TKI therapy to maintain a remission. This has resulted in most patients achieving a normal life expectancy. More recently, there has been a greater acceptance to the concept of TKI therapy discontinuation in carefully chosen patients, for example, chronic phase patients with a minimum TKI therapy duration of 3 years and sustained deep molecular remission of at least 2 years. In such patients, there is an emphasis on more frequent molecular testing and monitoring for adverse events associated with discontinuation (TKI withdrawal syndrome). The recent success of maintaining prolonged treatment-free remission (TFR) is promising. Importantly, in patients who lost a major molecular response (MMR), nearly all were able to regain their response with prompt resumption of TKI treatment.

#### Monitoring Response to Tyrosine Kinase Inhibitor Therapy

First-line TKI use in CML is aimed at achieving a maximal reduction of leukemia burden with the goal of obtaining a complete cytogenetic response within 12 months of therapy initiation. Peripheral CBCs with differential are frequently ordered until a complete hematologic response is achieved. Quantitative RT-PCR (international scale [IS]) is followed every 3 months to assess for residual *bcr-abl1* transcripts relative to *abl1* transcripts and for the degree of molecular response. Cytogenetics and FISH analysis can be helpful in patients with atypical translocations and atypical *bcr-abl1* transcripts and in those with additional chromosome abnormalities. Milestones of hematologic, cytogenetic, and molecular response to therapy and monitoring recommendations are summarized in [Tables 1 and 2](#). Testing for *bcr-abl1* kinase mutations is recommended in patients who fail to achieve a timely optimal response or display resistance/loss of response to a first-line TKI. Salvage therapy consists of alternative TKI use or consideration of allo-SCT for advanced phases of CML.

#### Treatment

There are currently four TKIs approved for first-line CML: imatinib (Gleevec), dasatinib (Sprycel), nilotinib (Tasigna), and bosutinib (Bosulif). Each of these TKI therapeutic agents are acceptable options for a patient with newly diagnosed chronic phase CML. The decision of which TKI to choose is dependent on a variety of factors including patient comorbidities, drug toxicity profile, cost, and disease characteristics.

In 2001, the development of imatinib mesylate (Gleevec) changed the treatment landscape for patients with CML. The first-generation TKI was established as the standard of care for first-line patients with chronic phase CML following the International Randomized Study of Interferon Versus STI571 (IRIS) trial. A total of 1106 patients with chronic phase CML were randomized to receive imatinib (400 mg daily) versus interferon alfa (Intron-A)<sup>1</sup> (5 million units/m<sup>2</sup> daily) plus low-dose cytarabine (Cytosar) (20 mg/m<sup>2</sup> daily for 10 days per month). At 18 months, the imatinib

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Milestones for Treating Chronic Myelogenous Leukemia Expressed as BCR-ABL1 on the International Scale

	OPTIMAL*	WARNING	FAILURE
Baseline	NA	High-risk ACA, high-risk ELTS score	NA
3 months	≤10%	>10%	>10% if confirmed within 1–3 months
6 months	≤1%	>1%–10%	>10%
12 months	≤0.1%	>0.1%–1%	>1%
Any time	≤0.1%	>0.1%–1%, loss of ≤0.1% (MMR) <sup>†</sup>	>1%, resistance mutations, high-risk ACA

\*For patients aiming at treatment-free remission, the optimal response (at any time) is BCR-ABL1 ≤0.01% (MR<sup>4</sup>). A change of treatment may be considered if MMR is not reached by 36 to 48 months.

<sup>†</sup>Loss of MMR (BCR-ABL1 >0.1%) indicates failure after TFR.

<sup>‡</sup>Not yet approved for use in the United States.

ACA, Additional chromosome abnormalities in Ph+ cells; ELTS, EUTOS long-term survival score; MMR, major molecular response; NA, not applicable; TFR, treatment-free remission.

From Hochhaus A, Baccarani M, Silver RT, et al.: European LeukemiaNet 2020 recommendations for treating chronic myeloid leukemia, *Leukemia* 34(4):966–984, 2020.

**TABLE 2** European LeukemiaNet Definitions and Monitoring Recommendations

HEMATOLOGIC RESPONSE	CYTOGENIC RESPONSE	MOLECULAR RESPONSE
<b>Definitions</b>		
Complete: Platelet count <450 × 10 <sup>9</sup> /L WBC count <10 × 10 <sup>9</sup> /L Differential without immature granulocytes and with <5% basophils Nonpalpable spleen	Complete: Ph+ 0% Partial: Ph+ <35% Minor: Ph+ 36–65% None: Ph+ >95%	Complete: transcript nonquantifiable and nondetectable Major: ≤0.10
<b>Monitoring</b>		
Check every 2 wk until complete response achieved and confirmed, then every 3 mo unless otherwise required	Check at 3 and 6 mo, then every 6 mo until complete response achieved and confirmed; thereafter every 12 mo if molecular monitoring cannot be ensured; check always for occurrence of treatment failure or unexplained cytopenia	Check every 3 mo until major response is achieved; conduct mutation analysis in case of failure, suboptimal response, or increase in transcript level

Ph, Philadelphia chromosome; WBC, white blood cell.

From Baccarani M, Saglio G, Goldman J, et al: Evolving concepts in the management of chronic myeloid leukemia: Recommendations from an expert panel on behalf of the European LeukemiaNet, *Blood* 108(6):1809–1820, 2006; Baccarani M, Cortes J, Pane F, et al.: Chronic myeloid leukemia: an update of concepts and management recommendations of European LeukemiaNet, *J Clin Oncol* 27(35):6041–6051, 2009.

arm was found to have superior outcomes including tolerability, hematologic response, complete cytogenetic response (76.2% vs. 14.5%,  $P < .001$ ), and freedom from progression to advanced phase (accelerated or blast) CML (96.7% vs. 91.5%,  $P < .001$ ). Long-term outcomes revealed that the imatinib-assigned group had an overall survival rate of 83.3%, a cumulative complete cytogenetic response rate of 83%, and a 10-year MMR rate of 93%. Because of the high crossover rate from the interferon alfa plus cytarabine arm, no comparative survival benefit was seen with use of the TKI.

The suggested starting dose of imatinib is 400 mg once daily taken with a meal. Higher doses (600 mg daily or 800 mg daily) are associated with increased toxicity without proven overall survival benefit. Although well tolerated by most patients, common side effects include superficial edema, muscle cramps, abdominal pain, nausea, rash, and diarrhea. Patients should be routinely assessed for low blood counts (cytopenias), and those with liver or kidney impairment may require closer monitoring and dose adjustments. Since its introduction, the cost of brand-name imatinib has risen from \$30,000 per year to an annual price of \$140,000, illustrating the financial toxicity associated with potential long-term TKI-based therapy for CML. Since 2015, the availability of generic imatinib has reduced the annual cost in the United States, albeit the price remains higher compared with other regions of the world.

Second-generation TKIs approved for first-line chronic phase CML include dasatinib (Sprycel), nilotinib (Tasigna), and bosutinib (Bosulif). Compared with the use of imatinib,

these agents have demonstrated faster and deeper responses as well as less disease progression to the advanced accelerated and blast phases. Thus second-generation TKIs may be the preferred choice for chronic phase CML patients with high-risk disease.

The phase III Evaluating Nilotinib Efficacy and Safety in Clinical Trials—Newly Diagnosed Patients (ENESTnd) trial evaluated the efficacy and safety of nilotinib versus imatinib in 846 newly diagnosed chronic phase CML patients. Patients in the nilotinib (300 mg twice daily) arm were shown to have improved cumulative rates of MMR (77.7% vs. 62.5%,  $P < .0001$ ) compared with imatinib 400 mg daily, with no difference in 10-year progression-free survival (86.2% vs. 87.2%). There are increased rates of ischemic heart disease, ischemic cardiovascular events, and peripheral artery disease among those treated with nilotinib, especially at a higher dose (400 mg twice daily). Additional adverse events associated with nilotinib therapy include elevation in blood glucose levels, headaches, rash, QTc prolongation, pancreatitis, and increased liver enzyme levels.

The Dasatinib versus Imatinib Study in Treatment-Naïve Chronic Myeloid Leukemia Patients (DASISION) was a randomized trial of 519 patients with first-line chronic phase CML assigned to dasatinib (100 mg daily) or imatinib (400 mg daily). Treatment with the second-generation TKI demonstrated earlier and more robust MMR rates at 3 months (84% vs. 64%,  $P < .0001$ ) and deeper molecular response with 4.5-log reduction of *bcr-abl1* transcripts (<0.0032 IS, MR<sup>4.5</sup>) (42% vs. 33%).

Dasatinib therapy is associated with less nausea, rash, and muscle aches. Patients should be monitored for potential low blood counts and the development of pleural effusions. We await longer follow-up for a recent trial, which has shown effective activity of lower-dose dasatinib (50 mg daily) with a more acceptable safety profile.

In the Bosutinib Versus Imatinib for Newly Diagnosed Chronic Myeloid Leukemia (BFORE) randomized trial, the bosutinib (400 mg daily) arm achieved significantly higher MMR rates (47% vs. 37%,  $P = .02$ ) and complete cytogenetic response rates (77% vs. 66%,  $P = .007$ ) at 12 months compared with imatinib (400 mg daily) therapy. There were similar rates of 2-year survival with both drugs. Patients taking the second-generation TKI are more likely to experience gastrointestinal adverse effects (diarrhea, liver enzyme elevation), which may necessitate dose reductions and temporary holding of the medication.

The preference of using a second-generation TKI as the initial treatment of chronic phase CML should be performed in the context of the available data, understanding the unique side-effect profile of each drug, assessing the cost-effectiveness of long-term treatment, and appropriate patient selection. The ability to achieve response milestones faster and with a deeper response (MR4.5 rates) displays the potential of using second-generation TKIs for patients in whom eventual TKI discontinuation would be considered. The lack of overall survival benefit of these agents compared with imatinib seen in clinical trials could be secondary to effective salvage therapy.

Continuation of long-term therapy with TKIs can be difficult for the patient and provides additional challenges to the treating physician. Routine monitoring for and managing TKI-associated toxicities is as vital as regular assessment of disease response. Despite many short- and long-term toxicities from TKIs graded as mild, they have resulted in poorer patient-reported quality-of-life scores and often can lead to treatment nonadherence. Newly prescribed medications should also be assessed for potential drug-drug interactions with the TKI, which may require dose adjustments.

#### Other Therapeutic Options

Patients on first-line TKI who fail to meet treatment response milestones, display intolerance to the medication, or have progression/relapse should be assessed for treatment adherence and evaluated for possible drug interaction affecting TKI metabolism. Bone marrow examination should be performed to ensure that the patient has not progressed to an advanced phase of the disease. Often acquisition of novel point mutations in *bcr-abl1* leads to treatment resistance. Determining the type of mutation guides appropriate switching to an alternative TKI. Most of the mutations displaying resistance to imatinib therapy can be overcome by the use of a second-generation TKI. These have the ability to once again achieve high rates of response, especially when compared with increased doses of imatinib (400 mg twice daily). The *T315I* mutation is a unique alteration that confers resistance to all available second-generation TKIs. Ponatinib (Iclusig), a third-generation TKI, is effective in heavily pretreated CML patients and is approved with activity displayed against the *T315I* mutation. However, the drug at the approved dose (45 mg daily) is associated with considerable risk of vascular occlusive disease, thrombotic events, heart failure, and hepatotoxicity. In an attempt to minimize toxicity, it is recommended to reduce the dose upon achieving *bcr-abl1*  $\leq 1\%$ .

In 2012, omacetaxine mepesuccinate (Synribo) subcutaneous injection was approved for patients with resistance or intolerance to two or more prior TKIs. The drug is dosed based on body surface area (1.25 mg/m<sup>2</sup>) twice daily with an induction and maintenance dosing schedule over 28-day cycles. The approval provided patients with acquired mutations, including *T315I*, an additional treatment option for their difficult-to-control disease. Treated patients should be monitored for cytopenias, bleeding, and hyperglycemia, which may necessitate dose adjustment. In 2021, asciminib (Scemblix) became the latest approved drug for

chronic-phase CML patients previously treated with two or more TKIs or for those with the *T315I* mutation. In the ASCEMBL multicenter, randomized clinical trial, asciminib at a dose of 40 mg twice daily was compared with bosutinib 500 mg once daily in the pretreated specified population. The novel agent showed an improvement in MMR rate (25% vs. 13%,  $P = 0.029$ ) compared with bosutinib in addition to a lower discontinuation rate (7% vs. 25%) as a result of adverse reactions. A second trial showed asciminib's ability to be an effective option for chronic phase CML patients presenting with the *T315I* mutation. The drug was given at 200 mg twice daily and showed an achievement of MMR at 24 weeks in 42% of the patients with the difficult-to-treat mutation status. Dose adjustments may be necessary for hematologic toxicities, hypertension, hypersensitivity reactions, and pancreatic toxicity.

As the only curative option for patients with CML, an evaluation for allo-SCT candidacy is appropriate if optimal response is not achieved after two or more TKIs as a result of resistance, drug intolerance, or inadequate response to newer agents for those harboring the *T315I* mutation. Patients with accelerated phase CML are treated initially with TKI therapy (second or third generation preferred) and early consideration of allo-SCT based on a lack of optimal response. Blast phase CML requires a more aggressive combined approach using the newer-generation TKIs and intensive chemotherapy, followed by immediate allo-SCT in responders. For the advanced phases of the disease, TKI therapy is typically administered at a higher starting dose: imatinib 600 mg daily for accelerated phase and 800 mg daily for blast phase, dasatinib 140 mg daily, nilotinib 400 mg twice daily, bosutinib 500 or 600 mg daily, and ponatinib 45 mg daily. A list of potential palliative options includes hydroxyurea, hypomethylating agents, cytarabine, and busulfan. Unfortunately, survival in end-phase CML is measured in months.

#### Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is a chronic, mature B-cell neoplasm and is the most common type of leukemia in Western countries. CLL is a heterogeneous disease, and not all patients require treatment at the time of diagnosis, as randomized trials have failed to demonstrate a survival advantage with early treatment strategies. Molecular profiling and whole-exome sequencing have led to improved understanding of the pathogenesis of CLL and significant improvements in our therapeutic approach. Historically, therapy for CLL included alkylating agents, purine analogues, and CD20-directed monoclonal antibodies. However, the treatment approach to CLL has rapidly evolved over the past several years with the advent of targeted agents such as Bruton tyrosine kinase (BTK) inhibitors, B-cell leukemia/lymphoma 2 (BCL2) inhibitors, and phosphoinositide 3-kinase (PI3K) inhibitors. The development of such agents has led to significant improvement in outcomes for these patients including those with high-risk genomic aberrations that had historically been resistant to standard chemotherapies.

#### Epidemiology and Risk Factors

CLL accounts for approximately 30% of all leukemias in the United States. It is a disease of older adults with a median age at diagnosis of 70 years. CLL occurs more commonly in men than in women, with a male-to-female ratio of approximately 1.7 to 1. The incidence of CLL also varies by race, with a higher incidence in Caucasians. Furthermore, the incidence of CLL in Asian countries is quite low. Although the exact reasons racial disparities exist are not clear, it appears that genetic factors are the most likely explanation. CLL does appear to be seen at a higher frequency among those with a first-degree family member with CLL. There are no clearly identified environmental or occupational risk factors. Most cases of CLL are preceded by development of monoclonal B-cell lymphocytosis (MBL). However, despite the presence of MBL, only a small portion of patients will progress to CLL at a rate of 1% to 2% per year.

### Pathogenesis

CLL is a disease of clonal B-cell lymphocytes arrested in B-cell differentiation. The pathogenesis of CLL is complex, and many steps in the developmental pathway have yet to be elucidated. Nevertheless, the development of CLL appears to follow a two-step process in which one first develops MBL due to an unknown event (i.e., gene mutation, epigenetic changes, cytogenetic abnormalities, antigenic stimulation) resulting in proliferation of a clone of B cells. A second event or “hit” occurs (i.e., further cytogenetic changes), leading to accumulation of the malignant clone and subsequent progression to CLL. Malignant cells accumulate as a result of their inability to undergo apoptosis. This is thought to be mediated by overexpression of anti-apoptotic proteins such as BCL2. The exact cell of origin likely differs among cases specifically related to the mutational status of the immunoglobulin variable region genes. FISH detects chromosomal abnormalities in 70% to 80% of patients with CLL, and certain genetic abnormalities are clearly associated with disease prognosis (discussed later in this chapter). Furthermore, it appears that karyotypic abnormalities are acquired throughout the disease course, and such clonal evolution has been associated with progressive disease.

### Clinical Manifestations

The clinical manifestations of CLL vary widely, with most patients displaying no clinical symptoms and diagnosis made by routine blood counts showing lymphocytosis. Persistent lymphadenopathy is another common presenting symptom and is present in up to 90% of patients. The spleen is the most commonly enlarged lymphoid organ, and splenomegaly is detected in up to 50% of patients. Splenomegaly can lead to a variety of clinical symptoms including abdominal discomfort or early satiety contributing to poor oral intake and weight loss. Up to 10% of patients may present with “B” symptoms such as unintentional weight loss (10% or more of body weight within previous 6 months), fevers not associated with infection, drenching night sweats, and/or profound fatigue. Importantly, patients with CLL are immunocompromised and can present with recurrent infections. Autoimmune complications of CLL should be considered including hemolytic anemia, immune thrombocytopenia, and pure red cell aplasia, to name a few. Anemia and thrombocytopenia are findings consistent with advanced disease.

### Diagnosis

A diagnosis of CLL is suspected when a patient presents with lymphocytosis with an absolute lymphocyte count greater than 5000/ $\mu$ L. Subsequent peripheral blood flow cytometry

demonstrates immunophenotypic evidence of a monoclonal B-cell population that coexpresses the T-cell antigen CD5 and B-cell surface antigens CD19, CD20 (usually low/dim expression), and CD23 (Table 3). Typically, there is a low level of surface membrane immunoglobulin (most often IgM) along with a single immunoglobulin light chain, kappa, or lambda, which confirms the clonal nature. The presence of a monoclonal B-cell population with the same immunophenotypic profile but with an absolute lymphocyte count less than 5000/ $\mu$ L is termed MBL. Bone marrow aspirate and biopsy are not required for the diagnosis of CLL but may be helpful in certain circumstances.

### Differential Diagnosis

Peripheral lymphocytosis can occur in viral or other infectious processes, and immunophenotyping by peripheral flow cytometry is helpful to distinguish between reactive and malignant causes and allows one to establish the diagnosis of CLL. Caution must be taken to differentiate from other low-grade B-cell malignancies (see Table 3). Importantly, one must distinguish mantle cell lymphoma from CLL. As CLL expresses CD23, MCL is typically CD23 negative and is characterized by strong expression of cyclin D1. A lymph node biopsy should be pursued when immunophenotyping of the peripheral blood fails to yield a diagnosis.

### Prognosis

Although most patients with CLL are diagnosed with early-stage disease, the prognosis and clinical course is highly heterogeneous. Historically, risk stratification using the Rai or Binet clinical staging systems have been the mainstay of predicting prognosis in clinical practice (Tables 4 and 5). Over the past several years, our understanding of the molecular biology and underlying genetic aberrations in CLL have led to complementary prognostic variables to predict survival, which are widely used in clinical practice today. FISH testing to identify cytogenetic aberrations before treatment has allowed for more robust risk stratification. Specifically, deletion of 13q and trisomy 12 are favorable prognostic abnormalities, whereas deletion of 17p and 11q are higher-risk abnormalities. Deletion of 17p and/or aberrations in *TP53* predict an aggressive disease course and refractoriness to conventional chemoimmunotherapy regimens. The mutational status of immunoglobulin heavy-chain variable genes (*IGHV*) is also associated with survival. Unmutated *IGHV* genes have a more aggressive clinical course and shorter survival compared with those with mutated

**TABLE 3** Differential Diagnosis of Chronic Lymphocytic Leukemia by Immunophenotype

DISEASE	CD5	CD10	CD20	CD23	SURFACE IMMUNOGLOBULIN	OTHER
Chronic lymphocytic leukemia	+	-	+ (dim)	+	+ (dim)	
B-cell prolymphocytic leukemia	±	-	+	±	+ (bright)

Splenic marginal zone lymphoma	±	-	+	±	+ (bright)	

**TABLE 4** Rai Staging System for Chronic Lymphocytic Leukemia

RISK	STAGE	CLINICAL DESCRIPTION
Low	0	Lymphocytosis
Intermediate	I	Lymphocytosis + lymphadenopathy
	II	Lymphocytosis + hepatomegaly or splenomegaly (± lymphadenopathy)
High	III	Lymphocytosis + anemia (Hb <11 g/dL)
	IV	Lymphocytosis + thrombocytopenia (<100,000/ $\mu$ L)

**TABLE 5** Binet Staging System for Chronic Lymphocytic Leukemia

STAGE	CLINICAL DESCRIPTION
A	Two or less lymphoid areas enlarged
B	Three or more lymphoid areas enlarged
C	Anemia (<10 g/dL) or thrombocytopenia (<100,000/ $\mu$ L)

*IGHV* genes. Other prognostic factors have also been identified such as lymphocyte doubling time, Beta-2 microglobulin levels, expression of CD38 by flow-cytometry, and ZAP-70 expression in addition to clinical factors (i.e., age, sex, performance status). The CLL-IPI score has been validated by several groups and uses five independent prognostic factors: *TP53* deletion and/or mutation, *IGHV* mutational status, serum B2-microglobulin concentration, clinical stage, and age. This has identified four distinct prognostic subgroups with 5-year overall survival rates ranging from 93% in the low-risk group to 23% in the very-high-risk group. More recently, the International Prognostic Score for Early-stage CLL (IPS-E) scoring system has been developed to predict time to first treatment in early-stage, asymptomatic patients. This system identified three covariates independently correlated with time to first treatment including unmutated *IGHV* genes, absolute lymphocyte count greater than 1500/ $\mu$ L, and the presence of palpable lymphadenopathy. However, it should be noted that none of these prognostic scoring systems have yet to affect the decision of when to initiate therapy.

### Treatment

Not all patients with CLL require treatment at the time of diagnosis. In fact, recent data suggest that although early therapy for high-risk, asymptomatic patients postpones the development of active disease, there is increased toxicity associated with therapy and no clinical data to suggest that such outcomes lead to improved long-term survival. Thus CLL-directed treatment is only indicated for those with active disease as defined by the International Workshop on Chronic Lymphocytic Leukemia Treatment (i.e., progressive marrow failure, symptomatic splenomegaly, bulky lymphadenopathy, rapid lymphocyte doubling time, and/or constitutional symptoms). Therapy for patients with active disease has rapidly evolved over the past several years. It is important to note, however, that patients with advanced CLL are not cured with conventional therapy, thus treatment is directed at alleviating symptoms, improving quality of life, and prolonging survival. With the incorporation of monoclonal antibodies into standard therapy with purine analogues, we began to see significant improvements in patient outcomes, with prolonged remissions in some patients. Additionally, the development of BTK and BCL2 inhibitors has yielded a significant advancement in the treatment of advanced-stage CLL leading to deep remissions, prolonged progression-free survival, and improved overall survival. Importantly, such therapies have

yielded marked improvement in outcomes in patients with high-risk disease who historically do not respond or relapse soon after conventional chemoimmunotherapy. Nevertheless, CLL remains an incurable disease, short of allo-SCT.

### First-Line Therapy

The choice of first-line therapy in CLL should be made based on patient characteristics and patient preferences/goals as well as on tumor characteristics. Typically, the preferred initial therapy depends on genetic risk stratification and the patient's ability to tolerate therapy. Genetic risk stratification is typically based on *IGHV* mutational status and the presence of 17p deletion or *TP53* mutation. Patients with *IGHV*-unmutated disease with or without 17p deletion or *TP53* mutations are typically treated with targeted agents such as BTK inhibitors or BCL2 inhibitors with or without monoclonal antibodies. For those with *IGHV*-mutated disease without 17p deletions or *TP53* mutations, conventional chemoimmunotherapy and targeted therapy remain treatment options, with no single agreed-upon standard treatment.

First-line therapy with fludarabine (Fludara), cyclophosphamide (Cytoxan), and rituximab (Rituxan) (FCR) has historically been the most commonly used chemoimmunotherapy combination. The addition of rituximab (Rituxan) to fludarabine and cyclophosphamide represented significant progress in the treatment of CLL, with an overall response rate approaching 95% and a complete response rate of 70%. FCR remains an acceptable initial treatment option for younger patients with active disease, specifically those with *IGHV*-mutated disease who do not harbor 17p deletions or *TP53* mutations. For older adult patients (>65 years of age) or those who cannot tolerate FCR, the combination of bendamustine (Treanda) and rituximab (Rituxan) (BR) offers similar efficacy with improved tolerability compared with FCR. Again, BR is a reasonable first-line therapy for those with *IGHV*-mutated disease without a 17p deletion or *TP53* mutation only.

BTK inhibitors such as ibrutinib (Imbruvica) and acalabrutinib (Calquence) and the BCL2 inhibitor venetoclax (Venclexta) are highly effective therapies that have been shown to improve progression-free survival and overall survival. In patients with high-risk disease (17p deletion and/or *TP53* mutations or *IGHV* unmutated), treatment with targeted agents are preferred given improved outcomes demonstrated in multiple clinical trials. In those with standard-risk disease (*IGHV*-mutated without 17p deletion or *TP53* mutation), chemoimmunotherapy and targeted agents appear to be similar in efficacy, and the choice of which agent to use must be individualized. There remains a lack of clinical data directly comparing targeted agents, and the choice of which agent to use must be based on patient preferences and comorbidities. Of note, data from a recent phase III study comparing ibrutinib to acalabrutinib (Calquence) in patients with previously treated disease shows similar efficacy but fewer cardiovascular adverse events with acalabrutinib. Based on this, acalabrutinib is approved by the U.S. Food and Drug Administration (FDA) as initial or subsequent treatment for adults with CLL. Thus options include single-agent ibrutinib (Imbruvica) with or without rituximab (Rituxan) or obinutuzumab (Gazyva) for younger patients or the combination of venetoclax plus obinutuzumab (Gazyva) or

acalabrutinib (with or without obinutuzumab). Although the combination of ibrutinib plus venetoclax has shown promise in early studies, this is not yet recommended in routine clinical practice.

### Other Therapeutic Options

Treatment of relapsed disease in those who achieve at least a partial remission to first-line therapy requires assessment of time to progression from prior therapy. Early relapse is considered for those who experience disease progression at a shorter interval than the median expected for that treatment (i.e., within 5 to 6 years of targeted therapy and 2 to 3 years of FCR). Targeted therapy with *BTK* inhibitors or *BCL2* inhibitors is the preferred treatment at the time of relapse, with the choice of therapy depending on numerous factors including patient preferences, comorbidities, and first-line therapy received. Additionally, PI3K inhibitors idelalisib (Zydelig) plus rituximab and duvelisib (Copiktra) have gained FDA approval for patients with relapsed CLL after one or two prior lines of therapy, respectively.

Hematopoietic stem cell transplantation remains the only curative therapy for CLL; however, the ideal timing is not clear, and data are limited in nature. Perhaps more important is the associated considerable treatment-related morbidity and mortality. Chimeric antigen receptor T-cell (CAR-T) therapy has been investigated in patients with relapsed or refractory CLL and has shown promising activity in early-phase studies with complete response rates in the largest series of ~28%. Further work is needed to better define the role of CAR-T therapy in patients with relapsed CLL. Patients with relapsed CLL should be encouraged to participate in ongoing clinical trials.

### Complications

The most common complications that occur in patients with CLL are related to intrinsic immune dysfunction. Specifically, patients with CLL have abnormal immune responses and thus are at a high risk for infectious complications. Infections are the major cause of mortality in patients with CLL, and patients with recurrent major bacterial infections should be considered for intravenous immunoglobulin therapy (IVIg) (Gammagard S/D). Anemia can be related to direct bone marrow infiltration or hypersplenism. In such circumstances, CLL-directed therapy results in improvement in anemia. Additionally, autoimmune hemolytic anemia and pure red cell aplasia can also occur. Similarly, thrombocytopenia may be related to autoimmune destruction, hypersplenism, or disease burden. CLL transformation to aggressive B-cell lymphomas (most commonly diffuse large B-cell lymphoma), called Richter's transformation, is seen in 5% to 10% of patients. Patients with CLL have a higher risk of secondary malignancies, both hematologic and solid tumors. A retrospective review of the Surveillance, Epidemiology and End Results (SEER) program showed that ~11% of patients with CLL developed a secondary solid tumor. Thus appropriate screening must be undertaken in this population.

## DISSEMINATED INTRAVASCULAR COAGULATION

Method of

Kenneth Byrd, DO

### CURRENT DIAGNOSIS

- Disseminated intravascular coagulation (DIC) is an abnormal activation of the coagulation system that is caused by predisposing conditions such as sepsis, malignancy, and trauma.
- Clinical manifestations include organ injury due to microvascular thrombosis and less commonly macrovascular thrombosis. DIC can alternatively present with severe bleeding.
- Laboratory findings include thrombocytopenia, elevated D-dimer, elevated international normalized ratio (INR) and partial thromboplastin time (PTT), and sometimes decreased fibrinogen.
- The International Society on Thrombosis and Haemostasis (ISTH) scoring system predicts overt DIC if score  $\geq 5$ .

### CURRENT TREATMENT

- Aggressive and prompt treatment of the underlying condition causing DIC is paramount.
- If the patient is bleeding or undergoing a procedure, aggressive transfusion support with platelets and fresh frozen plasma (FFP) or cryoprecipitate is often advised.
- Unless the patient is bleeding or undergoing a procedure, FFP or cryoprecipitate is usually not indicated, and platelets are only transfused if less than  $20 \times 10^9/L$ . The major exception is acute promyelocytic leukemia (APL).
- Prophylactic low-molecular-weight heparin (LMWH) is often indicated in DIC.
- Therapeutic heparin/LMWH is rarely indicated in DIC unless there is clear evidence of a severe prothrombotic state.
- No other treatments are routinely used for DIC, including antithrombin, activated protein C, antifibrinolytics, and thrombomodulin. However, the role of these agents continues to be evaluated.

### Introduction

Disseminated intravascular coagulation (DIC) is a complex and often life-threatening manifestation of an acquired disease process. This process is initiated by a strong procoagulant cascade that leads to microthrombi throughout the vasculature. A risk of hemorrhage often follows due to a depletion of platelets, consumption of coagulation factors, and accelerated plasmin formation.

### Epidemiology

DIC has been reported in approximately 10% to 20% of critical care admissions. It is an independent predictor of mortality and the risk of death in a patient with sepsis is doubled when accompanied by DIC. Mortality rates vary based on the scoring system used but can be as high as 46%. The mortality rate appears to correlate with the severity of laboratory abnormalities at diagnosis.

### Pathophysiology

DIC is primarily a coagulation dysfunction due to excessive procoagulant activity. The overactivation is multifactorial but is mainly due to the generation of excessive thrombin, which is mediated by the extrinsic pathway involving tissue factor and factor VIIa. Thrombin excess leads to increased platelet aggregation

and thrombotic occlusion of small and midsize vessels with fibrin. Vascular occlusion leads to the derangement of oxygen supply and tissue demand, which can compromise multiple organs. This effect is compounded by defects in inhibitors of coagulation along with fibrinolytic suppression. Antithrombin activity is diminished due to increased consumption, degradation, and impaired synthesis. Likewise, protein C, tissue factor-pathway inhibitor (TFPI), and thrombomodulin activity are decreased in part due to excess inflammatory cytokines. Fibrinolytic suppression occurs in many instances of DIC due to an increase in plasminogen activator inhibitor-1 (PAI-1), which is the principal inhibitor of the fibrinolytic system.

The excessive activation of the coagulation pathway predictably leads to the depletion of platelets and clotting factors. However, the cause of bleeding in DIC is multifactorial, including consumption of clotting factors, thrombocytopenia, platelet dysfunction, endothelial damage, and excess fibrin degradation products (FDPs) that cause feedback anticoagulant effect.

### Clinical Manifestations

The manifestations of DIC are often obscured by the underlying causative etiology. Many times, the diagnosis of DIC is solely laboratory based without any clear clinical manifestations. At other times, DIC may be overtly symptomatic. Recently, it has been suggested that DIC could be divided into clinical subtypes that include asymptomatic, bleeding, and organ failure types. The presentation depends on whether there is a predominance of thrombosis from excessive thrombin activation or bleeding from consumptive coagulopathy.

Overall, the incidence of major bleeding in DIC is 5% to 12%. DIC that presents with acute bleeding is most commonly seen in acute leukemia, obstetric disorders, and trauma. Typical hemorrhagic features of DIC include bleeding from venipuncture sites or indwelling catheters, generalized ecchymosis that develops spontaneously or with minimal trauma, bleeding from mucous membranes, unexpected and major bleeding from around drain sites or tracheostomies, and concealed hemorrhage in serous cavities such as retroperitoneal hemorrhage.

Thrombotic organ failure type of DIC is most commonly seen with sepsis. The incidence of organ involvement secondary to thrombosis is 10% to 40%. This occurs due to thromboses in small and midsize vessels. Many organs can be involved, but it is most commonly seen in the kidneys, lungs, liver, and brain. This can manifest as respiratory distress syndrome, acute kidney injury, confusion, and seizures. The skin can also be involved and present as purpura fulminans or acral ischemia. Macrovascular thrombosis such as venous thromboembolism may present as a later manifestation. COVID-19 frequently presents with a DIC-like coagulopathy. Unlike classic acute DIC, fibrinogen is often elevated and there is excessive thrombotic risk.

### Diagnosis

Making the diagnosis of DIC starts with identifying an underlying associated disease state. [Table 1](#) lists the known risk factors for DIC. Once this is established, the diagnosis entails a combination of laboratory values along with an analysis of the clinical presentation. The difficulty with diagnosing DIC is that there is no gold standard and no pathognomonic test. There have been several scoring systems developed for DIC to assist in standardizing the diagnosis. The most commonly utilized is the International Society on Thrombosis and Haemostasis (ISTH) scoring system, which was originally devised in 2001 and has been subsequently validated. The scoring system is outlined in [Table 2](#). A score of  $\geq 5$  suggests overt DIC. A score of  $< 5$  indicates a lack of DIC or nonovert DIC (i.e., subtle and compensated hemostatic dysfunction). The ISTH scoring system has a sensitivity of 93% and a specificity of 98%. Most other available scoring systems are more sensitive but less specific for DIC. Importantly, if DIC is suspected but not confirmed, then labs should be repeated to assess trends.

The decreased platelet count in DIC is due to excessive thrombin activation and is almost always less than  $100 \times 10^9/L$  and often

**TABLE 1** Risk Factors for Disseminated Intravascular Coagulation (Incidence of Disseminated Intravascular Coagulation Per Etiology)

- Sepsis (35%)
  - Most commonly bacterial
- Severe trauma (up to 50%)
  - Most commonly brain injury or burns
- Malignancy
  - Metastatic cancer (up to 20%)
  - Acute leukemia (15%)
  - Acute promyelocytic leukemia (90%)
  - COVID-19
- Obstetrical
  - Placental abruption
  - Amniotic fluid embolism
  - Postpartum hemorrhage
  - Acute fatty liver of pregnancy
- Vascular malformations
  - Kasabach-Merritt syndrome
  - Large aortic aneurysms
  - Other large vascular malformations
- Severe immunologic reaction
  - Acute hemolytic transfusion reaction
  - Anaphylaxis
- Heat stroke
- Postcardiopulmonary resuscitation

**TABLE 2** International Society on Thrombosis and Haemostasis Scoring System

Platelet count  $\times 10^9/L$

- $\geq 100 = 0$
- $< 100 = 1$
- $< 50 = 2$

Fibrin marker levels (D-dimer, fibrin degradation products)

- No increase = 0
- Moderate increase ( $>ULN$  but  $<5 \times ULN$ ) = 2
- Strong increase ( $\geq 5 \times ULN$ ) = 3

Prothrombin time

- $< 3$  s (\*INR  $< 1.3$ ) = 0
- $\geq 3$  but  $< 6$  s (\*INR 1.3–1.5) = 1
- $\geq 6$  s (\*INR  $\geq 1.6$ ) = 2

Fibrinogen

- $> 100$  mg/dL = 0
- $\leq 100$  mg/dL = 1

\*Assuming the International Survey Index value of the thromboplastin reagents used is close to 1

- A score of  $\geq 5$  points is compatible with overt DIC
- The scoring system is only appropriate in patients with an underlying disorder that can be associated with DIC
- If the score if  $< 5$  and DIC is still suspected, then consider repeating labs in 1–2 days

DIC, Disseminated intravascular coagulation; ULN, upper limits of normal.

trending down. A normal platelet count without a downward trend would essentially rule out DIC. The INR and PTT are often elevated due to consumption of coagulation factors but can be normal in up to 50% of cases. The vast majority of DIC is also marked by an increase in fibrin-related markers due to increased fibrinolysis. Traditionally, FDPs were used but have largely been replaced by D-dimer. Fibrinogen is traditionally decreased in DIC but is often normal as it frequently surpasses compensated consumption only later in the clinic course. It can also be falsely normal or even elevated as it is an acute phase reactant. It is only rarely severely diminished. A fibrinogen level of  $< 100$  mg/dL is seen in  $< 50\%$  of DIC and usually reflects the late, severe, consumptive stage of DIC.

Thromboelastography (TEG) and rotational thromboelastometry (ROTEM) testing have been evaluated to assess overall coagulation, including platelet function, and clot dissolving potential.

**TABLE 3** Differential Diagnosis of Disseminated Intravascular Coagulation

DISEASE	SIMILARITIES	DIFFERENCES	COMMENTS
Liver disease	Low plt; prolonged PT/PTT; low fibrinogen; increased FDP (DIC > Liver disease)	No schistocytes in liver disease; worsening labs in DIC and more stable in liver disease	Factor VIII not very helpful for differentiation. Normal or elevated in liver disease (not synthesized in liver). However, as an acute phase reactant, often normal or elevated in DIC
Thrombotic microangiopathy (TMA)	Low plt; increased FDP (DIC > TMA); decreased ADAMTS13 (TMA lower than DIC)	MAHA in TMA; normal PT/PTT and fibrinogen in TMA; numerous schistocytes common in TMA, but not DIC	Extremely low plt with normal PT/PTT is common in TMA but unusual in DIC; TMA includes TTP, HUS, secondary TMAs
Heparin-induced thrombocytopenia (HIT)	Low plt, increased FDP	Normal PT/PTT in HIT; low fibrinogen unusual in HIT	Plt <20 × 10 <sup>9</sup> /L is uncommon in HIT
Catastrophic antiphospholipid syndrome (CAPS)	Low plt; increased FDP; PTT elevation (false elevation of PTT commonly due to LA)	Normal PT in CAPS; lab diagnosis of APLS in CAPS	Normal plt often seen in CAPS and severe thrombocytopenia is rare; microvascular thromboses in both; macrovascular thrombosis is a more common initial presentation of CAPS than DIC
Hemophagocytic lymphohistiocytosis (HLH)	Low plt; prolonged PT/PTT; low fibrinogen; increased FDP	HLH with very high ferritin, TGs, organomegaly, and often hemophagocytosis	

APLS, Antiphospholipid antibody syndrome; DIC, disseminated intravascular coagulation; FDP, fibrin degradation products; LA, lupus anticoagulant; MAHA, microangiopathic hemolytic anemia; plt, platelet count; PT, prothrombin time; PTT, partial thromboplastin time; TG, triglycerides; TTP, thrombotic thrombocytopenic purpura.

TEG has demonstrated good correlation with clinically important organ dysfunction and survival, although its advantage over usual coagulation assays has not yet been confirmed. The role of these two modalities in DIC is still unclear.

DIC often presents with a small population of schistocytes. If the red blood cell population is > 10% schistocytes, then an alternative diagnosis is more likely (i.e., TMA). Of note, a low ADAMTS13 can be seen in DIC but is usually >30%. There is also frequently a reduction in antithrombin and protein C. These tests are not done routinely and are likely not as sensitive as the ISTH scoring system. Finally, factor VIII can be low in DIC due to consumption, but it can also be elevated at times as it is an acute phase reactant.

The differential diagnosis of DIC is explained in [Table 3](#).

### Therapy

The foundation of treatment for DIC is to treat the underlying disorder. If the underlying disorder is reversed, then DIC typically resolves.

During active DIC there may be a need for transfusion support. It is important to note that the following transfusion recommendations are mostly based on low-quality evidence, including expert opinion. In the presence of bleeding, platelet transfusions should be given to keep platelet count greater than 30 to 50 × 10<sup>9</sup>/L. Similarly, in the setting of invasive procedures, platelets should be maintained greater than 20 to 50 × 10<sup>9</sup>/L, depending on the risk of the procedure. Importantly, in the absence of bleeding or procedure, platelets should be transfused only if platelet count is less than 20 × 10<sup>9</sup>/L (a range of 10 to 30 × 10<sup>9</sup>/L has been proposed by various sources). The exception to this threshold would be acute promyelocytic leukemia (APL), in which platelets should be maintained greater than 30 to 50 × 10<sup>9</sup>/L even in the absence of bleeding (less commonly some suggest a 20 × 10<sup>9</sup>/L threshold).

A similar approach to the replacement of factors is indicated. If the patient is bleeding or undergoing a high risk procedure and fibrinogen is less than 150 mg/dL or PT/PTT is greater than 1.5

upper limits of normal (ULN), then fresh frozen plasma (FFP) or cryoprecipitate is recommended. Keep in mind that FFP contains all factors of the soluble coagulation system, while cryoprecipitate contains a concentrated subset of plasma factors including fibrinogen, factor VIII, von Willebrand factor, and factor XIII. The choice between FFP and cryoprecipitate is made on a case-by-case basis and can often be influenced by fluid status. The recommended dose of FFP is 15 to 30 mL/kg and cryoprecipitate is 5 to 10 units. A less frequently used option is 2 g of fibrinogen concentrate. Factor replacement is not indicated in the absence of bleeding or procedure. An exception to this threshold is APL, in which factor replacement could be considered if fibrinogen is less than 100 to 150 mg/dL, even in the absence of bleeding.

In addition to transfusion support and treatment of the underlying etiology, heparin<sup>1</sup> can be considered in a few circumstances. Most importantly, guidelines recommend prophylactic heparin or low-molecular-weight heparin (LMWH)<sup>1</sup> in the absence of bleeding as long as platelet count is greater than 20 to 30 × 10<sup>9</sup>/L, INR greater than 1.5, and fibrinogen greater than 100 mg/dL. This is especially vital in prothrombotic DIC (i.e., sepsis, solid tumor malignancy). An exception to the general use of LMWH prophylaxis is in hyperfibrinolytic DIC (i.e., APL and prostate cancer), in which more caution is advised with heparin use. Therapeutic heparin is uncommonly advised in DIC, but it can be considered in prothrombotic DIC, as evidenced by thromboembolism, purpura fulminans, or acral ischemia. As heparin can partially inhibit activation of the coagulation, it would make sense that it could help offset DIC. In small studies, heparin has shown beneficial effects on coagulation parameters. However, improvement in clinically important outcomes in DIC has not been clearly demonstrated.

Other therapies that have been studied in the treatment of DIC include antithrombin concentrate (AT [Thrombate III]),<sup>1</sup> activated protein C (APC), recombinant thrombomodulin, and

<sup>1</sup>Not FDA approved for this indication.

antifibrinolytics. Currently, these agents are rarely, if ever, indicated for use. AT and APC have been extensively studied in the setting of sepsis. One of the issues in assessing the benefit of AT and APC is that many clinical trials assess the general sepsis population and do not limit analysis to those specifically with DIC. For AT, there has been no significant reduction in mortality in these studies. However, there is a suggestion that there may be significant benefit in the subset of patients with severe sepsis and DIC. This requires prospective validation. APC has also shown promise at times, including improvement in mortality in an early randomized controlled trial (RCT). However, subsequent studies showed an increased risk of serious bleeding and lack of survival benefit. Therefore, the FDA advised to stop using APC for DIC in 2011.

Caution is advised with the use of antifibrinolytics in DIC. Since the excessive fibrin deposition appears in part to be due to insufficient fibrinolysis, further inhibition of the fibrinolytic system would clearly not be appropriate. This is especially the case in sepsis, but there are a few exceptions to this. Antifibrinolytics can be considered in hyperfibrinolytic DIC (i.e., APL or prostate cancer) only in the setting of life-threatening bleeding. The other exception is in acute trauma. A large RCT showed that early use of antifibrinolytics in trauma was beneficial. However, once the acute phase has passed, further thrombin generation eventually predominates, and the balance is tipped toward thrombosis.

Recombinant soluble thrombomodulin continues to be actively evaluated and shows some potential. While efficacy outcomes have been heterogeneous, a 2020 meta-analysis suggested a 28-day mortality benefit of recombinant thrombomodulin<sup>5</sup> in patients with sepsis and coagulopathy. Results of ongoing studies are pending.

Finally, it is worth mentioning that a Cochrane review evaluated recombinant factor VIIa (NovoSeven)<sup>1</sup> and concluded that it does not have proven efficacy in DIC and that there is an increased risk of arterial thrombotic events. Its use is not advised.

## HEMOCHROMATOSIS

Method of

Paul C. Adams, MD

### CURRENT DIAGNOSIS

- Consider the diagnosis in patients with Northern European ancestry.
- Initial testing is transferrin saturation or unsaturated iron binding capacity and serum ferritin.
- Secondary testing is the C282Y genetic test.
- More than 90% of typical hemochromatosis patients are homozygotes for the C282Y mutation.
- If genetic testing is not typical, reassess the diagnosis and consider secondary iron overload related to cirrhosis, alcoholism, viral hepatitis, or an iron-loading anemia.
- A number of other hemochromatosis genetic mutations are relevant to only a minority of patients.
- Not all patients need a liver biopsy.
- Siblings are at highest risk in a family study.

### CURRENT THERAPY

- Iron overload from hemochromatosis is treated by the weekly removal of 500 mL of blood until the serum ferritin is in the low-normal range of approximately 50 µg/L.
- Some but not all patients require maintenance therapy with three to four phlebotomies per year. In some countries, this can be a voluntary blood donation.
- Excess alcohol, high doses of vitamin C, and iron supplementation should be avoided, but strict dietary restrictions are not recommended.
- Siblings and children of patients should be tested for hemochromatosis with transferrin saturation, ferritin, and genetic testing.

Hemochromatosis is the most common genetic disease in populations of European ancestry. The diagnosis can be elusive because of the nonspecific nature of the symptoms. With the discovery of the hemochromatosis gene (*HFE*) in 1996 came new insights into the pathogenesis of the disease and new diagnostic strategies.

A fundamental issue that arose after the discovery of the *HFE* gene is whether the disease hemochromatosis should be defined strictly on phenotypic criteria such as the degree of iron overload (i.e., transferrin saturation, ferritin, liver biopsy, hepatic iron concentration, iron removed by venesection therapy), or whether the condition should be defined as a familial disease in Europeans most commonly associated with the C282Y mutation of the *HFE* gene and varying degrees of iron overload. Because the genetic test has been increasingly used as a diagnostic tool, most studies now use a combination of phenotypic and genotypic criteria for the diagnosis of hemochromatosis.

### Clinical Features

Although hemochromatosis is often classified as a liver disease, it should be emphasized that it is a systemic genetic disease with multisystem involvement. The liver is central in both diagnosis and prognosis. Hepatomegaly remains one of the more common physical signs in hemochromatosis, but it is not always present in the young, asymptomatic homozygote. In a study

of 717 homozygotes from Australia, 8% of men and 1.7% of women had cirrhosis of the liver at the time of diagnosis. The prevalence of cirrhosis in asymptomatic or screened patients is much lower. It is likely that there are factors other than iron overload that contribute to cirrhosis in hemochromatosis. These can include the effects of alcohol or comorbid genes. The effect of iron depletion therapy is usually stabilization of the liver disease, and fibrosis improves with repeat liver biopsy after iron depletion. This may account for the relatively small number of C282Y homozygotes that require liver transplantation. The other common clinical manifestations are arthralgias, pigmentation, congestive heart failure, impotence, and fatigue. Several large population studies failed to demonstrate an increase in diabetes compared with a control population. A population-based study estimated that only 28% of male and 1% of female C282Y homozygotes will develop symptoms of iron overload. A larger population-based screening study (UK Biobank) identified 2,890 C282Y homozygotes in 451,243 participants and found that male hemochromatosis patients had an odds ratio of 4.30 for liver disease and 10.5 for hepatocellular carcinoma. Women were much less affected.

### Diagnosis

A paradox of genetic hemochromatosis is that the disease is underdiagnosed in the general population and overdiagnosed in patients with secondary iron overload.

Preliminary population studies using genetic testing demonstrate a prevalence of homozygotes of approximately 1:227 among whites. The fact that many physicians consider hemochromatosis to be rare implies either a lack of penetrance of the gene (nonexpressing homozygote) or a large number of patients who remain undiagnosed in the community.

### Transferrin Saturation

Previous studies had suggested that transferrin saturation would be a good screening test and diagnostic test for hemochromatosis.

The sensitivity of transferrin saturation in population-screening studies designed to detect C282Y homozygotes (genotypic case definition) was only approximately 75%, and transferrin saturation can be in the normal range in young female homozygotes. A large biologic variation in transferrin saturation within an individual patient has also been reported.

### Serum Ferritin

The relationship between serum ferritin and total body iron stores was clearly established by strong correlations with hepatic iron concentration and the amount of iron removed by venesection. However, ferritin can be elevated secondary to chronic inflammation and histiocytic neoplasms. A major diagnostic dilemma in the past was whether the serum ferritin concentration was related to hemochromatosis or to another underlying liver disease, such as alcoholic liver disease, chronic viral hepatitis, or nonalcoholic steatohepatitis. It is likely that most of these difficult cases can now be resolved by genetic testing.

### MR Imaging

Liver MR imaging continues to advance and is ideally performed in centers with special expertise. Liver iron concentration, fat concentration, tumor detection, and fibrosis score from MR elastography can be provided with this noninvasive tool.

### Liver Biopsy

Liver biopsy was previously the gold-standard diagnostic test for hemochromatosis; however, it has shifted from a major diagnostic tool to a method of estimating prognosis and concomitant disease. The need for liver biopsy seems less clear now in the young, asymptomatic C282Y homozygote in whom there is a low clinical suspicion of cirrhosis based on history,

physical examination, and liver biochemistry. A large study conducted in France and Canada suggested that C282Y homozygotes with a serum ferritin concentration of less than 1000  $\mu\text{g/L}$ , a normal aspartate transaminase (AST) concentration, and no hepatomegaly have a very low risk of cirrhosis. C282Y homozygotes with a ferritin level greater than 1000  $\mu\text{g/L}$ , an elevated AST, and a platelet count of less than 200,000/ $\text{mm}^3$  have an 80% chance of having cirrhosis. Hepatic elastography is another noninvasive tool to assess liver fibrosis in hemochromatosis.

Patients with cirrhosis have a 5.5-fold relative risk of death compared with noncirrhotic hemochromatosis patients. Cirrhotic patients are also at increased risk of hepatocellular carcinoma. Liver biopsy is considered in typical C282Y homozygotes with liver dysfunction and in potentially iron-overloaded patients without the typical C282Y mutation. Simple C282Y heterozygotes, compound heterozygotes (C282Y/H63D), H63D homozygotes, and patients with other risk factors (e.g., alcohol abuse, chronic viral hepatitis) who have moderate to severe iron overload (ferritin > 1000  $\mu\text{g/L}$ ) may be considered for liver biopsy.

Since the introduction of genetic testing, hepatic iron concentration and hepatic iron index have become less useful in the diagnosis of hemochromatosis.

### Genetic Testing

A major advance stemming from the discovery of the hemochromatosis gene is the use of a diagnostic genetic test. Most studies report that more than 90% of typical hemochromatosis patients were homozygotes for the C282Y mutation. A second minor mutation, H63D, was also described in the original report. Compound heterozygotes (C282Y/H63D) and, less commonly, H63D homozygotes, resemble C282Y homozygotes with mild to moderate iron overload. Genetic mutations involving ferroportin, hemojuvelin, transferrin receptor 2, ceruloplasmin, and hepcidin are associated with iron overload. It is likely that, as more mutations are found, they will be relevant to only a minority of patients. Commercial tests are rarely available for these rare genetic mutations.

Some patients with clinical pictures indistinguishable from genetic hemochromatosis are negative for the C282Y mutation. Most of these cases appear to be isolated, although a few cases of familial iron overload with negative C282Y testing have been reported. A negative C282Y test should alert the physician to question the diagnosis of genetic hemochromatosis and to reconsider secondary iron overload related to cirrhosis, alcoholism, viral hepatitis, or an iron-loading anemia. If no other risk factors are found, the patient should begin phlebotomy treatment, similar to any other hemochromatosis patient.

The interpretation of the genetic test in several settings is shown in [Box 1](#). Genetic discrimination is a concern, given the widespread use of genetic testing, but discrimination has been rarely reported in screening studies. In the case of hemochromatosis, the advantages of early diagnosis of a treatable disease outweigh the disadvantages of genetic discrimination.

### Family Studies

Once the proband case is identified and confirmed with the genetic test for the C282Y mutation, family testing is imperative. Siblings have approximately one in four chance of carrying the gene and should be screened with the genetic test (C282Y and H63D mutation), transferrin saturation, and serum ferritin. A cost-effective strategy now possible with genetic testing is to test the spouse for the C282Y mutation to assess the risk in the children. If the spouse is not a C282Y heterozygote or homozygote, the children will be obligate heterozygotes, assuming paternity and excluding another gene or mutation causing hemochromatosis. This strategy is particularly advantageous if the children are geographically separated or in different health care systems.

**“C282Y Homozygote”**

This is the classic genetic pattern seen in more than 90% of typical cases. Expression of disease ranges from no evidence of iron overload to massive iron overload with organ dysfunction. Siblings have a one in four chance of being affected and should have genetic testing. For children to be affected, the other parent must be at least a heterozygote. If iron studies are normal, false-positive genetic testing or a nonexpressing homozygotic state should be considered

**“C282Y/H63D Compound Heterozygote”**

This patient carries two copies of the minor mutation. Most patients with this genetic pattern have normal iron studies. A small percentage have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (e.g., alcoholism, viral hepatitis)

**“C282Y Heterozygote”**

This patient carries one copy of the major mutation. This pattern is seen in approximately 10% of the white population and is usually associated with normal iron studies. In rare cases, the results of iron studies are high, in the range expected in a homozygote rather than a heterozygote. These patients may carry an unknown hemochromatosis mutation, and liver biopsy is helpful to determine the need for phlebotomy therapy

**“H63D Homozygote”**

Most patients with this genotype will have normal iron studies. A small percentage have mild to moderate iron overload. Severe iron overload is usually seen in the setting of another concomitant risk factor (e.g., alcoholism, viral hepatitis)

**“H63D Heterozygote”**

This patient carries one copy of the minor mutation. This pattern is seen in approximately 20% of the white population and is usually associated with normal iron studies. This pattern is so common in the general population that the presence of iron overload can be related to another risk factor. Liver biopsy is required to determine the cause of the iron overload and the need for treatment in these cases

**“No HFE Mutations”**

If iron overload is present without any mutations in the hemochromatosis gene (*HFE*), a careful history for other risk factors must be reviewed, and liver biopsy can be useful to determine the cause of the iron overload and the need for treatment. Most of these are isolated, nonfamilial cases. There are cases described involving genetic mutations in ferroportin, hemojuvelin, transferrin receptor 2, ceruloplasmin, and hepcidin genes. Genetic tests for these mutations are not widely available

**Treatment**

The treatment of hemochromatosis continues to use the medieval therapy of periodic bleeding. Blood is removed, with the patient in the reclining position over 15 to 30 minutes. Initial treatment consists of the weekly removal of 500 mL of blood. A hemoglobin test is done before each phlebotomy. If the hemoglobin concentration has decreased to less than 10 g/dL, the phlebotomy schedule is modified to 500 mL every 2 weeks. Phlebotomies are continued until the serum ferritin concentration is approximately 50 µg/L. Serum ferritin levels are drawn monthly in patients with significant iron overload and increased to weekly as the ferritin decreases to < 200 µg/L. The concomitant administration of a salt-containing sport beverage (e.g., Gatorade) is a simple method of maintaining plasma volume during the phlebotomy.

Maintenance phlebotomies after iron depletion, consisting of three to four phlebotomies per year, are performed in most patients, although the rate of iron reaccumulation is highly variable. Maintenance therapy is initiated when the serum ferritin rises from 50 µg/L to > 300 µg/L. The transferrin saturation remains elevated in many treated patients and does not normalize unless the patient becomes iron deficient. In some countries, patients with mild iron abnormalities are encouraged to become voluntary blood donors. Iron depletion has been demonstrated to improve fibrosis and reduce the risk of hepatocellular carcinoma.

Chelation therapy<sup>1</sup> is not recommended for hemochromatosis. Patients are advised to avoid oral iron therapy and alcohol abuse, but there are no dietary restrictions. Patient support groups have been concerned by the practice of iron fortification of foods, but much of this iron is in an inexpensive form with poor bioavailability.

Hemochromatosis is a common and often underdiagnosed disease. Early diagnosis and treatment result in an excellent long-term prognosis. The development of a diagnostic genetic test has improved the feasibility of the goal of prevention of morbidity and mortality from hemochromatosis.

## HEMOLYTIC ANEMIAS

Method of

Thomas G. DeLoughery, MD

### CURRENT DIAGNOSES

- Suspect hemolysis when anemia is accompanied by signs of red cell breakdown: high low-density lipoprotein (LDH) and indirect bilirubin with a low haptoglobin.
- The reticulocyte count is often high.
- A positive direct antibody test (DAT) confirms the diagnosis of autoimmune hemolytic anemia in the presence of hemolysis.
- In patients with non-immune hemolysis, specific testing is required to make the diagnosis.

At the most basic level, hemolytic anemias are caused by red cell destruction. This destruction can be caused by factors that are either intrinsic or extrinsic to the red blood cell (RBC). The pace of the hemolysis can vary from being only detectable by laboratory abnormalities to fulminant acute severe anemia. A useful way to think about hemolytic anemias is to divide them into hereditary disorders and acquired disorders (Table 1). Defects in any part of the RBC lead to inherited disorders, while acquired disorders are caused by immune-related processes and other etiologies extrinsic to the RBC.

### Pathophysiology

#### Congenital

The major components of the RBC are the membrane, hemoglobin, and enzymes; therefore the three major classes of hereditary hemolytic anemias are caused by defects in any of these three red cell components.

**TABLE 1** Hemolytic Anemia: Classification of Common Causes

#### Congenital

##### Membrane defects

Hereditary spherocytosis

Hereditary elliptocytosis

Hereditary pyropoikilocytosis

##### Enzymatic defects

G6PD deficiency

Pyruvate kinase deficiency

##### Hemoglobin defects

Sickle cell disease

Unstable hemoglobins

#### Acquired

##### Autoimmune

Warm antibody IgG

Cold antibody IgM

##### Drug-induced

Paroxysmal nocturnal hemoglobinuria

##### Mechanical

Microangiopathic

##### Toxins

Parasites

Hereditary spherocytosis is the most common hemolytic anemia caused by membrane defects. This condition is caused by mutation in the proteins that make up the red cell skeleton, which leads to an unstable membrane. The RBCs in hereditary spherocytosis initially have a normal biconcave disc structure, but after repeated passage through the spleen, they gradually lose portions of the membrane and become more spherical as they age (a process known as *splenic conditioning*). These spherocytes are less deformable and because of that are ultimately trapped and destroyed in the spleen. Less common anemias caused by membrane defects are hereditary elliptocytosis and pyropoikilocytosis. The skeletal defects are not as profound in elliptocytosis, so the clinical presentation is usually milder. Most patients with pyropoikilocytosis are homozygous for mutations that cause elliptocytosis and have very unstable red cell membranes; often fragments of RBCs are seen in the circulation.

The most common RBC enzyme defect is glucose-6-phosphate dehydrogenase (G6PD) deficiency. An adequate supply of reduced glutathione (GSH) is necessary to protect the erythrocyte from oxidative damage. G6PD catalyzes the conversion of glucose-6-phosphate to 6-phosphogluconate, in the process reducing NADP to NADPH. NADPH is necessary for the conversion of glutathione (GSSG) to reduced glutathione (GSH). The erythrocyte does not have any other source of NADPH and so is dependent solely on this pathway for reducing power. When G6PD is deficient, this leads to decreased NADPH, which results in decreased GSH. When the RBC undergoes oxidative stress, this lack of reducing power results in damage of red cell proteins, especially hemoglobin. These damaged proteins can aggregate, causing membrane damage and red cell destruction as the crystallized proteins are removed by the spleen.

Pyruvate kinase (PK) deficiency is a hemolytic anemia caused by an enzymatic defect in the glycolytic pathway. Pyruvate kinase catalyzes conversion of phosphoenolpyruvate (PEP) to pyruvate, generating ATP in the same reaction. Deficiency of PK results in decreased levels of erythrocyte ATP. Lack of ATP results in a leaky cell membrane and loss of water and potassium. This leads to cellular dehydration and rigid, nondeformable cells that are susceptible to destruction within the spleen.

By far the most common hereditary hemolytic hemoglobin defect is sickle cell anemia. The abnormal hemoglobin protein forms long polymers that disrupt red cell integrity. There are also very rare defects in hemoglobin that can cause unstable molecules that can crystallize and lead to hemolysis—most often resulting from splenic removal of damaged proteins.

#### Acquired

Autoimmune hemolytic anemias (AIHAs) can be mediated by either anti-red cell IgG or IgM antibodies. In IgG-mediated disease, the antibody binds to red cell membrane proteins. The antibody-coated RBCs are then phagocytized by macrophages found primarily in the spleen, leading to hemolysis.

In IgM-mediated hemolysis (*cold agglutinin disease*), the antibody binds to the RBC most often in the periphery of the body. The *cold* appellation comes from the fact that the antibody binds more strongly when below body temperature. Most commonly, complement is fixed only through C3, and then the C3-coated RBCs are taken up by the macrophages. In rare patients, the IgM can fix complement rapidly, leading to intravascular hemolysis by formation of the end product of complement, the membrane attack complex.

Rare patients can develop immune hemolysis induced by medication. There have been three mechanisms proposed for drug AIHA. The hapten mechanism is most often associated with the use of high-dose penicillin. High doses of penicillin lead to drug incorporation into the red cell membrane by binding to proteins. Another mechanism is the formation of an immune complex of drug, antibody, and red cell membrane which leads to hemolysis. Finally, patients taking certain drugs such as methyldopa will

develop a positive direct antibody (DAT) after 6 months of therapy and hemolysis that is indistinguishable from warm antibody AIHA.

In paroxysmal nocturnal hemoglobinuria (PNH), RBCs lack the regulatory membrane proteins that inhibit activated complement proteins. These proteins include membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55). The molecular defect in PNH is a mutation of the phosphatidylinositol glycan complementation group A (*PIG-A*) gene located on the X chromosome. This enzyme is required for synthesis of glycosyl phosphatidylinositol (GPI)-linked proteins. Cells derived from the PNH stem cells are deficient in all proteins that are linked to the membrane by a GPI molecule, including those that inactivate complement. Normally there is baseline activation of complement; it is thought that one of the functions of RBCs is inactivation of these active complement proteins. When activated complement binds PNH RBCs instead of being destroyed, the resulting membrane attack complex leads to lysis of the RBC.

Microangiopathic hemolytic anemias (MAHAs) result from destruction of circulating RBCs. Although MAHA is commonly associated with thrombotic microangiopathies such as thrombotic thrombocytopenia purpura (TTP) and hemolytic uremic syndrome (HUS), there are many other possible associated disease states. For example, patients with malignant hypertension can have very severe hemolysis resulting from increased shearing of RBCs traversing damaged glomeruli. There may also be associated thrombocytopenia, which can lead to concern that TTP may be present. Hemolysis associated with malignant hypertension resolves rapidly with control of the blood pressure. Scleroderma renal crisis is often accompanied by a MAHA due to both severe hypertension and renal damage.

Cardiac valvular disease can lead to MAHA. This is seen most commonly after mitral valve repair if there is a small defect at the site where the valve ring is sewn in. Ventricular contraction leads to a small resurgent jet that results in a high shear situation in the jet and red cell destruction. In some cases, this can result in severe hemolysis and a transfusion-dependent anemia.

Ventricular-assist devices (VADs) to support heart failure patients can also lead to hemolysis. This is blood flowing through the device being subjected to high shear rates. Most patients have low levels of hemolysis, but with VAD thrombosis there is an abrupt increase in hemolysis because of higher shear forces; an increasing LDH is an indication to look for VAD thrombosis.

Along with MAHA, there are several other syndromes which may cause mechanical damage to RBCs. *Clostridium* infections can lead to hemolysis by direct damage to red cell membranes. The bacteria secrete an alpha-toxin that has phospholipase activity and leads to the red cell membrane literally dissolving, which causes the hemoglobin to leak out of the cells. In some cases, this can be so severe that the measured hemoglobin may equal the hematocrit. Empty red cell “ghosts” may be seen on the smear.

Wilson disease may cause episodes of hemolysis along with the neurologic and hepatic disease. This is caused by large amounts of hepatic copper entering the circulation and inducing an oxidative hemolysis. The smear can show spherocytes and *bite cells* (RBCs with defects caused by splenic conditioning). The hemolysis is often transient as it is related to high levels of copper in the serum.

Spur cell anemia is a hemolytic process seen in patients with end-stage liver disease. The lipid metabolism alterations induced by severe liver disease lead to cholesterol crystal formation in the red cell membrane. These crystals are removed by the spleen and can lead to both hemolysis and deformed RBCs (*spur cells*).

### Prevention

There are a few supportive steps in patients with hemolysis. Although most food is supplemented with folate, high red cell

turnover can increase the need for this vitamin. Patients with hemolysis are often supplemented with folic acid 1 mg daily.<sup>1</sup>

A key preventive measure for those with G6PD deficiency is avoiding agents that can lead to oxidative stress of RBCs. The most complete list of medications found at <https://www.g6pd.org/> and common medications are listed in Table 2. Some rarer red cell enzymatic or hemoglobin defects are also sensitive to oxidative stress, so these medications also should be avoided in those diseases.

## Clinical Manifestations

### Inherited

The severity of congenital hemolytic anemia varies tremendously. Some children are very symptomatic right after birth, while older patients may only present with mild anemia and subtle laboratory findings. A common presentation is a burst of hemolysis with oxidative or other stressors. Hereditary hemolytic anemias are often more severe right after birth, and severity may decrease with age. Patients with congenital anemia can have presentation with extrahematologic problems. Given that the serum bilirubin is increased and more bilirubin is excreted in the bile, they may present with pigmented gallstones. Patients can present with gallbladder disease in their teens or 20s, and this should raise suspicion of a hemolytic anemia. These patients may be more prone to skin ulcers around the ankle that may not heal well.

Classically patients with congenital hemolytic anemias can develop three types of crises. The first is the *hemolytic crisis*. When patients develop fevers or encounter other stressors, the rate of hemolysis may increase, and any inflammation can suppress erythropoiesis, leading to severe anemia. The second type of crisis is the *megaloblastic crisis* in which patients become folic acid deficient because of high folate demand associated with increased red cell production. With mass supplementation of folate in the food supply, this incidence has decreased. The final crisis is the *aplastic crisis* in which RBC production is temporarily compromised and the reticulocyte count plummets. This is most commonly found with infections with

<sup>1</sup>Not FDA approved for this indication.

Sulfamethoxazole
Sulfanilamide
Sulfapyridine

There are a few supportive steps in patients with hemolysis. Although most food is supplemented with folate, high red cell

parvovirus B-19. The infection clears in most patients within 1 week, but patients often require transfusion support during this time.

Hereditary spherocytosis is most prevalent in northern European populations and occurs with a frequency of approximately 1 in 5000. The majority of cases (75%) show an autosomal dominant pattern of inheritance. The remainder result from autosomal recessive inheritance and new mutations. Common clinical features of hereditary spherocytosis include anemia, jaundice, reticulocytosis, splenomegaly, and microspherocytes. Anemia later in life is variable and usually mild. Complications include hemolytic crises, leg ulcers, and gallstones.

With hereditary elliptocytosis, the majority of patients are asymptomatic, and the frequent finding of elliptocytes on the blood smear is of no clinical consequence. However, approximately 10% to 15% of patients have significant hemolysis and may develop anemia. Mild hereditary elliptocytosis is inherited in an autosomal dominant fashion. The incidence is higher in African and Asian populations because of its beneficial impact on malarial infection. Patients with pyropoikilocytosis have severe hemolysis.

G6PD deficiency is the most common enzyme defect in humans and affects an estimated 600 million people worldwide. G6PD deficiency is transmitted as an X-linked recessive condition. There have been hundreds of G6PD variants identified. Enzymatic activity varies from normal with no clinical consequences to severe deficiency resulting in chronic hemolysis and shortened red cell life span, even in the absence of stressors. The two most common variants are the G6PD A-variant that has moderate enzyme deficiency (10% to 15% activity), and the G6PD Mediterranean mutation that has almost no detectable enzyme activity. Despite this, patients with the G6PD Mediterranean mutation have a nearly normal erythrocyte life span except under conditions of metabolic or oxidative stress.

The classic presentation of hemolysis with G6PD deficiency is with oxidative stress. For example, certain medications such as sulfonamides can lead to increased oxidative stress. Patients with G6PD deficiency cannot generate enough reducing power to overcome this stress, which leads to oxidative damage to proteins, especially hemoglobin. The patient presents with fulminant hemolysis that can lead to a severe anemia. As a result of membrane damage, the blood smear can show spherocytes and bite cells. Treatment is removing the offending agent and is otherwise supportive. A unique presentation is *favism*. After eating fava beans, an overwhelming hemolysis develops. This can be idiosyncratic and occur even in patients who have safely eaten the beans in the past.

Pyruvate kinase deficiency is inherited as an autosomal recessive condition. Anemia is variable and may range from a presentation in early infancy requiring transfusions to fully compensated hemolysis presenting with jaundice alone. Many patients have moderate anemia, jaundice, and splenomegaly. Patients with this disorder are also susceptible to the crises identified earlier. Splenectomy may be helpful in severe cases, but response is variable.

### Acquired

AIHA patients who have IgG as the offending antibody are said to have *warm antibody AIHA*. The name *warm* comes from the fact that the antibody reacts best at body temperature. The incidence varies by series but is about 1 in 100,000 patients per year, and women are more often affected than men.

Warm AIHA can complicate several diseases. Lupus patients can develop warm AIHA as part of their disease complex. Of the malignancies, the one with the strongest association with AIHA is chronic lymphocytic leukemia (CLL). Series show that 5% to 10% of patients with CLL will have warm AIHA. The disease can appear concurrently with CLL or may develop during the course of the disease.

A rare but important variant of warm AIHA is Evan syndrome. This is the combination of AIHA and immune thrombocytopenia (ITP). One to three percent of AIHA is the Evan variant. The ITP can precede, occur concurrently, or develop after the AIHA. The diagnosis of Evan syndrome should raise concern of underlying disorders. In pediatric and young adult patients, immunodeficiencies such as autoimmune lymphoproliferative disease (ALPS) must be considered. In older patients, Evan syndrome is often associated with T-cell lymphomas.

In rare patients with warm AIHA, IgA or IgM antibodies are implicated. Patients with IgM AIHA often have a severe course with a fatal outcome. Plasma may show spontaneous hemolysis and agglutination. The DAT may not be strongly positive or show C3 reactivity. The clinical clues are C3 reactivity with no cold agglutinins and severe hemolysis, sometimes with intravascular hemolysis.

In cold agglutinin disease, patients often note symptoms related to agglutination of RBCs in the peripheral circulation in addition to hemolysis. For example, acrocyanosis will be noted in cold weather. Rare patients will have abdominal pain when eating cold food resulting from ischemia related to agglutination of RBCs in the viscera. Some patients with cold agglutinins can experience exacerbation of their hemolysis with cold exposure.

In young patients, cold AIHA is often post-infectious (such as from viral and mycoplasma infections), and the course is self-limiting. The hemolysis usually starts 2 to 3 weeks after the illness and will last for 4 to 6 weeks. In older patients, the etiology in over 90% of cases is a B-cell lymphoproliferative disorder, usually with monoclonal kappa B cells. The most commonly seen are marginal zone lymphoma, small lymphocytic lymphoma, and lymphoplasmacytic lymphoma.

A unique cold AIHA is paroxysmal cold hemoglobinuria (PCH). This AIHA is most often postviral and affects children; in the past, it complicated any stage of syphilis. The antibody is IgG directed against the P antigen on the RBC. Binding is best in the "cold," but then complement is activated at body temperature. Because this antibody can fix complement, hemolysis can be rapid and severe, leading to extreme anemia.

Drug-induced AIHA is a rare drug reaction with a lower incidence than drug-related immune thrombocytopenia. The rate of severe drug-related AIHA is estimated at 1 in 1 million individuals, but less severe cases may be missed. Most patients will have positive DAT without signs of hemolysis, though rare patients will have relentless hemolysis resulting in death. With hapten-related AIHA, very few patients will have hemolysis; in these cases, the hemolysis will resolve a few days after discontinuation of the offending drug. With immune complex disease, most often the patient will only have a positive DAT, but rare patients will have life-threatening hemolysis upon exposure or reexposure. The onset of this hemolysis is rapid, with signs of acute illness and intravascular hemolysis. The classic associated drug is quinine, but many other drugs have been implicated.

A virulent form of immune complex hemolysis is associated with both disseminated intravascular coagulation (DIC) and brisk hemolysis. Patients who receive certain second- and third-generation cephalosporins (especially cefotetan and ceftriaxone) have developed this syndrome. The clinical symptoms start 7 to 10 days after receiving the drug. Often the patient has only received the antibiotic for surgical prophylaxis. Warm DAT hemolysis with an acute hematocrit decrease as well as hypotension and DIC develops. Patients are often believed to have sepsis and are then often reexposed to the cephalosporin, resulting in worsening of the clinical status. The outcome is often fatal as a result of massive hemolysis and thrombosis.

Hemolysis caused by methyldopa is indistinguishable from warm AIHA, which is consistent with the notion that methyldopa induces an autoimmune hemolytic anemia. The hemolysis often resolves rapidly after discontinuing the methyldopa, though

the Coombs test may remain positive for months. This type of drug-induced hemolytic anemia has been reported with levodopa, procainamide, and chlorpromazine.

In MAHA, the course of the presentation is dictated by the underlying cause. In valvular hemolysis, the onset of hemolysis is soon after the cardiac procedure and may require transfusion support. With VAD hemolysis, most patients have only mild hemolysis, but with pump thrombosis, the hemolysis can be severe. Patients with spur cell anemia have findings of severe liver disease: high INRs and bilirubin (mean of 9.5 mg/dL). Spur cell hemolysis is associated with an ominous prognosis and average survival of a few months.

PNH is characterized by episodes of hemolysis and a propensity for thrombosis and pancytopenia. Often patients can have PNH for years before the diagnosis is made. The hemolysis can range from being well-compensated to transfusion-dependent. Patients with PNH often have a severe thrombophilia; the leading cause of morbidity and mortality (before the release of effective therapy) has been thrombosis. The cause of the hypercoagulable state is unknown, but complement-activated platelets have been implicated.

### Diagnosis

There are two steps in the diagnosis of hemolytic anemia. The first step is determining the presence of hemolysis, and the second step is finding the cause. Hemolysis is demonstrated by evidence of both red cell breakdown as well as the compensatory increase in red cell production this stimulates. When RBCs undergo hemolysis, their contents, mostly hemoglobin and also the enzyme LDH, are released. Free hemoglobin is bound by haptoglobin, and the heme moiety is broken down, first to bilirubin and then to urobilinogen, which is excreted in the urine.

The following tests are performed to investigate hemolysis:

**LDH:** Lactic dehydrogenase is an enzyme found in high concentration in the RBC; hemolysis releases this enzyme into the plasma. Most patients with hemolysis will have an elevated LDH, making this a sensitive test. However, many other processes including liver disease, pneumonia, and so on, will also increase serum LDH.

**Serum bilirubin:** Heme is broken down to produce bilirubin. Initially unconjugated, the bilirubin is delivered to the liver, where it is conjugated and excreted into the bile. In hemolysis, the unconjugated (*indirect bilirubin*) is increased as opposed to liver disease, in which the conjugated (*direct bilirubin*) is increased. If a patient has coexisting liver disease with an elevated direct bilirubin, this test is not reliable.

**Serum haptoglobin:** Haptoglobin binds free serum hemoglobin and is taken up by the liver. Haptoglobin usually falls to very low levels in hemolysis. It is important to remember that haptoglobin is also an acute-phase reactant that can increase with systemic disease or inflammation. However, patients with advanced liver disease will have low haptoglobin as a result of lack of synthesis, and up to 2% of the population may congenitally lack haptoglobin.

**Hemoglobinemia:** If the hemolysis is very rapid, the amount of free hemoglobin that is released will overwhelm haptoglobin and lead to the presence of free hemoglobin in the plasma. This can be crudely quantified by examining the plasma. Even minute amounts of free hemoglobin will turn the plasma pink. In fulminant hemolysis, the serum will be cola colored.

**Urine hemosiderin:** When hemoglobin is excreted by the kidney, the iron is deposited in the tubules. When the tubule cells are sloughed off, they will appear in the urine. The urine can be stained for iron; if positive, this is another sign of hemolysis. This is a later sign as it takes a week for enough iron-laden tubule cells to be excreted in detectable quantities.

**Mean corpuscular volume (MCV):** The MCV may be larger in hemolysis for several reasons. The size of reticulocytes is larger than normal RBCs, so a brisk reticulocytosis will have a higher MCV. In cold agglutinin disease, the aggregation of RBCs will

falsely increase the MCV. Finally, hemolysis can lead to folate deficiency and an increase in MCV.

**Reticulocyte count:** With hemolysis, the breakdown of RBCs is accompanied by an increase in the reticulocyte count as marrow tries to compensate. The reticulocyte percentage must be adjusted for the hematocrit; a correct value above 1.5% is considered increased. Recently, automated complete blood count machines have taken advantage of the fact that reticulocytes will absorb certain stains, and these machines can directly measure the reticulocyte count via flow cytometry. This results in an “absolute” reticulocyte count. This does not have to be corrected for hematocrit, and levels about 90,000/ $\mu$ L are considered elevated. However, the reticulocyte count can also be increased in blood loss or in patients who have other causes of anemia (such as treated iron deficiency). In addition, as many of 25% of patients with AIHA will never have elevated reticulocyte counts for reasons such as nutritional deficiency, autoimmune destruction of red cell precursors, or lack of erythropoietin.

The blood smear provides vital information (Table 3). The finding of abnormal red cell shapes can be a clue to autoimmune hemolysis or red cell membrane defects. For example, spherocytes are seen in autoimmune hemolytic anemia, hereditary spherocytosis, Wilson disease, clostridial sepsis, and severe burns. Schistocytes are a sign of microangiopathic hemolytic anemia and should prompt concerns for such disease processes as thrombotic thrombocytopenia purpura, valvular hemolysis, VAD, march hemoglobinuria, among many others.

In hereditary spherocytosis, the blood smear suggests the diagnosis. Confirmation is by demonstrating an increased osmotic fragility, although direct genetic screening for the molecular defects is becoming more common. The blood smear is also critical for diagnosing hereditary elliptocytosis and hereditary pyropoikilocytosis, although there is an increasing role for genetic diagnosis. Patients with hereditary pyropoikilocytosis are usually homozygous or compound heterozygous for one of the mutations causing mild hereditary elliptocytosis.

Diagnosis of G6PD deficiency is made by measuring enzyme activity. This is best performed after the hemolytic episode is over as reticulocytes have higher G6PD levels and can lead to falsely normal enzyme activity levels.

Increasingly genetic sequencing is being used to screen for inherited disorders, but more experience is required for interpretation of mutations.

AIHAs demonstrate either IgG or complement on the RBC. This is done by the *direct antibody* or *Coombs* test. IgG bound to RBCs will not agglutinate them. However, if IgM that is directed against IgG or C3 is added, the RBCs will agglutinate, proving that there is IgG and/or C3 on the red cell membrane. The finding of a positive DAT in the setting of a hemolytic anemia is diagnostic of AIHA.

**TABLE 3** Typical Blood Smear Findings in Hemolysis

#### Bite Cells

Oxidative hemolytic anemia such as G6PD deficiency

#### Elliptocytes

Hereditary elliptocytosis

#### Schistocytes

Thrombotic thrombocytopenic purpura, valvular hemolysis

#### Spherocytes

Hereditary spherocytosis, autoimmune hemolytic anemia, Wilson disease, burns

#### Spur Cells

Severe liver disease

There are several pitfalls to the DAT. One is that a positive DAT can be found in 1 in 1000 patients in the normal population and up to several percent of ailing patients, especially those with elevated gamma globulin such as patients with liver disease or HIV. Administration of IVIG can also create a false-positive DAT. Conversely, patients can have AIHA with a negative DAT. Some patients have a low amount of IgG binding the RBC that is below the detection limit of the DAT reagents. Other patients can have IgA or “warm” IgM as the cause of the AIHA. Specialty laboratories can test for these possibilities. The diagnosis of DAT-negative AIHA should be made with caution, and other causes of hemolysis like hereditary spherocytosis or PNH should be excluded.

The DAT in patients with cold AIHA will show cells coated with C3. The blood smear will often show agglutination of the blood, and if the blood cools before being analyzed, the agglutination will interfere with the analysis. Titers of cold agglutinin can range from 1 in 1000 to 1 in over 1 million. The autoantibodies are most often directed against the *I*<sub>i</sub> antigen system, with 90% against I. The I specificity is typical with primary cold agglutinin disease and also following *Mycoplasma* infection. The i-specific antigen is most typical of Epstein-Barr and CMV infections.

In PCH, the DAT is often weakly positive but can be negative. The diagnostic test is the Donath-Landsteiner test. This complex test is performed by incubating samples in three temperature ranges: one set at 0° to 4°C, one set at 37°C, and one incubated first at 0° to 4°C and then 37°C. The diagnosis of PCH is made if only the third tube shows hemolysis.

For many patients, the first clue to drug-associated AIHA is the finding of a positive DAT in a patient taking a suspect drug (Table 4). Specialty laboratories such as Wisconsin Blood Center or the Los Angeles Red Cross can perform in-vitro studies of drug interactions that can produce a certain diagnosis.

For PNH, the diagnosis had been based on an in vitro demonstration of increased sensitivity of RBCs to complement lysis. Currently, flow cytometry is performed to examine cells for the absence of GPI-anchored proteins (CD55 or CD59 on RBCs, other GPI-anchored proteins on white blood cells).

In patients with microangiopathy, the smear will show abundant schistocytes with a marked elevated LDH.

### Therapy

Splenectomy is curative for most cases of hereditary spherocytosis but is reserved for patients with severe symptoms. For patients with hereditary pyropoikilocytosis, splenectomy can also be useful.

Most patients with G6PD deficiency require no special management beyond the avoidance of provocative medications and food. Highly symptomatic patients with pyruvate kinase deficiency may respond to splenectomy, and in clinical trials, a small molecule agent that can increase enzyme activity.

Initial management of warm AIHA is prednisone starting at 1 mg/kg daily. It can take up to 3 weeks to see a response. Once the hematocrit is above 30%, the prednisone is slowly tapered. Eighty percent of patients will respond to steroids, but the steroids can be fully tapered off in only 30%. For patients who can be maintained on 10 mg or less of steroids daily, this may be the most reasonable long-term therapy.

Current data show that adding rituximab (Rituxan)<sup>1</sup> to steroids for warm AIHA will improve overall response and should be considered early in most patients. These responses appear to be durable, and for relapses, repeating treatment is effective. It is important to remember that, for most patients, the response to rituximab is a gradual one over months; one should not expect a rapid response. Most studies have used the “traditional” 375 mg/m<sup>2</sup> dosing weekly for 4 weeks, and another option is 1000 mg repeated once 14 days apart.

Splenectomy is now reserved for patients with warm AIHA who do not respond to steroids or rituximab. Reported response rates in the literature range from 50% to 80%, with 50% to 60% remaining

**TABLE 4** Drugs Implicated in Autoimmune Hemolytic Anemia

#### Most Common

Thiazides

Thiopental (Pentothal)

Tolbutamide (Orinase)

Tricyclic antidepressants

in remission. Timing of the procedure is a balance between allowing time for the steroids to work versus the risk of toxicity of steroids. A patient who is at low risk associated with surgery and has either refractory disease or an inability to be weaned from high doses of steroids should have splenectomy considered early.

For patients who do not respond to either splenectomy or rituximab, therapy is less certain. Although intravenous immune

<sup>1</sup>Not FDA approved for this indication.

globulin is a standard therapy for immune thrombocytopenia, response rates are low in warm AIHA. Numerous therapies have been reported in small series, but there is no clear approach. Options include the following:

- Azathioprine (Imuran)<sup>1</sup> 75 to 150 mg/day
- Cyclophosphamide (Cytoxan)<sup>1</sup> 1000 mg monthly bolus IV
- Mycophenolate (CellCept)<sup>1</sup> 500 to 1000 mg bid
- Cyclosporine (Neoral)<sup>1</sup> 5 mg/kg daily divided in two doses
- Danazol (Danocrine)<sup>1</sup> 200 mg tid

Our approach has been to use mycophenolate for patients who require high doses of steroids or need transfusions. Patients who need lower doses of steroids may be good candidates for danazol to help wean them from the steroids.

The sparse literature on Evans syndrome suggests that it can be more refractory to standard therapy, with response rates to splenectomy being in the 50% range. In patients with lymphoma, antineoplastic therapy is crucial. Data is accumulating for patients with ALPS: mycophenolate or sirolimus (Rapamune)<sup>1</sup> starting at 2 mg/m<sup>2</sup>, may be effective for splenectomy or rituximab failures.

The importance of diagnosing cold AIHA and differentiating it from warm AIHA is the fact that standard therapy for warm disease steroids is ineffective. C3-coated RBCs are taken up through the reticulo-endothelial system, especially in the liver as well as the spleen, so splenectomy is also an ineffective therapy.

Simple measures to help with cold AIHA should be employed. Patients should be kept in a warm environment and should try to avoid the cold. If transfusions are needed, they should be infused via blood warmers to prevent hemolysis. In rare patients with severe hemolysis, plasma exchange can be considered. Given the culprit antibody is IgM (mostly intravascular), use of plasma exchange can slow the hemolysis to give time for other therapies to take effect.

Therapy of cold AIHA remains difficult. Currently the drug of choice is rituximab.<sup>1</sup> Response can be seen in 45% to 75% of patients but is almost always a partial response; retreatment is often necessary. As with other autoimmune hematologic diseases, there can be a delay in response. There is data to support adding either fludarabine (Fludara)<sup>1</sup> or bendamustine (Treanda)<sup>1</sup> 90 mg/m<sup>2</sup> to rituximab. The response rates are higher, but so are the complications of therapy. Although more toxic, this combination can be considered in patients with aggressive disease. For acute treatment, the monoclonal antibody sutimlimab (Enjaymo) is available.

For most patients with drug-induced AIHA, discontinuing the offending drug is sufficient. It is doubtful that steroids or other autoimmune-directed therapy is effective. For patients with the DIC-hemolysis syndrome, there are anecdotes that plasma exchange may be helpful. Therapy for patients with positive DAT without signs of hemolysis is uncertain. If the drug is essential, then the patient can be observed. If the patient has hemolysis, the drug must be stopped and the patient observed for signs of end-organ damage.

Transfusions can be very difficult in AIHA. The presence of the autoantibody can interfere with typing of the blood and almost always interferes with the cross-match because this final step consists of mixing the patient's serum with donor RBCs. In most patients with AIHA, the autoantibodies will react with any donor cells, rendering a negative cross-match impossible. Without the cross-match, the concern is that underlying alloantibodies can be missed, which can lead to transfusion reactions.

Some of these concerns may be allayed by remembering that patients who have never been transfused or pregnant will rarely have alloantibodies. Secondly, a patient who has been transfused in the remote past may have an amnestic antibody response but not an immediate hemolytic reaction.

When a patient is first suspected of having AIHA, a generous sample of blood should be given to the transfusion service. This will allow for adequate testing of the sample. Secondly, many centers will test the blood not only for blood groups ABO and D but will also perform full Rh typing and check for Kidd, Duffy, and Kell status. This can allow transfusion of phenotypically matched blood to lessen the risk of alloantibody formation.

One difficult issue is timing of transfusion. Clinicians are often hesitant to transfuse patients with AIHA because of fear of reactions. But in frail patients with severe anemia, especially older adults or those with heart disease, transfusion can be lifesaving. In some cases it can take hours to screen for alloantibodies; therefore it is often preferable to transfuse patients with severe anemia while carefully observing for reactions.

The treatment for PNH is the complement inhibitor eculizumab (Soliris), a humanized monoclonal antibody that targets complement protein C5, thereby preventing assembly of the terminal complement complex during complement activation. In studies, treatment with eculizumab has been shown to reduce hemolysis as well as improve anemia, fatigue, and quality of life in patients with PNH. In addition, eculizumab has demonstrated efficacy in reducing thrombosis. For patients who experience breakthrough hemolysis with eculizumab, pegcetacoplan (Empaveli) can be of benefit.

## Management of Complications

The most concerning complication of splenectomy is overwhelming postsplenectomy infection (OPSI). In adults, the spleen appears to play a minimal role in immunity, except for defense from certain encapsulated organisms. Patients will often present with DIC and will rapidly progress to purpura fulminans. Approximately 40% to 50% of patients will die from sepsis, even when detected early. The overall lifetime risk may be as high as 1 in 500. The organism most commonly found in these cases is *Streptococcus pneumoniae*, which is reported in over 50% of cases. *Neisseria meningitidis* and *Haemophilus influenzae* have also been implicated in many cases.

Patients who have undergone splenectomy must be warned about the risk of OPSI and instructed to report to the emergency department immediately if they develop a fever greater than 101°F or shaking chills. Once in the emergency department, blood cultures should be rapidly obtained and the patient started on antibiotic coverage with agents that cover encapsulated organisms. Patients who are planning to have or are being considered for a splenectomy should be vaccinated for pneumococcal, meningococcal, and *H. influenzae* infections. If patients are planning to be treated with rituximab first, they should also be vaccinated because they will not be able to mount an immune response after receiving rituximab.

The major side effects of rituximab are infusion reactions, and they are often worse with the first dose. These can be controlled with antihistamines, steroids, and, for severe rigors, meperidine (Demerol).<sup>1</sup> Rare patients can develop neutropenia (about 1 in 500) that appears to be autoimmune in nature. Infections appear to be only minimally increased with the use of rituximab. One group at higher risk are patients who are chronic carriers of hepatitis B. These patients may have reactivation of the virus that can be fatal in some cases; patients being considered for rituximab must be screened for hepatitis B. Progressive multifocal leukoencephalopathy is a very rare risk that is more common in cancer patients and heavily immunosuppressed patients. The overall risk is unknown but is less than 1 in 50,000.

Eculizumab is well tolerated except for a risk of meningococcal infection, which is estimated at 1 in 500. All patients receiving this agent should be vaccinated and must report to the emergency department with any sign of infection.

<sup>1</sup>Not FDA approved for this indication.

## HEMOPHILIA AND RELATED CONDITIONS

Method of

Bulent Ozgonenel, MD; Roshni Kulkarni, MD; and Meera Chitlur, MD

### CURRENT DIAGNOSIS

- The hemophilias and von Willebrand disease (VWD) account for 80% to 85% of inherited bleeding disorders. Hemophilia A and B are X-linked, whereas VWD and rare bleeding disorders (RBDs) are autosomal disorders.
- The diagnosis of hemophilia and other inherited bleeding disorders should be confirmed by specific laboratory assays because screening tests such as prothrombin time (PT) and activated partial thromboplastin time (aPTT) may be normal. Plasma levels of deficient factor determine clinical severity and management.
- Major complications associated with hemophilia are inhibitor development, hemarthrosis, and intracranial hemorrhage. Hemarthrosis is the most common and debilitating complication, and central nervous system (CNS) bleeding is the most common cause of mortality in hemophilia. Mucosal bleeding and menorrhagia are the most common manifestations of VWD. Bleeding manifestations of RBDs are mild, although homozygotes can present with severe disease.
- Newborns have normal levels of factor VIII; therefore the diagnosis of hemophilia A can be established at birth. Vacuum-assisted delivery should be avoided to prevent head bleeds.
- Women and adolescents with menorrhagia and no underlying pathology should be investigated for a bleeding disorder.

### CURRENT THERAPY

- Currently there is a paradigm shift in the treatment of hemophilia. In addition to the traditional plasma-derived and recombinant concentrates, the new extended half-life recombinant products have reduced the treatment burden by reducing the frequency of intravenous injections. Novel, subcutaneously administered, nonfactor replacement therapy with prolonged hemostatic efficiency has been a game changer for patients both with and without inhibitors. Gene therapy is on the horizon, offering a promise of cure. Even for von Willebrand disease (VWD) and rare bleeding disorders (RBDs) such as deficiencies of factors VII, XI, XIII, X, and fibrinogen, replacement factor concentrates are currently available. Early and effective treatment and prophylaxis can prevent bleeding episodes, including repeated hemarthrosis and joint destruction in persons with hemophilia. Patients should be tested annually for the presence of inhibitors. Cryoprecipitate is not recommended for the treatment of hemophilia because of concerns regarding transmission of bloodborne pathogens.
- For mild and moderate hemophilia A and VWD, the use of desmopressin (DDAVP) coupled with antifibrinolytics can obviate the use of concentrates. Continued vigilance should be implemented for inhibitory antibodies and new and emerging bloodborne pathogens.
- All patients with inherited bleeding disorders should be immunized against hepatitis A and B and followed in close collaboration with their local hemophilia treatment center (HTC) (<https://www.cdc.gov/ncbddd/hemophilia/htc.html>). The National Hemophilia Foundation's (<https://www.hemophilia.org>) Medical and Scientific Advisory Committee (MASAC) guidelines for updated recommendations and product choice should be followed.

### Hemophilia A and Hemophilia B

Hemophilia is an X-linked congenital bleeding disorder caused by a deficiency of factor VIII (hemophilia A) or factor IX (hemophilia B). Hemophilia A is the most common severe bleeding disorder and affects 1 in 5000 males in the United States; hemophilia B occurs in 1 in 30,000 males.

#### Pathophysiology

The *factor VIII* gene is one of the largest genes and spans 186 kb of genomic DNA at Xq28. Intron 22 of the *factor VIII* gene is particularly large and is therefore susceptible to inversion mutations. Inversions of this intron account for 50% of all severe hemophilia A cases, and inversions of other introns, deletions, point mutations, and insertions account for the remainder.

Hepatic and reticuloendothelial cells are presumed sites of factor VIII synthesis. Factor VIII is synthesized as a single-chain polypeptide with three A domains (A1, A2, and A3), a large central B domain, and two C domains (Figure 1). The binding sites for von Willebrand factor (VWF), thrombin, and factor Xa are on the C2 domain, and factor IXa binding sites are on the A2 and A3 domains. The B domain can be deleted without any consequences. VWF protects factor VIII from proteolytic degradation in the plasma and concentrates it at the site of injury.

The *factor IX* gene is 34 kb long and located at Xq26. It is a vitamin K–dependent serine protease composed of 415 amino acids. It is synthesized in the liver, and its plasma concentration is approximately 50 times that of factor VIII. Gene deletions and point mutations result in hemophilia B.

#### Role of Factors VIII and IX in Coagulation

Factor VIII circulates bound to VWF. It is a cofactor for factor IX and is essential for factor X activation. In the classic coagulation cascade, activation of the intrinsic or extrinsic pathway of coagulation results in sufficient thrombin generation. The fact that bleeding still occurs in hemophilia despite an intact extrinsic pathway has led to the revised cell-based model of coagulation.

The revised pathway incorporates all coagulation factors into a single pathway initiated by factor VII and tissue factor. The contact factors (XI, XII, kallikrein, and high-molecular-weight [HMW] kininogen) are not essential but serve as a backup. Following injury, encrypted tissue factor is exposed and forms a complex with F VIIa. The tissue factor–factor VIIa complex activates factor IX to IXa (which moves to the platelet surface) and factor X to Xa. This generates small amounts of thrombin that activates platelets, converts platelet factor V to Va and factor XI to XIa, and releases factor VIII from VWF and activates it. The factor XIa activates plasma factor IX to IXa on the platelet surface, which together with factor VIIa forms the tenase complex (factor VIIa/IXa) that converts large amounts of factor X to Xa. Factor Xa forms a prothrombinase complex with FVa and converts large amounts of prothrombin to thrombin, called *thrombin burst*. This results in the conversion of sufficient fibrinogen to fibrin to form a stable clot. In hemophilia, lack of factor VIII or IX produces a profound abnormality. Factor Xa generated by FVIIa and tissue factor is insufficient because this pathway is inhibited by tissue factor pathway inhibitor (TFPI) as part of a negative feedback, and factors VIII and IX, which are required for amplifying the production of Xa, are absent. The primary platelet plug formation and initiation phases of coagulation are normal. Any clot that is formed (from the initiation phase) is friable and porous.

#### Clinical Features

The diagnosis of hemophilia is often made following a bleeding episode or because of a family history; however, 50% of cases have no family history. Based on the plasma levels of factor VIII or IX (normal levels are 50% to 150%) that correlate with severity and predict bleeding risk, hemophilia is classified as mild (>5%), moderate (1% to 5%), and severe (<1%) (Table 1). Approximately 65% of persons with hemophilia have severe disease, 15% have moderate disease, and 20% have mild disease. Most cases of severe disease manifest by 4 years of age; moderate or mild disease is diagnosed later and often following bleeding secondary to trauma or surgery.

Figure 1 Factor VIII protein structure.

TABLE 1 Hemophilia Severity and Clinical Manifestations

CHARACTERISTICS	SEVERE (50%–70%)	MODERATE (10%)	MILD (30%–40%)
Factor VIII or IX activity (normal 50%–150%)	<1%	1%–5%	>5%
Age of diagnosis	Birth to 2 years	Childhood or adolescence	Adolescence or adulthood
Bleeding patterns	2–4 per month	4–6 per year	Rare
Clinical manifestations	Hemarthroses, muscle, central nervous system, gastrointestinal bleeding, hematuria	Bleeding into joints or muscle following minor trauma, surgical procedure, dental bleeding Rarely spontaneous	Surgical procedures (including dental) and major trauma

Hemophilia can be diagnosed in the first trimester, using chorionic villus sampling and gene analysis. In the second trimester, fetal blood sampling can be performed. Prenatal diagnosis to determine fetal gender can aid in the management of pregnancy and delivery.

The hallmark of severe hemophilia is hemarthrosis, or bleeding into the joint, that can occur spontaneously or with minimal trauma. The immediate effects of a joint bleed are excruciating pain, swelling, warmth, and muscle spasms, and the long-term effect of recurrent hemarthrosis is the hemophilic arthropathy, which is characterized by synovial thickening and chronic inflammation. Repeated hemorrhage results in a target joint. Knees, elbows, ankles, hips, and shoulders are commonly affected. Disuse atrophy of surrounding muscles leads to further joint instability. Limitation of joint range of motion resulting from hemarthrosis often correlates positively with older age, non-White race, and increased body mass index, and it adversely affects quality of life.

Muscle hematomas, another characteristic site of bleeding, can lead to compartment syndrome, with eventual fibrosis and peripheral nerve damage. Iliopsoas bleeds manifest with pain and flexion deformity. Gastrointestinal bleeding and hematuria occur less often.

Central nervous system (CNS) hemorrhage is a rare but serious complication with a 10% recurrence rate, and it is the leading cause of mortality in hemophiliacs. Although most newborns with severe hemophilia experience an uneventful course following vaginal delivery, vacuum extraction is associated with an increased CNS bleeding risk. The incidence of intracranial hemorrhage in newborns with hemophilia is 1% to 4%.

### Diagnosis

Hemophilia A and B are clinically indistinguishable, and specific factor assays are the only way to differentiate and confirm the diagnosis. Both should be differentiated from VWD. The prothrombin time (PT), platelet function analysis (PFA)-100, and fibrinogen activity are normal. (PFA replaces bleeding time because the bleeding time has low sensitivity and specificity and is operator dependent.) The activated partial thromboplastin time (aPTT) is prolonged when the factor levels are less than 30%. Table 2 shows the characteristics and differences between the hemophilias and VWD.

Female carriers may be asymptomatic except for those with extreme lyonization resulting in low factor VIII or IX levels. Carrier women and girls, whose factor VIII or IX levels are <40%, are therefore also considered to have hemophilia, with the same criteria for severity as boys and men. In fact, the most current terminology reserves the term *carrier* only for women whose factor

levels are  $\geq 40\%$ . Carriers are further classified as symptomatic (i.e., with bleeding manifestations) or asymptomatic. It is important to note that carriers may experience bleeding episodes (such as heavy menstrual bleeding, postpartum hemorrhage, or joint bleeding), even with levels of FVIII or IX in the 40% to 60% range. Often with the onset of menarche, asymptomatic girls may become symptomatic as a result of heavy menstrual bleeding. Factor VIII levels increase throughout pregnancy and drop to prepregnancy levels following delivery, but factor IX levels remain constant throughout pregnancy.

### Treatment

The treatment for hemophilia consists of replacement therapy with intravenous factor VIII or factor IX concentrates produced by purification of donor plasma (plasma derived) (e.g., factor VIII [human]: Hemofil M, Koate; factor IX [human]: AlphaNine SD, Mononine) or in cell culture bioreactors (recombinant) (e.g., factor VIII [recombinant]: Advate, Afstyla, Kogenate FS, Nuwiq, Xyntha; factor IX [recombinant]: BeneFIX, Ixinity, Rixubis). Careful screening of donors combined with heat treatment and viral inactivation methods have made plasma-derived products safer. Plasma-derived and recombinant products appear to have equivalent clinical efficacy. Cryoprecipitate is no longer recommended because of concerns regarding pathogen safety.

Treatment administered only during bleeding symptoms is known as *episodic therapy*, and periodic administration of factor concentrates to prevent bleeding is known as *prophylactic therapy*. Response to treatment is more effective when it is administered early. Although prophylaxis prevents the development of joint disease, the high cost of factor replacement coupled with the need for venous access makes it expensive, difficult, and out of reach for patients in the developing world.

The goal of treatment is to raise factor levels to approximately 30% or more for minor bleeds (hematomas or joint bleeds) and 100% for major bleeds (CNS or surgery). Administering 1 U/kg of factor concentrate raises plasma factor VIII levels by 2% and factor IX levels by 1.5% (except with the recombinant factor IX product, in which it increases by 0.8%). The half-life of factor VIII is 8 to 12 hours and that of factor IX is up to 24 hours with standard factor products.

Factor concentrates can also be given by continuous infusion (3–4 U/kg/h). The bolus dose varies from 25 to 50 U/kg depending on the severity, site, and type of bleeding and is dosed to the available vial size because of the cost of the products. Table 3 lists the dosing schedule for various types of bleeds.

**TABLE 2** Hemophilias and von Willebrand Disease: Key Characteristics and Differences

CHARACTERISTIC	HEMOPHILIA A	HEMOPHILIA B	VON WILLEBRAND DISEASE
Incidence	1:5000	1:30,000	1%–3% of U.S. population
Abnormality	Factor VIII deficiency	Factor IX deficiency	VWF (qualitative and quantitative defect)
Inheritance	X-linked, affects males	X-linked, affects males	Autosomal dominant (gene: chromosome 12)
	Gene at the tip of X chromosome	Gene at the tip of X chromosome	Some are recessive or compound heterozygotes
Production site	Unknown, liver endothelium	Liver (vitamin K–dependent)	Megakaryocytes and endothelial cells
Function	Cofactor; forms tenase complex with factor IX and activates factor X, leading to a thrombin burst that results in conversion of large amounts of fibrinogen to fibrin	Serine protease (inactive form: zymogen) activated by factor XI or VIIa; forms a tenase complex with factor VIII and activates factor X	Platelet adhesion to site of injury or damaged endothelium
			Protects factor VIII from proteolysis
Classification (normal levels 50%–150%)	Mild (>5%)	Mild (>5%)	Type 1
	Moderate (1%–5%)	Moderate (1%–5%)	Type 2 (2A, 2B, 2M, 2N)
	Severe (<1%)	Severe (<1%)	Type 3
Clinical presentation	Positive family history (30% new mutation)  Hemarthroses, hematomas, hematuria, intracranial hemorrhage, gastrointestinal hemorrhage, and so on.	Positive family history (30% new mutation)  Milder disease, although identical hemorrhage sites as hemophilia A	Positive family history Mucocutaneous bleeding (epistaxis, menorrhagia, postdental bleeding, gastrointestinal bleeding in adults) Type 3 can manifest as hemophilia A
PFA, bleeding time	Normal	Normal	May be prolonged
PT	Normal	Normal	Normal
aPTT	Prolonged	Prolonged	Prolonged or normal
Factor VIII assay	Decreased or absent	Normal	Decreased or normal (absent type 3)
Factor IX assay	Normal	Decreased or absent	Normal
VWF:Ag	Normal	Normal	Decreased or absent (type 3)
VWF:RCo	Normal	Normal	Decreased or abnormal
VWF multimers	Normal	Normal	Abnormal in types 1, 2A, 2B; absent in type 3
Specific treatment	Recombinant factor VIII (preferred)	Recombinant factor IX	DDAVP (intranasal or intravenous) (FDA approved for type 1)
	Pathogen-safe plasma-derived concentrates	Pathogen-safe plasma-derived concentrates	VWF concentrates (pathogen-safe plasma derived or recombinant VWF)
	DDAVP for mild cases	DDAVP ineffective	
Inhibitor patients	Immune tolerance, recombinant factor VIIa, APCC	Immune tolerance, recombinant factor VIIa	Inhibitors are rare
Adjunct therapy	Antifibrinolytics	Antifibrinolytics	Hormonal therapy (oral contraceptives), antifibrinolytics

APCC, Activated prothrombin complex concentrates; aPTT, activated partial thromboplastin time; DDAVP, desmopressin; FDA, U.S. Food and Drug Administration; PFA, platelet function analyzer; PT, prothrombin time; RCo, ristocetin cofactor; VWF, von Willebrand factor; VWF:Ag, von Willebrand factor antigen.

For prophylaxis, factor VIII 25 to 40 U/kg administered every other day or factor IX 100 U/kg once weekly for BeneFIX and 40 U/kg once weekly for Rebinyn (because of the longer half-life of factor IX) is aimed at preventing joint disease. Prophylaxis may begin at 1 to 2 years of age and is continued lifelong. Self-infusion before

any planned strenuous activity is recommended. Because of the complications of central venous catheters (infections, thrombosis, and mechanical), use of a peripheral vein is encouraged.

Extended half-life (EHL) factor products have increased the half-lives by 1.5-fold in the case of factor VIII products and

**TABLE 3** Treatment of Bleeding Episodes and Desired Plasma Levels in Hemophilias A and B

TYPE OF BLEEDING	FACTOR DOSE*	DURATION OF TREATMENT	COMMENTS
Persistent or profuse epistaxis Oral mucosal bleeding (including tongue and mouth lacerations) Dental procedures Acute hemarthrosis Intramuscular hematomas Physical therapy	Single dose	1–2 days	Local pressure, antifibrinolytics, fibrin glue for local control, WoundSeal Powder for epistaxis Sedation in small children with tongue laceration
Dental procedures	Single dose	1 hour before procedure	Antifibrinolytics for 7–10 days
Acute hemarthrosis, intramuscular hematomas	Single dose	1–3 days	Use lower doses if treated early. Non-weight bearing on affected joint.
Physical therapy	Single dose	Treat before PT	Consider synovectomy (surgical, radioisotope or chemical) for target joints
Gastrointestinal bleeding	Single dose	2–3 days	May use oral antifibrinolytics
Persistent painless gross hematuria	Single dose	1–2 days	Increase PO or IV fluids with low-dose antifibrinolytics; risk of clotting in the urinary tract with factor replacement
Life-threatening bleeding such as intracranial hemorrhage, major surgery, and trauma	Double dose	10–14 days	Bolus dose followed by continuous infusion (3–4 U/kg/h); may switch to bolus before discharge

\*Single dose refers to a factor dose that aims to achieve 40% to 50% factor level and is ~20 to 25 units/kg for factor VIII products and ~50 units/kg for factor IX products. Double dose refers to a factor dose that aims to achieve 80% to 100% factor level and is ~40 to 50 units/kg for factor VIII products and ~80 to 100 units/kg for factor IX products. Factor doses are dosed closest to the vial.  
PT, Physical therapy.

2.4- to 4.8-fold in the case of factor IX products. EHL factor products have been developed with an aim to decrease the frequency of infusions and improve quality of life for patients with hemophilia, achieved through PEGylation or fusion of the factor protein to the Fc fragment of an immunoglobulin (Ig) or albumin. The first of these EHL products was approved by the U.S. Food and Drug Administration (FDA) in 2014: factor IX (recombinant), Fc fusion protein (Alprolix) for use in patients with hemophilia B, and factor VIII (recombinant), Fc fusion protein (Eloctate) for use in patients with hemophilia A. Subsequently, PEGylated recombinant factor VIII (Adynovate, Takeda Pharmaceuticals, Palo Alto, CA) was approved in 2015; PEGylated recombinant factor IX (Rebinyx, Novo Nordisk, Plainsboro, NJ) was approved in 2017, but not for prophylaxis; and recombinant albumin fusion factor IX (Idelvion, CSL Behring) was approved in 2016 for use in patients with hemophilia. Recently further extension of the half-life of factor VIII was achieved by a novel fusion protein called *BIVV001*<sup>5</sup> consisting of a single recombinant FVIII protein fused to a dimeric FC, a D'D3 domain of VWF (FVIII binding domain), and two XTEN polypeptides. The mean half-life of BIV001 was three to four times that of recombinant FVIII (37.6 to 42.5 hours vs. 9.1 to 13.2 hours, respectively), thereby allowing weekly dosing.

#### Novel Therapies for the Treatment of Hemophilia

In recent years, the field of hemophilia treatment has seen dramatic changes. Treatment options that do not target replacement of the missing factor are currently being tested. Factor VIII mimetics such as the bispecific factor IXa- and factor X-directed antibody emicizumab (Hemlibra) (see later) are FDA-approved nonfactor therapy. Rebalancing agents that inhibit endogenous anticoagulants and restore coagulation are in clinical trials and include small interfering RNA (siRNA) targeting antithrombin (Fitusiran; Sanofi Pharmaceuticals, Bridgewater,

NJ),<sup>5</sup> anti-TFPI antibody (Concizumab, Novo Nordisk),<sup>5</sup> and products targeting the anticoagulant effect of activated prothrombin complex (APC). The advantages are that these rebalancing agents can be given to either hemophilia A or B patients, provide the benefits of prophylaxis, and can be given subcutaneously, thereby eliminating the need for intravenous injection. More data are needed regarding the safety and efficacy of these medications.

Gene therapy offers promise of a cure, and trials of gene therapy for both hemophilia A and B are currently in process. This has been a significant breakthrough in the treatment of hemophilia. Two gene therapy trials for hemophilia B showed subtherapeutic or transient expression of factor IX. In December 2011, Nathwani and colleagues reported that a single injection of factor IX-expressing adeno-associated virus (AAV) vector was effective in treating patients with hemophilia B for more than 1 year. Since this breakthrough, more successful gene therapy trials have been currently underway for the treatment of both hemophilia A and B. The trials have incorporated modifications of promoters, transgenes and AAV serotypes, and lentiviral vectors. Results from the initial factor IX gene therapy trials have demonstrated continued factor IX expression at levels shown to decrease bleeding episodes for up to 9 years. Gene therapy trials in hemophilia A, although still showing benefits in some patients, have shown lower levels of factor VIII expression in the long term compared with hemophilia B. A major limitation to this therapeutic option has been hepatotoxicity typically occurring 1 to 4 months postdelivery of the vector, resulting in transaminitis followed sometimes by loss of gene expression. The long-term outcomes and safety remain to be determined. Table 4 lists novel and current treatments for hemophilia.

## Complications of Treatment

One of the most serious complications of hemophilia treatment is the development of inhibitors or neutralizing antibodies (IgG) that inhibit the function of substituted factor VIII and factor IX. Five percent to 10% of all hemophiliacs and up to 30% of patients with severe hemophilia A develop inhibitors. The incidence of inhibitors in hemophilia B is lower (1% to 3%). Most

factor VIII inhibitors arise after a median exposure of 9 to 12 days in patients with severe hemophilia A. They can be transient or permanent and should be suspected if a patient fails to respond to an appropriate dose of clotting factor concentrate. Inhibitors can exacerbate bleeding episodes and hemophilic arthropathy.

Inhibitor levels, measured using Bethesda units (BU), are classified as high titer (>5 BU) or low titer (<5 BU). In patients with low-titer inhibitors, higher-than-normal doses of factor VIII or IX may be used to treat bleeding. For those with high-titer inhibitors, agents that bypass factor VIII or factor IX are used. These include recombinant activated factor VII and, in the case of hemophilia A, activated prothrombin complex concentrates (APCCs) or recombinant porcine factor VIII (currently in prelicensure clinical trials). Immune tolerance induction, a long-term approach designed to eradicate inhibitors, is effective in 70% to 85% of patients with severe hemophilia A; the most important predictor of success of immune tolerance induction is an inhibitor titer of less than 10 BU at the start of immune tolerance induction.

A novel treatment for hemophilia A with inhibitors is emicizumab (Hemlibra), a chimeric humanized antibody that triggers and propagates thrombin generation by binding to both factor IX and factor X. By binding to these coagulation factors, the antibody mimics the function of factor VIII. The medication is given subcutaneously, making it a preferred drug in young children. Emicizumab (Hemlibra) showed remarkable success in preventing bleeding complications in patients with severe hemophilia A with inhibitors. The FDA initially approved emicizumab in 2017 for routine prophylaxis to prevent or reduce the frequency of bleeding episodes in patients with hemophilia A with inhibitors, but they extended the approval to hemophilia A without inhibitors in 2018 following studies in non-inhibitor patients. Emicizumab can be administered subcutaneously once a week, every 2 weeks, or every 4 weeks, and all regimens have been found to be equally effective. In general, emicizumab has been well accepted by hemophilia patients, especially children and those with difficult venous access as its treatment regimen does not require intravenous dosing, and the dose frequency is much easier to manage than prophylaxis with conventional factor VIII products. Emicizumab treatment is safe by itself, but thrombotic microangiopathy and thrombotic complications have been observed in hemophilia A with inhibitor individuals receiving concomitant high doses of APCC for management of breakthrough bleeds while on emicizumab (>100 U/kg of FEIBA for ≥24 hours). Hence it is recommended that recombinant factor VIIa (NovoSeven RT) be used as the first line of treatment for management of breakthrough bleeds in inhibitor patients on emicizumab (MASAC document #255).

Although inhibitors are rare in hemophilia B, they can result in anaphylaxis with exposure to factor IX-containing products. Immune tolerance regimens are associated with nephrotic syndrome and are successful in eradicating the inhibitor only in 40% of cases.

Another important complication of treatment is the transmission of blood-borne pathogens such as hepatitis B and C viruses and human immunodeficiency virus (HIV). In the 1970s, lyophilized plasma factor concentrates of low purity resulted in the transmission of HIV, causing the deaths of many hemophiliacs. Currently, donor screening for pathogens coupled with viral attenuation by heat or solvent detergent technology make these products pathogen safe. However, nonenveloped viruses (parvovirus and hepatitis A) and prions can resist inactivation and can be potentially transmitted.

Patients with bleeding disorders should be encouraged to attend the comprehensive hemophilia treatment centers (HTCs), where they are seen by a multidisciplinary team of hematologists, nurses, social workers, geneticists, physical therapists, dental hygienists, nutritionists, and so on, who educate patients and address issues such as self-care, transitions, and quality of life. Patients are trained to self-infuse and calculate dosage, maintain treatment logs, and call for serious bleeding episodes. The mortality rate among patients who receive care at HTCs is lower than among those who do not: 28.1% versus 38.3%, respectively. At the HTCs, hemovigilance for bloodborne and emerging pathogens was maintained through participation in the Centers for Disease Control and Prevention (CDC) Universal Data Collection (UDC)

project. The grant cycle of the UDC was completed in 2012, and a new surveillance instrument is currently in use (Community Counts) that incorporates collecting information on comorbidities and complications of bleeding disorders in this population. Routine vaccination against hepatitis A and B is recommended.

### Von Willebrand Disease

VWD is an inherited (autosomal dominant) bleeding disorder caused by deficiency or dysfunction of VWF, a plasma protein that mediates platelet adhesion at the site of vascular injury and prevents degradation of factor VIII. A defect in VWF results in bleeding by impairing platelet adhesion or by decreasing factor VIII.

VWF is synthesized in endothelial cells and undergoes dimerization and multimerization, forming low, intermediate, and HMW multimers. The HMW multimers are most effective in promoting platelet aggregation and adhesion. Circulating HMW multimers are cleaved by the protease ADAMTS13, which is deficient in patients with thrombotic thrombocytopenic purpura.

VWD is the most common bleeding disorder, affecting 1% or more of the population. It occurs worldwide and affects all races. VWD is classified into three major categories: partial quantitative deficiency (type 1), qualitative deficiency (type 2), and total deficiency (type 3). There are several different variants of type 2 VWD: 2A, 2B, 2N, and 2M based on the phenotype. Approximately 75% of patients have type 1 VWD.

### Clinical Presentation

Mucous membrane-type bleeding (e.g., menorrhagia, epistaxis) and excessive bruising are characteristic clinical features in VWD. Bleeding manifestations vary considerably, and in some cases the diagnosis is not suspected until excessive bleeding occurs with a surgical procedure or trauma. Although excessive menstrual bleeding may be the initial manifestation, it takes 16 years for a diagnosis of bleeding disorder. It is for this reason that the American College of Obstetrics and Gynecology recommended screening for hemostatic disorders in all adolescents and women presenting with menorrhagia and no pathology and before hysterectomy for menorrhagia. In infants or small children with type 3 (severe) VWD, excessive bruising and even joint bleeding (caused by very low levels of factor VIII) can mimic hemophilia A.

### Diagnosis

Laboratory evaluation for VWD requires several assays to quantitate VWF and characterize its structure and function. Many variables affect VWF assay results, including the patient's ABO

blood type. Persons of blood group AB have 60% to 70% higher VWF levels than those of blood group O.

Clinical conditions and disorders with elevated VWF levels include pregnancy (third trimester), collagen vascular disorders, postoperative period, liver disease, and disseminated intravascular coagulation. Low levels are seen in hypothyroidism and the first 4 days of the menstrual cycle.

Symptoms are modified by medications like aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which can exacerbate the bleeding; oral contraceptives can decrease the bleeding in women with VWD by increasing VWF levels. VWF levels in African American women are 15% higher than in White women. Clinical symptoms and family history are important for establishing the diagnosis of VWD, and a single test is sometimes not sufficient to rule out the diagnosis.

Initial workup should include a complete blood count, aPTT, PT, fibrinogen level, and thrombin time. These tests do not rule out VWD but help rule out thrombocytopenia or factor deficiency as the cause for bleeding. The closure times on the PFA-100, which has replaced the bleeding time as a screening test in some centers, may be prolonged. The aPTT in VWD is only abnormal when factor VIII is sufficiently reduced.

Specific tests for VWD include ristocetin cofactor assay, a factor VIII activity, and VWF antigen (VWF Ag) assay. The ristocetin cofactor activity measures induced binding of VWF to platelet glycoprotein Ib and is subject to significant intralaboratory and interlaboratory variability, making it an unreliable assay for the diagnosis. In addition, certain mutations in the A1 domain of the VWF, especially the *D1472H* mutation, have been found to attenuate the VWF-ristocetin binding, leading to misdiagnosis of VWD. This has led to the development of the glycoprotein 1bM assay (direct measure of platelet-binding activity of VWF), collagen binding assay (measure of multimeric function), and genotyping (especially for type 2 VWD, which are the new tests available to assist with the diagnosis). Multimer analysis is done by agarose gel electrophoresis using anti-VWF polyclonal antibody and is available at reference laboratories.

In type 1 VWD, the VWF is subnormal in amount, with normal multimer structure. Those with types 2A and 2B VWD lack the HMW multimers. In type 2B, the VWF has a heightened affinity for platelets, often resulting in some degree of thrombocytopenia from platelet aggregation. A useful laboratory test for type 2B is the low-dose ristocetin-induced platelet aggregation (RIPA) assay.

In type 3 (severe) VWD, the affected person has inherited a gene for type 1 VWD from each parent, resulting in very low levels (3%) of VWF (and low factor VIII, because there is no VWF to protect factor VIII from proteolytic degradation). Less commonly, a person with type 3 is doubly heterozygous. Table 5 provides an overview of the laboratory findings in the different variants of VWD.

**TABLE 5** Clinical Variants of von Willebrand Disease

TYPE	FACTOR VIII	VWF AG	RISTOCETIN COFACTOR	RIPA	MULTIMER
1	↓	↓	↓	↓ or normal	Normal
2A	↓ or normal	↓↓	↓	↓↓	Large and intermediate multimers absent
2B	↓ or normal	↓↓	↓ or normal	↓ to low dose	Large multimers absent
2M	Variably ↓	Variably ↓	↓	Variably ↓	Normal
2N	↓↓	Normal	Normal	Normal	Normal
3	↓↓↓	↓↓↓	↓↓↓	None	Absent
Platelet type	↓ or normal	↓ or normal	↓	↓ to low dose	Large multimers absent

Ag, Antigen; RIPA, ristocetin-induced platelet aggregation; VWF, von Willebrand factor.

## Treatment

See the “General Hemostatic Agents” section later in this chapter for a discussion on the use of desmopressin (DDAVP) and antifibrinolytic agents.

For type 3 patients and in patients with type 1 VWD who do not respond adequately to desmopressin, an intermediate-purity plasma-derived concentrate rich in the hemostatically effective HMW multimers of VWF (such as Humate-P) should be used to treat moderately severe or severe bleeding episodes and before surgery. Prophylaxis with VWF concentrates is effective in reducing the bleeding episodes and joint disease in severe VWD. A recombinant VWF concentrate enriched with HMW multimers, Vonvendi (Baxalta, Illinois City, IL) does not contain any factor VIII and is now available and approved for use only in adults.

As in hemophilia, antifibrinolytics are an effective adjunctive treatment for invasive dental procedures or other bleeding in the oropharyngeal cavity. These may be effective even when used alone in some VWD women with menorrhagia. For epistaxis, Nosebleed QR, a hydrophilic powder (over-the-counter [OTC] product), can help.

## Special Situations

### Pregnancy

VWF (and factor VIII) levels increase during the third trimester of pregnancy, and women with type 1 VWD have a decrease in bruising or other bleeding symptoms. However, those with type 2 VWD (abnormal VWF) and type 3 (no VWF) have no change in bleeding tendency. Even in type 1 VWD, VWF levels decrease following delivery, so treatment (with intravenous DDAVP or Humate P) may be needed. Antifibrinolytic agents can be used to prevent/treat postpartum hemorrhage.

### Acquired von Willebrand Disease

Acquired VWD occurs in persons who do not have a lifelong bleeding disorder. Conditions associated with acquired VWD include underlying autoimmune disease (lymphoproliferative disorders, myeloproliferative disorders, or plasma cell dyscrasias), valvular and congenital heart disease, Wilms tumor, chronic renal failure, and hypothyroidism. The mechanism of acquired VWD is unknown. Medications such as valproic acid can also cause VWD. Removal of the underlying condition often corrects the VWF. DDAVP, Humate P, recombinant factor VIIa (NovoSeven RT)<sup>1</sup>, or plasma exchange may be tried, if necessary, to treat bleeding.

### Rare Bleeding Disorders

The RBDs account for 3% to 5% of inherited coagulation deficiencies other than factor VIII, factor IX, or VWF deficiencies. They are autosomal recessive and affect both sexes. The prevalence of RBDs ranges from 1 in 500,000 to 1 in 2,000,000. Bleeding manifestations are restricted to persons who are homozygotes or compound heterozygotes. RBDs are common in countries such as Iran, where consanguineous marriages are customary. Ashkenazi Jews are particularly affected by factor XI deficiency. Deficiency of factor XII is a risk factor for thrombosis but not for bleeding. Most cases of RBDs are identified by abnormal screening tests coupled with specific factor assays.

Factor concentrates (recombinant or plasma derived) are available for some of the deficiencies such as FVII, X (Coagadex [human]; Bio Products Laboratory, Durham, NC), XIII (Tretten [recombinant], Novo Nordisk; Corifact [human], CSL Behring, King of Prussia, PA), XI (in Europe), and fibrinogen concentrate (human) (Fibryga, Octapharma, Switzerland; RiaSTAP, CSL Behring). The advantages of concentrates are pathogen safety and small volume. The use of antifibrinolytics and fibrin glue as adjunct therapy for bleeding manifestations is encouraged. Table 6 lists the inheritance, frequency, manifestations, and treatments of the RBDs.

<sup>1</sup>Not FDA approved for this indication.

## General Hemostatic Agents

For short-term therapy (before dental procedures and minor bleeding episodes), the synthetic vasopressin analogue desmopressin acetate (DDAVP injection, Stimate Nasal Spray) is useful both in mild hemophilia A and type 1 VWD, and occasionally in type 2A VWD.<sup>1</sup> Some young women with menorrhagia have also benefited from its use at the onset of menses, with a second dose given after 24 hours. The mechanism of action for desmopressin is increase in plasma concentrations of factor VIII and VWF by stimulating release of the endothelial stores of VWF. The levels of both factor VIII and VWF increase threefold to fivefold within 15 to 30 minutes following infusion. A DDAVP trial to determine response is helpful in selecting patients who might benefit from such therapy. For hemostatic purposes, intravenous (0.3 µg/kg in 50 mL of normal saline infused over 15 to 30 minutes) or intranasal dose (150 µg) can be used. The intranasal dose is 15 times larger than that recommended for diabetes insipidus. A multidose intranasal spray formulation (Stimate nasal spray in the United States and Octostim nasal spray in Canada; Ferring Pharmaceuticals, Parsippany, NJ) of 1.5 mg/1 mL delivers 150 µg per spray. The recommended dosage is one spray for patients who weigh less than 50 kg and two sprays (one in each nostril) for those who weigh more than 50 kg. (Note that Ferring Pharmaceuticals issued a voluntary recall of Stimate in July 2020 because of higher-than-specified doses in the sprays. Stimate is not anticipated to be released until 2024. This recall does not affect intravenous doses). The intravenous route, which was usually used for surgical coverage or for severe bleeding episodes requiring hospitalization, is now the only available route until the intranasal medication is released again.

When necessary, repeat doses may be given at 12- to 24-hour intervals. Tachyphylaxis (diminished response to repeated doses of the medication) occurs as a result of depletion of endothelial VWF stores. Tachyphylaxis is less commonly seen in VWD patients than in hemophilia patients. It is important to monitor free water intake following DDAVP administration because it can cause hyponatremia and seizures.

Desmopressin can also be used in the treatment of bleeding in patients with platelet dysfunction secondary to uremia.<sup>1</sup> Desmopressin seems to be effective in reducing blood loss during cardiac surgery in patients who are taking antiplatelet medications.<sup>1</sup> Because desmopressin requires the presence of either factor VIII or VWF to be able to show its effect, it is ineffective in moderate to severe hemophilia A, type 2M VWD, type 2N VWD, and type 3 VWD (there is no VWF to be released from storage sites). Desmopressin should be used with caution in type 2B VWD<sup>1</sup> as it can exacerbate the thrombocytopenia. Some patients with type 2A VWD may respond to desmopressin,<sup>1</sup> and a desmopressin test may be needed to determine benefit. Desmopressin is ineffective in hemophilia B and other coagulation disorders.

Antifibrinolytics such as ε-aminocaproic acid (Amicar; Akorn Inc., Lake Forest, IL) and tranexamic acid (Cyclokapron [Pfizer, New York, NY] or Lysteda [Amring Pharmaceuticals, Berwyn, PA])<sup>1</sup> are used as adjunct therapies in hemophilia, VWD, and other rare bleeding disorders, reducing the need for factor concentrates. The recommended dosage for ε-aminocaproic acid is 50 to 100 mg/kg/dose intravenously or orally (adult dose 4–5 g/dose IV or 5 g/dose PO) every 4 to 8 hours (maximum daily dose 24 g/24 h for children, 30 g/24 h for adults). The recommended dosage for tranexamic acid is 10 mg/kg/dose intravenously or 25 mg/kg body weight orally, three times daily (for adults 1300 mg tid for a total of 5 days).

## General Measures

Aspirin and aspirin-containing compounds should be avoided in patients with bleeding disorders because they interfere with platelet function and can exacerbate bleeding.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 6** Rare Bleeding Disorders: Inheritance, Clinical Features, and Treatment

FACTOR	PREVALENCE	TYPE	INHERITANCE	MANIFESTATION AND DIAGNOSIS	TREATMENT	HEMOSTATIC LEVELS	HALF-LIFE
Factor I	1:1,000,000	Afibrinogenemia Dysfibrinogenemia Hypofibrinogenemia	AR AD AD	Mild bleeding CNS, umbilical, joint bleeding Recurrent miscarriage Prolonged PT, aPTT, TT Low FI levels Paradoxical thrombosis	FFP 15–20 mL/kg Cryoprecipitate 1 bag/5–10 kg Fibrinogen concentrate (RiaSTAP) treatment q3–5d	50mg–1 g/dL	2–5 days
Factor II	1:2,000,000	Type I: hypoprothrombinemia Type II: dysprothrombinemia	AR AR	Hematomas, hemarthroses, menorrhagia CNS, umbilical, postpartum hemorrhage PT abnormal	FFP, PCC 20–30 U/kg for prophylaxis or treatment	20%–30%	3–4 days
Factor V	1:1,000,000	Parahemophilia, labile factor, proaccelerin, Owren disease	AR	Mucosal bleeding, postpartum hemorrhage CNS bleeding Platelet factor V deficiency more reflective of bleeding potential Prolonged PT, aPTT Normal TT	FFP Platelet transfusions Antiplatelet antibodies can develop with repeated platelet transfusions	15%–20%	36h
Factor VII	1:500,000	Proconvertin or stable factor	AR	Menorrhagia; mucosal, muscle, intracranial bleeds (15%–60%); hemarthrosis Prolonged PT Normal aPTT, TT, FI, liver function tests	Recombinant factor VIIa (NovoSeven), 15–30 µg/kg q 2h for major bleeds FFP, PCC 20–30 U/kg for prophylaxis or treatment Plasma-derived factor VII concentrates <sup>2,*</sup>	15%–20%	4–6 h
Factor X	1:1,000,000		AR	Menorrhagia; umbilical, joint, mucosal, muscle, intracranial bleeding Prolonged PT, aPTT	FFP, PCCs 25–40 U/kgPd FX (Coagadex)	15%–20%	24–48 h
Factor XI (common in Ashkenazi Jews)	1:1,000,000		AR	Posttraumatic bleeding, menorrhagia Prolonged aPTT Normal PT	Hemoleven <sup>*,5</sup> FFP 15–20 mL/kg Inhibitors can occur	15%–20%	
Factor XIII	1:2,000,000		AR	Intracranial, joint, umbilical bleeding Delayed wound healing Recurrent miscarriages Normal PT, aPTT ↓ FXIII assay	Factor XIII concentrate (Corifact) 40 IU/kg q28d to maintain trough level of 5%–20% FFP 15–20 mL/kg Tretten, a recombinant FXIII-A subunit concentrate 35 units/kg/month for prophylaxis. Use in patients with FXIII A subunit deficiency Cryoprecipitate 1 bag/5–10 kg q3–4 weeks	2%–5%	11–14 days
Combined factor V and VIII	1:2,000,000			Mucosal bleeding Prolonged PT, aPTT (disproportionately)	Factor VIII concentrates and FFP	15%–20%	
Vitamin K–dependent multiple deficiencies	1:2,000,000			Umbilical stump, intracranial, postsurgical bleeding Skeletal abnormalities Hearing loss	Oral vitamin K, FFP, PCC	15%–20%	

\*Available in Europe.

AD, Autosomal dominant; aPTT, activated partial thromboplastin time; AR, autosomal recessive; CNS, central nervous system; FFP, fresh-frozen plasma; FI, fibrinogen; PCC, prothrombin complex concentrate; PT, prothrombin time; TT, thrombin time.

<sup>2</sup>Not available in the United States.

<sup>5</sup>Investigational drug in the United States.

## HODGKIN LYMPHOMA

Method of

Anusha Vallurupalli, MBBS

### CURRENT DIAGNOSIS

- Typically presents as painless cervical or mediastinal lymphadenopathy.
- “B” symptoms (fevers, drenching night sweats, and weight loss >10% of body weight) may be present.
- Tissue diagnosis is made by identifying Reed Sternberg cells on either excisional (preferable) or incisional biopsy. Fine needle aspiration (FNA) is never adequate and should be avoided.

### CURRENT THERAPY

- Limited-stage disease (stages I to IIA) with favorable risk factors, termed “early favorable” can be treated with combined modality therapy, (Adriamycin, bleomycin, vinblastine, and dubarbazine [ABVD]), for 2 cycles followed by 20 Gy involved-field radiation.
- Limited-stage disease (I to IIA) with unfavorable risk factors, termed “early unfavorable,” may be treated with either combined-modality therapy, 4 cycles of ABVD followed by 30 Gy involved-field radiotherapy, or with 6 cycles of ABVD alone. Decisions about therapy should be decided in a multi-disciplinary setting and are usually based on patient age and sex, disease bulk, and area of involved field radiation.
- Advanced-stage disease (IIB to IV) can now be treated with either ABVD or A +AVD for 6 cycles.
- Clinical trials should always be considered for the treatment of disease at any stage, if available.

### Epidemiology

There were 8500 estimated new cases of Hodgkin lymphoma (HL) in 2018 with 1050 deaths according to the SEER database. 86.6% patients who underwent treatment were surviving at 5 years between 2008 and 2014. There has been a downward trend in new cases and deaths due to HL over the last 10 years. The median age at diagnosis is 39 years and there is a bimodal age distribution with the highest risk in the age group of 20 to 34 years.

### Pathology

HL is classified broadly into classical Hodgkin lymphoma (CHL) and nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) based on the WHO classification system. CHL is the most common type, accounting for 95% of the cases. There are four distinctive histologic subtypes of CHL, Nodular Sclerosis (NS), Mixed Cellularity (MC), Lymphocyte Rich (LR), and Lymphocyte depleted (LD) with NS being the most common subtype.

Pathologically, CHL is characterized by the presence of definitive “Reed Sternberg” (RS) cells, which express CD30 and CD15 on their cell surface. NLPHL, on the other hand, is characterized by “popcorn cells” that express CD20 and CD45 on the cell surface.

### Risk Factors

Most cases of CHL are sporadic with no clear risk factors. NS is the most common subtype in United States and developed countries. MC and LR are more common in developing countries and are associated with prior Epstein Barr Virus (EBV) infection. HIV infection is associated with a 5 to 10 times higher risk due to immune suppression and associated EBV infection. The incidence of HL in HIV patients may be increasing in the era of antiretroviral therapy. Increased risk is also seen in other acquired or congenital immunodeficiencies.

There is also increased risk of CHL in families with an index case. According to a Nordic study, there is a threefold increase over the general population risk and the risk is the highest in siblings. Familial risk varies by subtypes and is the highest in the LR subtype.

### Clinical Presentation

Painless lymphadenopathy either in the neck (75%) or mediastinal lymph nodes (60%) is the most common presentation for CHL, whereas NLPHL usually presents with painless peripheral lymphadenopathy. “B” symptoms, which include fever higher than 38°C, unintentional weight loss of more than 10% of body weight over 6 months, and drenching night sweats can be present and are often considered unfavorable risk factors. Patients may present with local symptoms from bulky lymphadenopathy such as dyspnea, chest

pressure or cough due to mediastinal masses, and neck discomfort and trouble swallowing from cervical lymphadenopathy. Prolonged dyspnea, cough, or chest pressure should be evaluated with appropriate imaging in a young patient when CHL is a consideration in the differential diagnosis. Pruritus can also be seen in some patients and often improves with the treatment of CHL.

Spleen involvement can be seen in 20% of cases and is considered as nodal involvement in CHL. Other extra nodal involvement (e.g., bone marrow, lungs, liver, and bone) is uncommon and is usually associated with advanced unfavorable disease and a poor prognosis. CNS involvement is extremely rare.

Initial lab testing may not show any major abnormalities in early stage and favorable risk patients. The Erythrocyte Sedimentation Rate (ESR) is prognostic in CHL and should be performed at diagnosis in all patients. Anemia, lymphopenia, leukocytosis, and hypoalbuminemia may be seen on labs in advanced and unfavorable risk patients and are a result of cytokine response.

## Diagnosis

Adequate tissue sampling is essential in the diagnosis of any lymphoma and is even more indispensable in HL. CHL is characterized by background inflammatory cells, which include polyclonal reactive lymphocytes, neutrophils, and eosinophils with the actual malignant RS cells configuring only 1% to 2% of the total cellularity. As a result, diagnosis is often missed on FNA, which is considered a very insensitive diagnostic methodology. Excisional biopsy is preferable and in cases where it is not possible, multiple core needle biopsies or mediastinoscopic biopsies can be considered, based on the location.

On Haematoxylin and eosin (H&E) staining of the biopsy, the classic presentation for CHL is a rich inflammatory background interspersed with positive CD15 and CD30 RS cells. RS cells are typically large with bilobed eosinophilic nucleoli and abundant cytoplasm. Mononuclear variants also occur. On immunohistochemistry, RS cells are usually negative for the panlymphoid marker CD45 and the B-cell marker CD20. The presence of RS cells will rule out other conditions in the differential diagnosis, including Non-Hodgkin lymphoma, autoimmune diseases, and infections. The NS subtype also presents with dense bands of fibrosis on H&E staining.

NLPHL is also characterized by atypical malignant cells amidst a polyclonal inflammatory microenvironment composed primarily of small lymphocytes in large nodular meshworks of follicular dendritic cells. The “popcorn” cells characteristic of NLPHL express CD20 and CD45, rather than CD15 and CD30, which is the major pathologic differentiating factor from CHL.

## Staging and Risk Prognostication

Staging starts with a thorough history and physical exam. “B” symptoms, pruritus, fatigue, alcohol intolerance, and decrease in performance status may all be noted on the history. Careful palpation and measurements of lymph nodes and spleen as well as documentation of extra nodal involvement are important and can be followed after the initiation of treatment for a clinical response assessment.

The Ann Arbor classification is used for staging. CHL is broadly divided into four stages based on the spread of the lymphoma. Stage I disease is confined to a single lymph-node region, while Stage II is the involvement of multiple lymph-node regions on the same side of the diaphragm, Stage III has involvement of nodal regions on both sides of the diaphragm and Stage IV has extensive involvement of an extranodal site or sites. Each stage is subdivided into “A” and “B” depending on the presence or absence of B symptoms. The Cotswold classification includes an “X” category for bulky disease (Table 1).

Radiographic staging is performed with CT scans in conjunction with PET scanning at diagnosis and repeated after two cycles of chemotherapy and at the end of treatment (EOT). Positron emission tomography-computed tomography (PET-CT) imaging leads to a change in staging in 10% to 30% of patients, more often upstaging. Bone marrow aspirate/biopsy is no longer required for the routine evaluation of patients with HL due to the high sensitivity of PET scan. CNS staging with lumbar puncture (LP) and MRI of the brain is only done if there is a high suspicion based on

**TABLE 1** Staging Hodgkin Disease

STAGE	DEFINITION
I	Confined to single lymph-node region*
II	Involvement of multiple lymph-node regions on a same side of diaphragm
III	Involvement of nodal regions on both sides of the diaphragm
IV	Extensive involvement of extranodal site(s)
<b>Sub Classification</b>	
A	Absence of “B” symptoms
B	Presence of “B” symptoms
<b>Modifiers</b>	
E	Localized focus of extranodal disease or localized extension of nodal disease into an extranodal site.
S	Splenic involvement (the spleen is considered a nodal site in Hodgkin lymphoma)
X (Cotswold modifier)	Bulky disease (>10 cm or >0.33 of the maximal intrathoracic diameter for mediastinal mass per NCCN guidelines)

\*Lymph node regions include: right cervical (including cervical, supraclavicular, occipital, and preauricular lymph nodes), left cervical, right axillary, left axillary, right infraclavicular, left infraclavicular, mediastinal, hilar, periaortic, mesenteric, right pelvic, left pelvic, right inguinal femoral, and left inguinal femoral. NCCN, National Comprehensive Cancer Network.

symptoms and physical examination. Routine staging laparotomy and bilateral bone marrow biopsies are no longer performed.

Laboratory evaluation includes a complete blood count with differential, complete metabolic profile, including albumin, ESR, and baseline HIV testing. Due to the routine use of anthracyclines, an echocardiogram or multigated acquisition scan (MUGA; also called equilibrium radionuclide angiogram) is necessary prior to initiation of chemotherapy to assess left ventricular ejection fraction. Pulmonary function testing is performed and a detailed tobacco smoking history should be obtained due to the use of bleomycin. A pregnancy test should be performed on all women of childbearing age prior to the initiation of therapy. Fertility counseling is recommended for age appropriate patients even though the infertility risk is low (2% to 10%) with the ABVD regimen. The risk of infertility is higher with other regimens such as bleomycin, etoposide, doxorubicin hydrochloride (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone (BEACOPP).

Regardless of the stage, CHL is highly curable and 86.6% patients were alive at 5 years following treatment. Therefore, it is highly important to diagnose and treat patients appropriately and to monitor for long-term complications in survivors. Staging and risk prognostication are essential in deciding the appropriate treatment regimen. Age greater than 50, bulky disease more than 10 cm, elevated ESR, presence of “B” symptoms, involvement of greater than three nodal groups, and bulky mediastinal mass greater than 0.33 (maximum width of the mass/maximum intrathoracic diameter) are all unfavorable factors in limited stage disease (Stage I to II). In advanced-stage CHL, the international prognostic score is generated using seven adverse risk factors, which include male sex, age greater than 45 years, stage IV disease, serum albumin of less than 4 g per deciliter, a hemoglobin level of less than 10.5 g per deciliter, leukocytosis (a white-cell count of at least 15,000 per cubic millimeter), and lymphocytopenia (a lymphocyte count of less than 600 per cubic millimeter, a count that was less than 8% of the white-cell count, or both). The score predicted the rate of freedom from progression of disease with 42% survival in patients with a score of 5 or higher.

## Treatment

Stage I to IIA constitutes limited stage disease and Stage IIB to IV constitutes advanced disease.

### Limited Stage Classical Hodgkin Lymphoma

Combined modality treatment using a combination of radiotherapy (RT) and chemotherapy is the treatment of choice for early stage limited disease with favorable risk factors. Various trials over decades have established the role of combined modality treatment with RT alone or chemotherapy alone being the comparator arms.

The HD 10 trial investigated the reduction of number of cycles of doxorubicin (Adriamycin,<sup>1</sup> bleomycin, vinblastine, and dabarbazine [ABVD]) and the dose of involved field radiation (IFRT) in patients with no unfavorable risk factors. One thousand three hundred and seventy patients were randomized into four different groups. Early stage favorable risk factor patients who received 2 cycles of ABVD followed by 20 Gy IFRT had similar 5 year overall survival (OS) as the patients who received 4 cycles of ABVD followed by 30 Gy IFRT. ABVD for 2 cycles followed by 20 Gy IFRT is now the standard of care for Stage IA to IIA disease with favorable risk patients. Four cycles of ABVD followed by 30 Gy of IFRT or 6 cycles of ABVD is recommended for limited stage (stage I to IIA) disease with unfavorable risk factors or bulky disease. Stanford V and BEACOPP (bleomycin, etoposide [Toposar],<sup>1</sup> Adriamycin,<sup>1</sup> cyclophosphamide, vincristine [Oncovin], procarbazine [Matulane], and prednisone) regimens are considered alternate treatment options and generally yield similar excellent results with 5 year OS rates of 90% to 95%. ABVD is the most commonly used regimen due to greater tolerability and less cumulative dosage of anthracyclines.

### Advanced-Stage Classical Hodgkin Lymphoma

Advanced-stage CHL (Ann Arbor stages IIB to IV) used to be a fatal disease until the development of the MOPP (mechlor-ethamine, vincristine [Oncovin], procarbazine, and prednisone) regimen in the 1960s. ABVD for 6 to 8 months was compared to MOPP in a randomized landmark clinical trial and ABVD was found to be equally or more effective and was associated with less toxicity. ABVD is administered on days 1 and 15 of a 28-day cycle for 6 total cycles. Modern outcomes with ABVD for advanced-stage disease produced 5-year freedom from progression and OS of 78% and 90%, respectively. Combined modality treatment with IFRT is considered in patients with bulky disease for tumor consolidation or in patients with an incomplete response to chemotherapy.

Alternative regimens include escalated BEACOPP and Stanford V. Neither of these regimens improved OS when compared to ABVD and were associated with increased treatment-related toxicity. Most recently, brentuximab vedotin (BV) (Adcetris) in combination with an Adriamycin, vinblastine, and dacarbazine (A+AVD) regimen has been approved in the United States for advanced stage CHL based on the phase III randomized ECH-ELON-1 study. This regimen had a 4.9 percentage-point lower combined risk of progression, death, or noncomplete response when compared with the use of subsequent anticancer therapy at 2 years in comparison to ABVD with a tolerable safety profile. The modified end point is considered a caveat for this study and long-term survival data for this study is still pending. Both ABVD and A+AVD are reasonable first line options in patients with Stage III and IV disease and should be chosen based on the patient's age, financial status, and preference and comorbidities. There are not enough data at this time to recommend A+AVD over ABVD. There are ongoing clinical trials evaluating the efficacy and tolerability of combination regimens with BV and checkpoint blockade (nivolumab [Opdivo]) in front line settings. As of now, ABVD is still the preferred regimen in United States with ongoing debate in regard to alternative regimens.

<sup>1</sup>Not FDA approved for this indication

### Relapsed/Refractory Classical Hodgkin Lymphoma

CHL carries an overall excellent prognosis and approximately 85% of patients are cured. However, approximately 15% of patients do relapse or have primary refractory disease and will require salvage treatment. Prognosis, especially in patients with refractory disease or who relapse within 12 months of treatment, has historically been poor with conventional salvage chemotherapy. However, with the advent of targeted therapy and checkpoint blockade, response rates and OS rates for this group have improved significantly. Currently, conventional salvage chemotherapy followed by autologous stem cell transplant, which offers a 50% cure rate, remains the second line option.

BV maintenance is offered starting 30 to 45 days after stem cell transplant for a total of 16 cycles, 3 weeks apart based on phase III randomized AETHERA trial data. Patients randomized to receive brentuximab consolidation had significantly improved progression-free survival of 43 months, compared with 24 months in placebo-treated patients. There are ongoing clinical trials evaluating newer agents in second-line settings and enrollment in clinical trials is preferable for these patients. Patients who relapse after autologous stem cell transplant are usually considered for allogeneic stem cell transplant after they have demonstrated a response with next line options.

BV is a monoclonal antibody that is active against CD30 bound to the microtubule toxin monomethyl auristatin E (MMAE). BV has been FDA approved for third-line treatment after a pivotal phase II study resulted in an ORR of 75% and CR of 34% compared to single agent treatment. BV is administered every 3 weeks by intravenous infusion at a dose of 1.8 mg/kg. BV is now also used in combination with Bendamustine (Bendeka)<sup>1</sup> which, in multiple single institutional retrospective data, showed improved response rates of around 92% compared to BV alone.

Mostly recently, immunotherapy with checkpoint blockade has been studied in CHL after identification of 9p24.1 amplification, which results in universal overexpression of programmed death-1 (PD-1) ligands. Nivolumab and pembrolizumab (Keytruda), which are both PD-1 inhibitors, have been studied in phase II studies and have shown overall response rates of around 69% and 67%, respectively. Nivolumab is FDA approved for patients who have relapsed after autologous stem cell transplant and have failed BV. Pembrolizumab is approved for patients who have failed BV. Further studies are evaluating the role of combination treatments with these agents. There are also ongoing clinical trials evaluating newer treatment options such as CD30 engineered CAR T cells.

### Treatment of Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) is typically an indolent disease and presents with early stage disease in peripheral nodal locations. Early stage patients are treated with IFRT alone with excellent response rates. Ten year OS is 95% in these patients. Advanced-stage NLPHL is relatively uncommon and can be treated with either single agent rituximab (Rituxan),<sup>1</sup> due to CD20 positivity on malignant cells, or combination chemotherapeutic regimens such as ABVD and RCHOP (rituximab, cyclophosphamide, hydroxydaunomycin [doxorubicin], Oncovin, and prednisone), depending on the extent of disease and patient comorbidities.

### Response Assessment

End-of-treatment (EOT) assessment is more accurate with PET-CT imaging. The Deauville score, which is a 5-point scoring system, is used to assess responses with PET scan imaging. A score of 1, 2, or 3 is considered a complete metabolic response. There is no indication for routine surveillance scans after the EOT assessment. A score of 4 or 5 is considered a suboptimal response and

<sup>1</sup>Not FDA approved for this indication

may require a change of treatment plan. Interim PET scanning after two cycles of ABVD therapy has prognostic significance. However, the significance of interim PET scanning with newer combination regimens has not been validated.

### Complications and Long-Term Monitoring

CHL is a curable cancer. Short- and long-term complications from treatment require close monitoring, especially given the young age of presentation in most patients. Most short-term side effects are fatigue, nausea, emesis, constipation, increased risk of infections, and peripheral neuropathy. Patients need long-term cardiac monitoring due to the risk of congestive heart failure with anthracyclines and combination IFRT, and the risk of coronary artery disease with IFRT. Bleomycin can cause long-term pulmonary toxicity and patients should be monitored while on active treatment. Prompt discontinuation of bleomycin is warranted if there is any suspicion of pulmonary complications. There is a long-term risk of secondary malignancies and myelodysplastic syndrome in patients treated for HL.

Patients should undergo regular cancer screenings. Yearly complete blood count is warranted. Thyroid evaluation once a year is recommended for patients who have received neck or superior mediastinal IFRT. Mammography is recommended for women starting 8 years after IFRT to mediastinum.

## IRON DEFICIENCY ANEMIA

Method of  
Susan Evans, MD

### CURRENT DIAGNOSIS

- The presence of symptoms and signs depends on the degree of iron deficiency, the time course of the development of iron deficiency, and the overall physiologic state of the patient. Patients may be asymptomatic. Signs and symptoms are more likely if anemia and/or hemodynamic instability are present.
- Symptoms include fatigue, poor exercise tolerance, weakness, headache, pica, dyspnea, dizziness, vertigo, and angina pectoris.
- Signs include pallor, dry and rough skin, brittle nails, defects of the nail bed (koilonychia), atrophy of the lingual papillae, and cheilosis.
- Systolic heart murmur if anemia is present
- Neonates: delayed growth and development
- Adolescents: learning and behavior problems
- Blood loss is the most common cause of iron deficiency
- Iron deficiency is the most common cause of anemia

### Laboratory Findings

- Decreased iron on bone marrow aspirate is the gold standard but is rarely used
- Low serum hemoglobin to diagnose anemia
- Low mean corpuscular hemoglobin: late finding
- Low mean corpuscular volume: late finding
- Low serum iron
- High serum iron-binding capacity
- Low percent transferrin saturation (TSAT)
- Low serum ferritin, but may be normal in the presence of inflammation

### CURRENT THERAPY

#### Oral Replacement

- Ferric sulfate (or another equivalent iron preparation) 325 mg (65 mg elemental iron) three times daily.
- Avoid taking with meals to increase absorption.

#### Parenteral Replacement

- Recommended when blood loss exceeds the ability to replace orally, in the context of malabsorption and if oral iron is not tolerated
  - Ferric carboxymaltose (Ferinject and Injactafer)
  - Ferric gluconate (Ferlecit)
  - Ferumoxytol (Feraheme)
  - Iron sucrose (Venofer)

#### Unstable Patient

- If the patient is hemodynamically unstable due to anemia, consider blood transfusion

#### Treatment Endpoint

- Continue iron replacement for 3 months after anemia is resolved and iron replaced.

### Epidemiology

Anemia affects more than one-third of the world's population, or 2 billion people. Iron deficiency continues to be the most common cause of anemia. Iron deficiency is the only micronutrient deficiency that remains a significant problem in both developing and developed countries. Iron deficiency refers to a decrease in iron stores below a normal level and can cause

fatigue even without anemia. In the case of iron deficiency without anemia, iron stores are still adequate for erythropoiesis. Iron deficiency anemia is a more serious condition in which there is not enough erythroid iron available, leading to anemia. Worldwide levels of iron deficiency are estimated to be twice that of iron deficiency anemia.

### Risk Factors

Risk factors for iron deficiency anemia include age, socioeconomic status, female gender, diet low in iron, disease, and medical treatment. Several groups of people are at an increased risk of iron deficiency based on age or their stage in life. Infants and children ages 0 to 5 years old are at risk for iron deficiency because of their rapid rate of growth, which necessitates increased iron stores. Based on 2019 World Health Organization information, 39.8% of children aged 6 to 59 months were anemic. Adolescent girls and women of child bearing age are also at risk due to iron loss through menstruation. In 2019, 29.9% of women aged 15 to 49 were anemic. During pregnancy, a woman's iron needs triple because of the expansion of red cell mass, the placenta, and the growth of the fetus. Worldwide, anemia affects 36.5% of pregnant women and is known to increase the risk of cesarean section and maternal mortality. Elderly people are also at risk for iron deficiency for a number of reasons, including inadequate diet, poor absorption due to disease or antacid medicines, or as a complication of chronic disease. The 2025 Global Nutrition Targets aim to decrease the prevalence by 50%.

Dietary causes of iron deficiency anemia include lack of access to or preference against eating a diet including iron rich foods. While 90% of iron in the body is recycled every day, dietary iron is essential for replacing lost iron, which is mainly excreted in bile. Iron supplementation of common foods such as breads and rice in the United States decreases the risk of dietary iron deficiency. Iron is found naturally in both animal products such as meat and in plant based foods such as green leafy vegetables, sweet potatoes, and legumes. As long as they eat a healthy and well-balanced diet, vegetarians and vegans have not been shown to be at an increased risk for iron deficiency; such diets have many other health benefits.

Any illness or therapy that leads to decreased iron absorption or blood loss may cause iron deficiency. Common causes of blood loss include gastrointestinal diseases such as cancer, inflammatory bowel disease, and ulcer disease. Taking aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or anticoagulants also increases the risk of gastrointestinal blood loss. Iron absorption is decreased in the context of celiac disease, post gastric bypass surgery, and *Helicobacter pylori* infection. Chronic diseases associated with iron deficiency include chronic kidney disease, rheumatoid arthritis, cancer, obesity, and chronic heart failure. There are also medical treatments that may cause iron deficiency such as antacid medicines, which decrease iron absorption, dialysis that causes blood loss, and erythropoietin therapy that depletes iron stores through increased erythropoiesis. Frequent phlebotomy, including repetitive blood donation or treatment for polycythemia or hemochromatosis, decrease iron stores. Rarely, there may be a genetic cause for iron deficiency anemia such as iron-refractory iron deficiency anemia.

### Pathophysiology

Iron in the body can be broken down into two main types: functional iron and storage iron. Functional iron plays many essential roles in the human body. It is found in hemoglobin, which carries oxygen from the lungs to body tissues, and in myoglobin, which helps with oxygen use and storage. Iron plays a role in enzymatic reactions, DNA synthesis, mitochondrial energy generation, and cell proliferation. Storage iron is found in ferritin, hemosiderin, and transferrin. Iron homeostasis is very important to the body and is regulated through the diet, gastrointestinal absorption, and the recycling of the iron in red blood cells. Total body iron stores are about 3.5 g for men and 2.5 g

for women. Approximately 20 to 25 mg of iron is needed daily for red cell production and body processes. Dietary absorption of iron is limited to about 1 to 2 mg/day; the daily requirement is produced through the recycling of iron in used red blood cells by macrophages.

Dietary iron is found in two forms. Heme iron ( $\text{Fe}^{2+}$ ) is found in animal products such as meat, poultry and seafood and is more easily absorbed than plant-based iron. Nonheme iron ( $\text{Fe}^{3+}$ ) is found in plant sources such as beans and lentils, baked potatoes, dark green leafy vegetables, tofu, and cashews. Dietary iron is also found in iron fortified breakfast cereals and enriched breads. Adding foods high in vitamin C to a meal with nonheme iron can increase iron absorption. There are other foods that inhibit the absorption of iron, including polyphenols found in some vegetables, tannins found in tea, and calcium found in dairy products. Dietary iron absorption takes place almost exclusively in the duodenum and upper jejunum.

The recycling of iron from used red blood cells provides about 90% of body iron and is essential for maintaining normal iron levels in the body. Hepcidin, a peptide hormone mainly synthesized in the liver, controls the process of iron absorption and recycling. When serum iron levels are high, hepcidin levels increase in response, which leads to breakdown of the iron transporter called ferroportin. A decrease in ferroportin leaves more iron inside macrophages, enterocytes, and hepatocytes, and the serum iron level decreases. When serum iron levels drop, expression of hepcidin should decrease as well. However, inflammation and infection can cause hepcidin to increase inappropriately; this is one of the ways in which chronic disease contributes to iron deficiency.

### Prevention

Prevention plays a large role in the treatment of iron deficiency anemia worldwide and includes both dietary interventions and supplementation. A food-based approach to prevention would include encouraging patients to eat more iron rich foods such as meats and dark green leafy vegetables. A list of iron rich foods is found in Table 1. Heme iron, found in animal sources, is easily absorbed; however, the absorption of nonheme iron from plant sources is affected by the foods with which they are eaten. Foods that can inhibit the absorption of iron include the tannins in tea and coffee and the calcium found in milk. It is best to eat these foods separately from iron rich foods to increase iron absorption. Certain foods increase the absorption of non-heme iron when they are eaten at the same time, including foods that contain heme (such as meat) or foods that contain vitamin C (such as fruit, orange juice, or broccoli). Encouraging iron fortified foods, which in the United States include cereals, rice, pasta, and bread, is another effective way to prevent deficiency. There are some cases when the risk of developing iron deficiency is so high that supplementation with an oral iron supplement is recommended. The World Health Organization recommends universal

**TABLE 1** Iron Rich Foods

IRON TYPE	DIETARY SOURCES
Heme Iron	Beef Chicken Fish Organ Meats Oysters
Nonheme Iron	Dark Green Leafy Vegetables Beans Lentils Tofu Baked Potato Cashews Fortified Cereals, Breads and Pasta

supplementation for low-birth-weight infants with 2 mg/kg daily from age 2 months to 23 months. They also recommend universal supplementation for pregnant women with 60 mg iron per day. While supplementation for pregnant women is common practice in the United States, the US Preventive Services Task Force states that there is insufficient evidence to show that these practices help prevent adverse maternal health and birth outcomes. According to the US Preventive Services Task Force, evidence is also insufficient to recommend screening children age 6 months to 2 years of age for iron deficiency anemia in the United States.

### Clinical Manifestations

Patients with iron deficiency may be asymptomatic. The presence of symptoms and signs of iron deficiency depend on the degree of deficiency, the time course of the development of iron deficiency, and the overall physiologic state of the patient. Common symptoms of iron deficiency include fatigue, weakness, irritability, poor concentration, decreased exercise intolerance, dry mouth, headache, and restless leg syndrome. Severe iron deficiency can cause pica, a craving to eat substances such as ice, dirt, clay, or paint. Signs of iron deficiency include pallor and a systolic heart murmur if anemia is present, hair loss, atrophy of lingual papillae, and nail changes such as koilonychia.

### Diagnosis

Normal hemoglobin levels depend on age, gender, pregnancy status, altitude, and smoking, but in general, an adult male is considered anemic with a hemoglobin level less than 13 g/mL and an adult female at less than 12 g/mL. However, these thresholds were first recommended by the World Health Organization in 1968 and were not developed using current laboratory and epidemiological methods. The World Health Organization is in the process of evaluating and updating the guidelines for assessment and diagnosis of anemia. Iron deficiency may be present with or without anemia; therefore, measuring hemoglobin level is neither a sensitive nor a specific test for iron deficiency. Absolute iron deficiency occurs when the amount of total body iron is low. Functional iron deficiency occurs when there is not enough iron available to meet the demand of body tissues and processes because iron is sequestered either in macrophages or the reticuloendothelial system.

Diagnosing iron deficiency is not straightforward because serum ferritin level, which is often used as a screening test, is affected by gender, age, inflammation, infection, and chronic diseases such as liver disease and cancer. While a serum ferritin concentration less than 12 µg/L makes iron deficiency very likely, a person with inflammation or chronic disease may have iron deficiency at much higher ferritin levels. Increasing the cutoff for normal ferritin concentration to 30 µg/L has been shown to increase sensitivity for iron deficiency, and an even higher cutoff of 100 µg is recommended by some specialty societies. For this reason, utilizing more than one iron status indicator to make the diagnosis is important. A low iron level (<50 µg/dL) and an elevated total iron binding capacity (TIBC >450 µg/dL) also support the diagnosis of iron deficiency. Other supporting labs include a drop in transferrin saturation (TSAT) to less than 16% or less than 20% if inflammation or disease is present. Low mean corpuscular volume (MCV) may be another sign of iron deficiency, but this is generally a late finding, so MCV may be in the normal range. Low MCV can also be seen in thalassemia. Low mean corpuscular hemoglobin concentration (MCHC) is another late finding in iron deficiency. Decreased iron seen on bone marrow aspiration is still considered the gold standard for diagnosing iron deficiency, but it is rarely done due to both cost and patient discomfort. A new test being developed to diagnose iron deficiency measures the level of serum soluble transferrin receptors (sTfR), which increase in the context of iron deficiency and are not affected

by inflammation. A drawback for the test is that the sTfR level may be elevated in those with hemolytic anemia or chronic lymphocytic leukemia as well as in those using recombinant human erythropoietin.

### Differential Diagnosis

The differential diagnosis of iron deficiency includes causes of fatigue and exercise intolerance such as hypothyroidism, electrolyte disturbances due to diuretic therapy, left ventricular dysfunction, chronic lung disease, malignancies, or liver disease.

Anemia of chronic disease can mimic iron deficiency anemia and may be found concurrently in the same patient. The differential diagnosis for iron deficiency also includes thalassemia, sideroblastic anemias, and lead poisoning.

### Treatment

The goal of treatment is to replace iron so that hemoglobin levels normalize, and iron stores are replenished. Treatment of iron deficiency must take into consideration the type of patient being treated and the source and amount of iron deficit or blood loss. Patients who are severely anemic and hemodynamically unstable may be candidates for blood transfusion. For people in groups that are at high risk for iron deficiency, such as infants, toddlers, adolescents, and menstruating women, it is reasonable to start with oral supplementation with iron and only proceed with further work up if that is unsuccessful. However, in patients at low risk for iron deficiency, such as men and post-menopausal women, it is important to determine the underlying cause of iron deficiency. Blood loss is the most common cause of iron deficiency, so this work-up includes evaluation for a source of bleeding. Urinalysis and heme-occult testing are preliminary tests, and upper and lower endoscopy is needed to evaluate for gastrointestinal pathology including cancer, colitis, or celiac disease. If those tests are inconclusive, consider proceeding to video capsule endoscopy to further evaluate the small intestine. Heavy gynecologic bleeding may require further evaluation and treatment. Persistent blood noted on urinalysis would warrant referral to urology for further testing.

Oral iron supplementation continues to be the first line treatment for iron deficiency anemia. Common forms include ferrous sulfate (Feosol), ferrous gluconate (Fergon), and ferrous fumarate (Ferro-Sequels). A typical dose of ferrous sulfate is 325 mg, which is 65 mg elemental iron, three times daily. However, there is now evidence that a dose of oral iron increases serum hepcidin, which then decreases iron absorption. Based on these findings, an alternate recommendation would be to give a single dose of iron on alternate days. This dosing schedule may increase iron absorption and adherence to treatment due to simpler regimen with decreased side effects. Iron is best absorbed when taken between meals; however, this can also worsen side effects. It is best to take iron separate from acid reducing medicines and foods that inhibit iron absorption. Common side effects of oral iron include diarrhea, nausea, epigastric discomfort, and constipation. Side effects can be lessened by taking iron with food and taking smaller doses, or changing to ferrous gluconate 325 mg (38 mg elemental iron).

Parenteral iron may be indicated when oral therapy is unsuccessful due to malabsorption, when oral iron is not tolerated, or when the rate of absorption with oral supplementation is insufficient due to the rate of blood loss. New forms of parenteral iron are safer, less likely to cause hypersensitivity reactions, and their use is increasing. The dose of IV iron needed can be calculated with the following formula: body weight in kilograms  $\times$  2.3  $\times$  hemoglobin deficiency (target hemoglobin level—patient hemoglobin level). Add another 500 to 1000 mg iron to replace low iron stores. Parenteral iron preparations licensed for use in the United States include iron sucrose (Venofer), ferumoxytol (Feraheme), ferric carboxymaltose (Ferinject and Injectafer), and ferric gluconate (Ferrlecit). A common dose for iron sucrose is 200 mg IV over 2 to 5 minutes, which is often repeated 5 times or

until the target dose of iron is reached. Ferumoxytol has a usual dose of 510 mg IV infusion over at least 15 minutes which can be repeated 3 to 5 days after the initial dose. For patients who weigh  $\geq 50$  kg, the dose of ferric carboxymaltose is 750 mg IV over 15 to 30 minutes, and this can be repeated 7 days after the first dose. Ferric gluconate is generally used for patients on dialysis, and the typical dose is 125 mg IV over 10 minutes or IV infusion over 60 minutes per dialysis session.

### Monitoring

The earliest marker for successful iron replacement is an increase in the reticulocyte count, which occurs within 5 to 10 days of initiation of iron replacement. Darkening of stools after 2 or 3 days of starting oral iron replacement is a reliable marker of compliance. A hemoglobin increase of 2 g/dL is considered an appropriate response to oral iron replacement. Reaching a serum ferritin level of 100  $\mu\text{g/L}$  will ensure good iron stores in nearly all patients. Once iron deficiency has been corrected, a complete blood count and labs to evaluate iron stores should be checked monthly for 3 months and then every 3 months for a year. If iron levels are not maintained, then further work up is indicated to discover the cause.

### Management of Complications

If properly treated, iron deficiency has few complications in adults. Untreated iron deficiency in infants and small children can lead to cognitive development and growth deficits. Treating iron deficiency without identifying the source and cause of blood loss could result in a delay or failure to diagnose gastrointestinal malignancies or other serious clinical problems.

Plummer–Vinson syndrome is a rare clinical condition characterized by a triad of iron deficiency anemia, post-cricoid esophageal webs, and dysphagia. The pathogenesis of Plummer–Vinson syndrome remains unclear, though iron and other nutritional deficiencies, genetic predisposition, and autoimmunity have all been implicated in the formation of the webs. Treatment includes the correction of iron deficiency and endoscopic dilation of the esophageal webs to relieve dysphagia.

## MULTIPLE MYELOMA

Method of

S. Vincent Rajkumar, MD; and Robert A. Kyle, MD

### CURRENT DIAGNOSIS

- Malignant clonal plasma cell disorder
- Characterized by presence of a monoclonal immunoglobulin in the serum or urine in most patients
- Typical manifestations include anemia, osteolytic bone lesions, and renal failure
- Initial work-up should include a bone marrow aspiration and biopsy with fluorescent in situ hybridization studies to determine molecular cytogenetic t(11;14), and t(6;14)
- Standard risk: trisomies (hyperdiploidy), t(11;14), and t(6;14)
- High risk: del(17p), gain 1q, t(4;14), (t14;16) or t(14;20)

### CURRENT THERAPY

- Do not begin treatment until symptomatic multiple myeloma develops (CRAB: calcium elevated, renal failure, anemia, bone lesions) or other myeloma defining events are present. Patients with high risk smoldering multiple myeloma are candidates for preventive therapy with lenalidomide (Revimid) or lenalidomide plus dexamethasone (Decadron)<sup>1</sup> (Rd)
- Decide whether an autologous stem cell transplant is feasible. If it is, one must avoid melphalan (Alkeran) therapy as initial treatment.
- Initial therapy typically consists of a triplet regimen such as lenalidomide (Revimid), bortezomib (Velcade), dexamethasone (VRd), daratumumab (Darzalex), lenalidomide, and dexamethasone (DRd).
- Patients who are candidates for autologous stem cell transplantation should collect stem cells after 3 to 4 cycles of induction. After collection, patients proceed to either early transplantation, or resume initial therapy and postpone transplant until relapse. After transplant, and after initial therapy in patients who delay transplant, patients should receive maintenance therapy.
- Patients who are not stem cell transplant candidates who are treated with VRd receive about 8 to 9 cycles of triplet therapy followed by maintenance. If DRd is used as initial therapy, the triplet is continued at maintenance doses. Frail patients can be treated with the doublet regimen of Rd, in which case therapy is continued until progression if tolerated.
- Relapsed or refractory myeloma should be treated with one of the active drugs given alone or in combination. Active agents include thalidomide, lenalidomide, bortezomib, carfilzomib (Kyprolis), pomalidomide (Pomalyst), daratumumab (Darzalex), ixazomib (Ninlaro), elotuzumab (Empliciti), isatuximab (Sarclisa), belantamab mafodotin (Blenrep), selinexor (Xpovio), ide-cel (Abecma), cilta-cel (Carvykti), corticosteroids, anthracyclines, and alkylators.

Multiple myeloma is characterized by the neoplastic proliferation of clonal plasma cells. It is typically associated with a monoclonal (M) protein in the serum and/or urine.

### Epidemiology

In the United States, multiple myeloma constitutes 1% of all malignant diseases and slightly more than 10% of hematologic malignancies. The annual incidence is 4 to 5 per 100,000; the incidence in African Americans is twice that in whites. The

apparent recent increase in rates is probably caused by increased availability and use of medical facilities and improved diagnostic techniques, particularly in the older population. The median age at diagnosis is approximately 70 years.

### Risk Factors

The cause of multiple myeloma is unclear. Exposure to radiation might play a role. Persons in agricultural occupations who are exposed to pesticides, herbicides, or fungicides have an increased risk of multiple myeloma. Benzene and petroleum products, hair dyes, engine exhaust, furniture worker products, obesity, and chronic immune stimulation have also been reported as risk factors. The risk of developing multiple myeloma is higher for patients with a first-degree relative with the disease. Clusters of two or more first-degree relatives or identical twins have been recognized.

### Clinical Manifestations

Weakness, fatigue, bone pain, recurrent infections, and symptoms of hypercalcemia or renal insufficiency should alert the physician to the possibility of multiple myeloma. Anemia is present in 70% of patients at the time of diagnosis. An M protein is found in the serum or urine in more than 97% of patients with multiple myeloma by immunofixation studies and the serum free light chain (FLC) assay. Lytic lesions, osteoporosis, or fractures are present at diagnosis in 80% of patients and are best detected by whole body low-dose computed tomography (CT) or positron emission tomography (PET)/CT. Magnetic resonance imaging (MRI) and PET/CT are also helpful in patients who have skeletal pain but no abnormality on radiographs or when there are other clinical concerns about the extent of the disease. Conventional radiography is less sensitive and is no longer recommended. Hypercalcemia is present in 15% of patients, and the serum creatinine value is 2 mg/dL or greater in almost 20% of patients at diagnosis.

### Diagnosis

If multiple myeloma is suspected, the patient should have, in addition to a complete history and physical examination:

- Determination of values for hemoglobin, leukocytes with differential count, platelets, serum creatinine, calcium, and uric acid
- A radiographic survey of bones, including humeri and femurs using low-dose whole body CT or PET-CT.
- Serum protein electrophoresis with immunofixation
- Quantitation of immunoglobulins (Igs), serum FLC assay
- Bone marrow aspirate and biopsy
- Routine urinalysis
- Electrophoresis and immunofixation of an adequately concentrated aliquot from a 24-hour urine specimen
- Fluorescence in situ hybridization (FISH)
- Measurement of  $\beta_2$ -microglobulin, C-reactive protein, and lactate dehydrogenase

**Box 1** lists the International Myeloma Working Group updated criteria for diagnosis of myeloma and related disorders. Metastatic carcinoma, lymphoma, leukemia, and connective tissue disorders can resemble multiple myeloma and must be considered in the differential diagnosis. Patients with multiple myeloma must be differentiated from those with monoclonal gammopathy of undetermined significance (MGUS) and smoldering (asymptomatic) multiple myeloma (SMM). Patients with MGUS and low-risk SMM may remain stable for long periods and not require treatment (see **Box 1**). Patients with high-risk SMM (any two or more of the following:  $>20\%$  bone marrow plasma cells,  $>2\text{g/dL}$  serum M protein,  $>20$  serum FLC ratio) should be considered for lenalidomide (Revlimid)<sup>1</sup> or lenalidomide plus dexamethasone (Decadron)<sup>1</sup> as preventive therapy.

## BOX 1 International Myeloma Working Group Diagnostic Criteria.

### Monoclonal Gammopathy of Undetermined Significance

- Serum M protein  $<3$  g/dL
- Clonal bone marrow–plasma cells  $<10\%$
- Absence of end-organ damage (CRAB) attributable to a plasma cell proliferative disorder

### Smoldering Multiple Myeloma

- Serum M protein  $\geq 3$  g/dL and/or clonal bone marrow–plasma cells  $10\%$ – $60\%$
- Absence of myeloma defining events or amyloidosis

### Multiple Myeloma

- Presence of clonal bone marrow plasma cells  $10\%$  or greater or biopsy-proven plasmacytoma
- Presence of end-organ damage (CRAB) thought to be related to a plasma cell proliferative disorder or other myeloma defining event (clonal bone marrow plasma cells  $60\%$  or higher, serum free light chain ratio 100 or more provided involved free light chain level is 100 mg/L or more, more than one focal lesion on magnetic resonance imaging)

CRAB, Calcium elevated, renal failure, anemia, bone lesions; M, monoclonal.

Derived from Rajkumar SV, Dimopoulos MA, Palumbo A, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. *Lancet Oncol*. 2014;15:e538–e548.

### Treatment

Patients with symptomatic multiple myeloma may be classified as having high-risk or standard-risk disease. High-risk disease is defined as the presence of del(17p), gain 1q, t(4;14), t(14;16), or t(14;20) with FISH. Detection of p53 mutations by sequencing is also considered a cytogenetic high-risk factor. The presence of two high-risk cytogenetic abnormalities is considered “double-hit” myeloma; and the presence of three high-risk abnormalities is considered triple-hit myeloma. Lactate dehydrogenase, circulating plasma cells, and  $\beta_2$ -microglobulin levels are additional important risk factors. Approximately 15% to 20% of patients with symptomatic multiple myeloma have high-risk disease.

Initially, patients are classified into those eligible for an autologous stem cell transplant (SCT) versus those not eligible. An autologous SCT adds approximately 1 year of survival on average when compared with patients treated with conventional-dose chemotherapy alone.

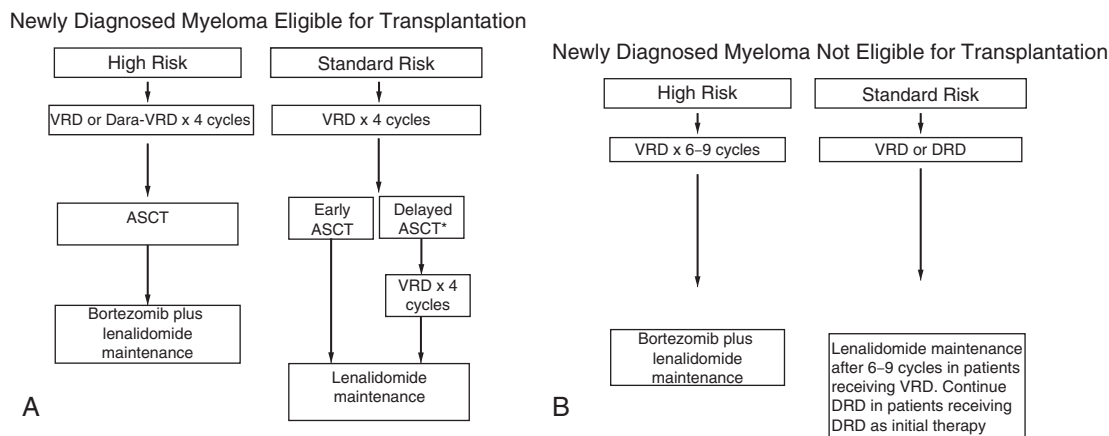

Eligibility for autologous SCT in multiple myeloma varies from country to country. In the United States, decisions are made on a patient-by-patient basis depending on the physiologic age rather than the chronologic age. In most institutions, patients older than 70 years or with serum creatinine greater than 2.5 mg/dL, Eastern Cooperative Oncology Group (ECOG) performance status of 3 or 4, or New York Heart Association (NYHA) functional status class III or IV are considered ineligible for autologous SCT. Although patients with kidney failure may have an autologous SCT, the morbidity and mortality are higher.

### Initial Therapy for Transplant-Eligible Patients

The approach to treatment of newly diagnosed myeloma in patients eligible for stem cell transplantation is summarized in **Figure 1A**. Bortezomib (Velcade), lenalidomide (Revlimid), dexamethasone (Decadon) (VRD)<sub>1</sub> is the preferred standard initial therapy for multiple myeloma. In a randomized trial conducted by the Southwest Oncology Group, VRD was superior to lenalidomide plus dexamethasone (Rd) in terms of progression-free survival (PFS) and overall survival (OS). Bortezomib and dexamethasone are typically administered once weekly. In the VRD regimen lenalidomide is given at a dose of 25 mg daily on days 1 to 14 of a 21-day cycle. Bortezomib should be given using the once-weekly schedule to reduce the risk of peripheral neuropathy.

<sup>1</sup>Not FDA approved for this indication.

**Figure 1** Approach to the treatment of newly diagnosed myeloma in patients eligible for stem cell transplantation (A) and approach to the treatment of newly diagnosed myeloma in patients not eligible for stem cell transplantation (B). ASCT, Autologous stem cell transplantation; DRD, daratumumab, lenalidomide, dexamethasone; Dara, daratumumab; VRD, bortezomib, lenalidomide, dexamethasone. Modified from Rajkumar SV. Multiple myeloma: 2020 update on diagnosis, risk-stratification, and management. *Am J Hematol.* 95(5):548–567, 2020.

It is also preferable to administer bortezomib subcutaneously to diminish the risk of neuropathy. An alternative to VRD is daratumumab (Darzalex), lenalidomide, dexamethasone (DRD). For patients who are initiated on DRD, all three drugs are continued until progression, with daratumumab administered once-monthly after the first 6 months of therapy. The addition of daratumumab (Darzalex) to VTD (Velcade, thalidomide, dexamethasone) has shown better response rates and PFS compared with VTD, but more data on OS are needed before this approach can be recommended. Similar results are also available with the addition of daratumumab to the current standard of VRD. Daratumumab plus VRD can be considered as pre-transplant induction therapy instead of VRD in young patients with high-risk disease. Bortezomib plus cyclophosphamide (Cytoxan) 300 mg/m<sup>2</sup> orally once weekly plus dexamethasone 40 mg once weekly (VCD) is an option for patients presenting with acute renal failure. If lenalidomide is not available, an alternative for initial therapy is bortezomib, thalidomide (Thalomid), and dexamethasone (VTD). For high-risk patients less than 65 years of age, daratumumab plus VRD can be considered as an alternative. In all regimens, it is preferable to administer dexamethasone at a dose no greater than 40 mg per week unless there is need for urgent cytoreduction as in patients with acute renal failure and cast nephropathy.

### Autologous Stem Cell Transplantation

Following 3 to 4 months of induction therapy with one of the initial regimens, one must collect the stem cells in patients eligible for transplantation. The stem cells must be collected before the patient is exposed to prolonged therapy, especially melphalan (Alkeran). Granulocyte colony-stimulating factor (G-CSF, Neupogen) with or without cyclophosphamide (Cytoxan) is used for mobilizing stem cells. G-CSF plus cyclophosphamide is preferred in patients who are treated with lenalidomide plus dexamethasone induction, who are older than 65 years, or who have received such therapy for over 4 months. Plerixafor (Mozobil) may also be used for mobilization of hematopoietic stem cells. It is advisable to collect  $6 \times 10^6$  CD34<sup>+</sup> cells/kg, which is sufficient for two transplants in patients below 65 years of age.

The timing of autologous SCT takes into account the patient's wishes, and it may be done early (when the patient recovers from stem cell collection) or delayed until relapse. There is no difference in OS even at 8 years of follow up among patients who receive an autologous SCT immediately following collection of stem cells and those who receive it at first relapse. In general, we prefer an early transplant because this provides a better quality of life and time without therapy.

Melphalan 200 mg/m<sup>2</sup> is the preferred conditioning regimen for autologous SCT. Tandem transplantation is not recommended for most patients. An exception would be young patients (below

65 years of age) with high-risk multiple myeloma, in whom such an approach can be considered on a case-by-case basis.

The mortality rate with autologous SCT is approximately 1%. Unfortunately, multiple myeloma is not eradicated, and the autologous peripheral stem cells are contaminated by myeloma cells or their precursors.

Bone marrow transplantation from an identical twin donor (syngeneic) is the treatment of choice if such a donor is available. Results are superior to allogeneic transplantation.

### Maintenance Therapy Following Autologous Stem Cell Transplantation

Randomized trials have tested the value of lenalidomide as maintenance therapy following stem cell transplantation. An OS benefit has been observed in a meta-analysis of three trials. This benefit appears to be mainly restricted to standard-risk patients. An increased risk of second cancers has been noted with lenalidomide maintenance and further follow-up is needed. In another randomized trial improved OS with bortezomib maintenance has been reported, but it is not clear whether the benefit is due to the maintenance therapy or differences in induction therapy between the two groups. We recommend lenalidomide maintenance for standard-risk patients following autologous SCT, and following approximately 12 months of initial therapy in patients not eligible for SCT and in patients who delay SCT. In high-risk patients, we recommend bortezomib plus lenalidomide maintenance.

### Allogeneic Transplantation

Allogeneic bone marrow transplantation (myeloablative and non-myeloablative) has been tested in myeloma, but treatment-related mortality is high and graft-versus-host disease is a troublesome problem. Furthermore, only a small proportion of patients with multiple myeloma are eligible. Allogeneic transplantation is currently not recommended for routine use outside of a clinical trial. An exception to this are young patients with high-risk disease in first relapse after autologous transplantation who are willing to assume the high treatment-related mortality associated with allogeneic SCT.

### Initial Therapy for Patients Who Are Ineligible for Autologous Stem Cell Transplantation

The initial therapy for patients not eligible for transplantation now resembles that of transplant-eligible patients. The current approach to treatment of newly diagnosed myeloma in patients not eligible for stem cell transplantation is summarized in Figure 1B. Currently, we prefer VRD as initial therapy. An alternative that has been recently approved for initial therapy in the United States is DRD. Other options include VCD and VTD. For frail patients, the doublet regimen of Rd can be used.

When using VRD, we continue the initial chemotherapy regimen for approximately 6 to 9 cycles followed usually by lenalidomide maintenance in standard-risk patients and bortezomib plus lenalidomide maintenance in high-risk patients.

### Relapsed or Refractory Multiple Myeloma

Almost all patients with multiple myeloma who survive eventually relapse. If relapse occurs more than 6 months after treatment is discontinued, the initial chemotherapy regimen should be reinstated. Most patients respond again, but the duration and quality of response are usually inferior to the initial response. Recently, several new drugs have been approved for the treatment of multiple myeloma including pomalidomide (Pomalyst), carfilzomib (Kyprolis), daratumumab (Darzalex), elotuzumab (Empliciti), ixazomib (Ninlaro), selinexor (Xpovio), isatuximab (Sarclisa), belantamab mafodotin (Blenrep), idecabtagene vicleucel (ide-cel [Abecma]), and ciltacabtagene autoleucel (ciltacel [Carvykti]).

### Thalidomide

Thalidomide (Thalomid) is usually instituted in a dose of 50 to 100 mg daily and, if necessary, escalated to 200 mg daily if tolerated. It is most often used in combinations such as VTD. Side effects include sedation, fatigue, constipation, rash, deep venous thrombosis (DVT), edema, bradycardia, and hypothyroidism. Virtually all patients develop a sensorimotor peripheral neuropathy. The use of thalidomide in pregnancy is contraindicated, and the System for Thalidomide Education and Prescribing Safety (STEPS) program must be followed to prevent teratogenic effects.

### Bortezomib

Bortezomib (Velcade) is a proteasome inhibitor that produces a response rate of approximately 35% in patients with relapsed or refractory myeloma. It is most often used in combinations such as VRD, VCD, or VTD to maximize response rates. The most troublesome side effect is peripheral neuropathy, which can occur in 35% to 40% of patients. The neuropathy is often painful but does improve in most patients after discontinuing bortezomib. The risk of neuropathy can be greatly reduced by using bortezomib in a once-weekly subcutaneous schedule.

### Lenalidomide

Lenalidomide (Revlimid) as a single-agent produces an objective response in approximately 30% of patients with relapsed or refractory multiple myeloma. The major side effects are cytopenias, and the dose needs to be modified accordingly. The combination of lenalidomide plus low-dose dexamethasone (Rd) is the backbone of several myeloma treatment regimens.

### Carfilzomib

Carfilzomib (Kyprolis) is a new proteasome inhibitor approved for the therapy of patients with multiple myeloma who have received at least two prior therapies, including both an immunomodulatory agent and bortezomib, and have disease progression on or within 60 days of the completion of the last therapy. Carfilzomib needs to be administered intravenously twice weekly. In a recent randomized trial, the combination of carfilzomib, lenalidomide, and dexamethasone (KRd) was found to have superior response rate, PFS, and OS compared with Rd.

### Pomalidomide

Pomalidomide (Pomalyst) is an analog of lenalidomide and thalidomide. It has shown significant clinical activity in patients who are refractory to both bortezomib and lenalidomide (dual refractory). It is approved for patients with multiple myeloma who received at least two prior therapies, including both lenalidomide and bortezomib, and have disease progression on or within 60 days of the completion of the last therapy. It is administered orally at a dose of 2 to 4 mg daily for 21 days every 28 days. The major side effects are cytopenias and fatigue.

### Elotuzumab

Elotuzumab (Empliciti) is a monoclonal antibody that is approved for the treatment of relapsed myeloma. It targets the signaling lymphocytic activation molecule F7 (SLAMF7). In a randomized trial of 646 patients, elotuzumab plus Rd was superior to Rd, median PFS 19.4 months versus 14.9 months, respectively ( $P < .001$ ).

### Daratumumab

Daratumumab (Darzalex) is a monoclonal antibody that is approved for the treatment of relapsed myeloma. It targets CD38, a molecule universally expressed on myeloma cells. Daratumumab has a response rate of approximately 30% in heavily pretreated patients. Two randomized trials have found improvement in PFS with the addition of daratumumab to Rd and bortezomib-dexamethasone, respectively.

### Ixazomib

Ixazomib (Ninlaro) is an oral proteasome inhibitor approved for the treatment of relapsed myeloma. It is a boronic acid derivative similar to bortezomib. It is administered once weekly orally. Compared with bortezomib, it has a lower risk of peripheral neuropathy.

### Selinexor

Selinexor (Xpovio) is an oral drug that acts by binding to nuclear export protein 1 (XPO1) and selectively blocking the transport of various proteins within the cell. It has been approved in combination with low dose dexamethasone for patients with relapsed or refractory multiple myeloma who have received at least 4 prior therapies, and whose disease is refractory to at least 2 proteasome inhibitors, at least 2 immunomodulatory agents, and an anti-CD38 monoclonal antibody. It is administered orally at a dose of 80 mg twice a week. However, due to toxicities, a once weekly regimen is likely more preferable.

### Belantamab mafodotin

Belantamab mafodotin (Blenrep) is an antibody drug conjugate targeting B-cell maturation antigen (BCMA) that is expressed on plasma cells. Belantamab mafodotin has been approved as a single agent in patients with relapsed or refractory multiple myeloma who have received at least 4 prior therapies, including an anti-CD38 monoclonal antibody, a proteasome inhibitor, and an immunomodulatory agent. It has a response rate of approximately 30%. The main adverse effect of concern is grade 3 to 4 keratopathy, which can be seen in approximately 40% of patients, necessitating ophthalmologic evaluation prior to starting therapy and periodically during therapy.

### Chimeric Antigen Receptor T (CAR-T) Cell Therapy

Idecabtagene vicleucel (ide-cel; Abecma) and ciltacabtagene autoleucel (cilta-cel; Carvykti) are CAR-Ts targeting BCMA. They have been approved for patients with relapsed refractory myeloma after 4 or more prior therapies, including an immunomodulatory drug, a proteasome inhibitor, and an anti-CD38 antibody. Ide-cel is well tolerated, with less than 5% of patients experiencing severe cytokine release syndrome or neurological toxicity. It has a response rate of 73%, with a response duration of approximately 9 months. Cilta-cel is also well tolerated and has a 2-year progression free survival rate of approximately 60%.

### Isatuximab

Isatuximab (Sarclisa) is a monoclonal antibody targeting CD38 and is an alternative to daratumumab. It has been approved in combination with pomalidomide and dexamethasone, as well as in combination with carfilzomib and dexamethasone. In certain patients, isatuximab may be significantly less expensive than daratumumab, which may be a consideration.

### Other New Drugs

New drugs that are in clinical trials include new bi-specific antibodies such as teclistamab<sup>5</sup> and AMG-701<sup>5</sup> (targeting BCMA and CD3), talquetamab<sup>5</sup> (targeting GPRC5D and CD3), and cevostamab<sup>5</sup> (targeting FcRH5 and CD3). Venetoclax (Venclexta)<sup>1</sup> has shown promise against t11;14 subtype of multiple myeloma. Iberdomide<sup>5</sup> is a new cereblon targeting agent that has also shown promise.

### Supportive Therapy

#### Radiotherapy

Palliative radiation in a dose of 20 to 30 Gy should be limited to patients who have disabling pain and a well-defined focal process that has not responded to chemotherapy. Analgesics in combination with chemotherapy usually can control the pain. This approach is preferred to local radiation because pain often occurs at another site, and local radiation does not benefit the patient with systemic disease. In addition, the myelosuppressive effects of radiotherapy and chemotherapy are cumulative and can restrict future therapy. Radiation is required for spinal cord compression from plasmacytoma. Postsurgical radiation after stabilization of fractures or impending fractures is rarely needed.

#### Hypercalcemia

Hypercalcemia must be suspected if the patient has anorexia, nausea, vomiting, polyuria, increased constipation, weakness, confusion, stupor, or coma. If it is untreated, renal insufficiency usually develops. Hydration, preferably with isotonic saline and prednisone (25 mg orally four times daily), is effective in many patients with mild to moderate hypercalcemia (calcium < 13 mg/dL). If more-severe hypercalcemia occurs, zoledronic acid (Zometa) at a dose of 4 mg intravenously over 15 minutes or pamidronate (Aredia) 90 mg given intravenously over at least 2 hours is indicated. Calcitonin (Miacalcin) may be used if rapid reduction of calcium levels is needed. Hemodialysis may be necessary for extremely severe hypercalcemia. The dosage of prednisone must be reduced and discontinued as soon as possible.

#### Renal Insufficiency

Approximately 20% of patients with multiple myeloma have a serum creatinine level of 2.0 mg/dL or more at diagnosis. Myeloma kidney (cast nephropathy) and hypercalcemia are the two major causes. Myeloma kidney is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. Some light chains are very nephrotoxic, but no specific amino acid sequence of the nephrotoxic light chain has been identified.

Dehydration, infection, nonsteroidal antiinflammatory agents, and radiographic contrast media can contribute to acute kidney failure. Hyperuricemia or amyloid deposition can produce renal insufficiency. Nephrotic syndrome rarely occurs in multiple myeloma unless amyloidosis is present.

Maintenance of a high fluid intake producing 3 L of urine per 24 hours is important for preventing kidney failure in patients with Bence Jones proteinuria. If hyperuricemia occurs, allopurinol (Zyloprim) in doses of 300 mg daily provides effective therapy.

Acute kidney failure should be treated promptly with appropriate fluid and electrolyte replacement. Patients with kidney failure should be treated with either VCD or VTD to reduce the tumor mass as quickly as possible. A trial of plasmapheresis is reasonable in an attempt to prevent chronic dialysis. Hemodialysis and peritoneal dialysis are equally effective and are necessary for patients with symptomatic azotemia.

#### Anemia

Almost every patient with multiple myeloma eventually becomes anemic. Increased plasma volume from the osmotic effect of the

M protein can produce hypervolemia and can spuriously lower the hemoglobin and hematocrit values. Patients with significant symptoms should be considered for red blood cell transfusion. If a transfusion is indicated, irradiated leukocyte-reduced red cells are preferred.

In patients with newly diagnosed myeloma, induction chemotherapy is often associated with a prompt improvement in hemoglobin levels, so it is better to avoid the use of erythropoietin. Erythropoietin (Epoen) should be seriously considered in relapsed patients receiving chemotherapy who have a persistent, symptomatic hemoglobin level of 10 g/dL or less.

Erythropoietin reduces the transfusion requirement and increases hemoglobin concentration in more than half of patients. Those with low serum erythropoietin values are more likely to respond. Most physicians proceed with a trial of erythropoietin 150 U/kg three times weekly or 40,000 U once a week. Darbepoetin, a long-lasting erythropoietin (Aranesp), may be given weekly or biweekly. Erythropoietin should be discontinued when the hemoglobin reaches 11 g/dL.

#### Skeletal Lesions

Bone lesions manifested by pain and fractures are a major problem. A skeletal radiographic survey should be repeated at 6-month intervals or sooner if pain develops. Patients should be encouraged to be as active as possible because confinement to bed increases demineralization of the skeleton. Trauma must be avoided because even mild stress can result in a fracture. Fixation of long bone fractures or impending fractures with an intramedullary rod and methyl methacrylate gives excellent results.

All patients with multiple myeloma who have lytic lesions, pathologic fractures, or severe osteopenia should receive an intravenous bisphosphonate. Pamidronate (Aredia) 90 mg intravenously over 2 hours every 4 weeks or zoledronic acid (Zometa) 4 mg intravenously over 15 minutes every 4 weeks are equally efficacious. The dosage of bisphosphonates should be reduced with renal insufficiency. Because renal insufficiency or nephrotic-range proteinuria can occur, serum creatinine and 24-hour urine protein monitoring is necessary. One should seriously consider stopping the intravenous bisphosphonate in patients who have responsive or stable disease after 2 years of therapy. In other patients, we recommend reducing the dose to once every 3 months. A randomized trial has found that denosumab (Xgeva), a monoclonal antibody targeting RANKL, may be as effective in reducing skeletal events as zoledronic acid and may be an option for selected patients with significant renal impairment.

Bisphosphonates should be resumed upon relapse with new-onset skeletal-related events. Osteonecrosis of the jaw can occur in patients receiving bisphosphonates. Although the relationship is unclear, it is essential to obtain a complete dental evaluation and perform preventive dental treatment before beginning bisphosphonates. The patient should practice good oral hygiene during therapy. Invasive procedures (especially dental extractions) should be avoided during bisphosphonate therapy. Osteonecrosis of the jaw should be managed conservatively.

Vertebroplasty or kyphoplasty may be helpful for patients with an acute compression fracture of the spine. Both have been associated with pain relief. Results appear to be better when the procedure is performed shortly after the compression fracture. Leakage of the methyl methacrylate is a potential adverse event. A choice between vertebroplasty and kyphoplasty depends on the expertise of the physician performing the procedure.

#### Infections

Bacterial infections are more common in patients with myeloma than in the general population. All patients should receive pneumococcal and influenza immunizations despite their suboptimal antibody response. Substantial fever is an indication for appropriate cultures, chest radiography, and consideration of antibiotic

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

therapy. The greatest risk for infection is during the first 3 months after chemotherapy is initiated, and prophylactic antibiotics (levofloxacin [Levaquin] or cotrimoxazole [Bactrim]) should be considered during this period. Antiviral prophylaxis (acyclovir [Zovirax] 400 mg twice daily or valacyclovir [Valtrex] 500 mg once daily) should be given to all patients receiving bortezomib because of the increased risk of herpes zoster. Intravenous immunoglobulin (IVIg, Gammagard)<sup>1</sup> may be helpful in selected patients who have recurrent serious infections despite the use of prophylactic antibiotics. It is inconvenient, associated with side effects, and very expensive. Consequently, few of our patients receive IVIg.

### Hyperviscosity Syndrome

Symptoms of hyperviscosity can include oronasal bleeding, gastrointestinal bleeding, blurred vision, neurologic symptoms, or congestive heart failure. Most patients have symptoms when the serum viscosity measurement is more than 4 cP, but the relationship between serum viscosity and clinical manifestations is not precise. The decision to perform plasmapheresis, which promptly relieves the symptoms of hyperviscosity, should be made on clinical grounds rather than serum viscosity levels. Hyperviscosity is more common in IgA myeloma than in IgG myeloma.

### Extradural Myeloma (Cord Compression)

The possibility of cord compression must be considered if weakness of the legs or difficulty in voiding or defecating occurs. The sudden onset of severe radicular pain or severe back pain with neurologic symptoms suggests compression of the spinal cord. MRI or CT of the entire spine must be performed immediately. Radiation therapy in a dose of approximately 30 Gy is beneficial in about one half of patients. Dexamethasone (Decadron)<sup>1</sup> should be administered in addition to radiation therapy. Surgical decompression is necessary only if the neurologic deficit does not improve.

### Venous Thromboembolism

Patients with multiple myeloma have an increased risk of venous thromboembolism. This is due to the malignancy itself, as well as therapy with lenalidomide, thalidomide, or pomalidomide. All patients receiving lenalidomide (or thalidomide or pomalidomide) need DVT prophylaxis with aspirin<sup>1</sup> (81 mg or 325 mg daily) or full-dose warfarin (Coumadin)<sup>1</sup> or low-molecular-weight heparin.<sup>1</sup>

### Emotional Support

All patients with multiple myeloma need substantial and continuing emotional support. The physician's approach must be positive in emphasizing the potential benefits of therapy. It is reassuring for patients to know that some survive for 10 years or more. It is vital that the physician caring for patients with multiple myeloma has the interest and capacity for dealing with incurable disease over the span of years with assurance, sympathy, and resourcefulness.

<sup>1</sup>Not FDA approved for this indication.

## MYELOYDYSPLASTIC SYNDROMES

Method of

Jamile M. Shammo, MD

### CURRENT DIAGNOSIS

- Myelodysplastic syndromes (MDSs) are diseases of the elderly.
- Chronic unexplained cytopenias should be evaluated to rule out MDS.
- Bone marrow biopsy with cytogenetic testing is necessary to make the diagnosis.
- The International Prognostic Scoring System (IPSS) and the Revised IPSS (IPSS-R) are important tools for risk stratification and choice of therapy.

### CURRENT THERAPY

- MDSs are broadly divided into two therapeutic categories per the IPSS: low-risk disease (encompassing low and intermediate-1 risk groups), and high-risk disease (encompassing intermediate-2 and high-risk groups).
- The IPSS-R defines five prognostic groups (very low, low, intermediate, high, and very high risk). Treatment options are also dependent on risk category.
- Patients with low-risk disease should receive supportive care and hematopoietic growth factors or luspatercept (Reblozyl); those with the deletion 5q abnormality should be treated with lenalidomide (Revlimid).
- Patients with high-risk disease should be treated with a hypomethylating agent and should be considered for allogeneic stem cell transplantation.

## Epidemiology

The MDSs represent a group of heterogeneous clonal stem cell disorders that affect the elderly. The reported annual incidence of approximately 4.4 per 100,000 of the general US population is highest among Caucasians and non-Hispanics. The onset of an MDS before the age of 50 years is rare; the incidence rises with age such that in patients older than 70 years, the incidence exceeds 45 per 100,000 persons. Men are nearly twice as likely to be affected as women (5.8 vs. 3.3 per 100,000 per year).

## Risk Factors

De novo or primary MDS refers to cases in which no prior toxic exposure can be documented. Therapy-related MDS, on the other hand, occurs in patients who have previously been treated with either chemotherapy, radiotherapy, or both. Median onset of therapy-related MDS varies with the agents used and usually occurs 2 to 5 years after initial exposure to radiation or chemotherapy.

Tobacco use and occupational exposure to solvents and agricultural chemicals have also been associated with the development of MDS. A minority of MDS cases might have evolved from an antecedent hematologic disorder such as aplastic anemia or paroxysmal nocturnal hemoglobinuria (PNH). Several rare and inherited genetic disorders—such as Fanconi anemia, dyskeratosis congenita, Diamond-Blackfan syndrome, and Shwachman-Diamond syndrome—have been associated with a higher risk of developing MDS.

## Pathophysiology

A variety of pathophysiologic processes resulting in ineffective hematopoiesis and peripheral cytopenias have been described in association with MDS. These processes include excessive apoptosis of myeloid progenitors, abnormal responses to cytokines and growth factors, epigenetic aberrations resulting in gene silencing, chromosomal abnormalities, and a defective bone marrow microenvironment. Several somatic point mutations affecting multiple genes have recently been identified in up to 80% of MDS patients. However, the initiating events remain unknown.

## Clinical Manifestations

Some patients with MDS are symptom free, but the majority present with peripheral blood cytopenias, of which anemia is the most common. Patients might complain of fatigue, weakness, and exercise intolerance. Those with significant neutropenia and thrombocytopenia can present with infections or bleeding. Systemic symptoms are less common; when present, however, they can herald disease progression to acute leukemia. Similarly, the presence of Sweet syndrome (acute febrile neutrophilic dermatosis) can herald transformation to acute myelogenous leukemia (AML). Organomegaly and lymphadenopathy are uncommon. Infection is the cause of death in approximately 20% to 35% of cases. Transformation to acute leukemia occurs in about 30% of all patients with MDS.

## Diagnosis

The diagnosis of MDS can be challenging because its clinical and pathologic characteristics can overlap with those of other disorders such as aplastic anemia, myeloproliferative neoplasms, and acute leukemia.

A thorough history and physical examination should be performed on every patient with one or more peripheral blood cytopenias, along with basic laboratory tests such as iron studies, vitamin B12, and folate levels. However, many disorders can cause pancytopenia; therefore consideration for a hematology referral should be entertained for the evaluation of pancytopenia or persistent otherwise unexplained cytopenias, in which case a bone marrow biopsy may be necessary to identify an etiology.

The diagnosis of MDS requires an evaluation of the peripheral blood smear, a bone marrow biopsy, and aspirate to ascertain the presence of myeloid dysplasia; iron stains, which are necessary for the detection of ring sideroblasts; and cytogenetic studies to

detect abnormal clones. Bone marrow dysplasia involving at least 10% of the cells of a specific myeloid lineage is the hallmark of MDS. Conventional karyotyping can detect cytogenetic abnormalities in 50% of patients with de novo MDS and in 95% of patients with therapy-related MDS. The presence of certain cytogenetic abnormalities can aid in making the diagnosis of MDS, particularly when dysplastic features are not prominent. It should be noted that the presence of +8, -Y, or del(20q) is not considered to be MDS-defining in that setting.

Next-generation sequencing (NGS) has recently allowed for the identification of point mutations in the majority of patients with MDS. These mutations involve genes encoding for splicing factors, epigenetic modifiers, and transcription factors, among others. NGS is increasingly utilized in this patient population to assist in making the diagnosis (SF3B1 in MDS-RS) or to provide important prognostic information (TP53 in del 5q MDS).

## Differential Diagnosis

MDS should be distinguished from a variety of disorders including megaloblastic anemia, aplastic anemia, large granular lymphocyte leukemia, myelofibrosis, copper deficiency, autoimmune disorders, and HIV infection, which can cause anemia and dysplastic features in the bone marrow. Exposure to certain drugs and toxins can result in marrow dysplasia. These include mycophenolate mofetil (Cellcept), ganciclovir (Cytovene), lead, and excess zinc. Such changes are reversible once the offending agent has been discontinued. The diagnosis of MDS can be made by performing a bone marrow biopsy to detect dysplasia and rule out other disorders that can also cause pancytopenia. Every effort should be made to rule out other reactive causes of dysplasia prior to making a diagnosis of MDS.

## Classification and Risk Stratification

Since 1982, there have been various proposals for the classification and risk stratification of MDS. The French-American-British (FAB) classification scheme was the first attempt developed to address the broad range of morphologic features and clinical outcomes in MDS. It identified five subtypes based on morphology and percentage of marrow blasts: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML). This classification allowed MDS to be separated into distinct subsets relative to survival and evolution to acute leukemia.

The World Health Organization (WHO) revised the FAB system to further refine MDS subsets by adding a category of refractory cytopenia with multilineage dysplasia, recognizing 5q-deletion syndrome as a separate clinical and pathologic entity, and lowering the blast percentage from 30% to 20% to diagnose AML. The WHO system was revised in 2008 and again in 2016. The most recent revision eliminated reference to RA and modified the terminology to identify six general MDS categories based on the presence of single- or multilineage dysplasia, ring sideroblasts, blast percentage, and del(5q) (Table 1).

The IPSS was introduced in 1997 to address the variability in prognosis within FAB subtypes. It predicts survival and risk of evolution to acute leukemia. The IPSS is calculated by adding scores assigned to three variables: blast cell count, cytogenetics, and number of cytopenias (Table 2). The IPSS was revised in 2012 (IPSS-R) to incorporate five cytogenetic categories and account for the depth of cytopenias in MDS (Tables 3 and 4). The IPSS and IPSS-R are widely used to predict the prognosis and clinical behavior of patients with various forms of MDS and to guide choice of therapy.

## Treatment

A variety of therapeutic options exist for the treatment of MDS patients, spanning the spectrum from supportive care to allogeneic stem cell transplantation. Choice of therapy should take into account the patient's age, comorbidities, and the IPSS/IPSS-R score.

**TABLE 1** World Health Organization 2016 Classification of Myelodysplastic Syndromes

NAME	DYSPLASTIC LINES	CYTOPENIAS*	RING SIDEROBLASTS AS % OF MARROW	BM AND PB BLASTS	CYTOGENETICS BY CONVENTIONAL KARYOTYPE ANALYSIS
MDS with single-lineage dysplasia (MDS-SLD)	1	1 or 2	<15% <5% + <i>SF3B1</i> mutation	BM <5%, PB <1%, no Auer rods	Any unless patient fulfills all criteria for MDS with isolated del(5q)
MDS with multilineage dysplasia (MDS-MLD)	2 or 3	1–3	<15% <5% + <i>SF3B1</i> mutation	BM <5%, PB <1%, no Auer rods	Any unless patient fulfills all criteria for MDS with isolated del(5q)
<b>MDS with ring sideroblasts (MDS-RS)</b>					
MDS-RS with single-lineage dysplasia (MDS-RS-SLD)	1	1 or 2	≥15% ≥5% + <i>SF3B1</i> mutation	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS-RS with multilineage dysplasia (MDS-RS-MLD)	2 or 3	1–3	≥15% ≥5% + <i>SF3B1</i> mutation	BM <5%, PB <1%, no Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with isolated del(5q)	1–3	1–2	None or any	BM <5%, PB <1%, no Auer rods	del(5q) alone with 1 additional abnormality except –7 or del(7q)
<b>MDS with excess blasts (MDS-EB)</b>					
MDS-EB-1	0–3	1–3	None or any	BM 5%–9% or PB 2%–4%, no Auer rods	Any
MDS-EB-2	0–3	1–3	None or any	BM 10%–19% or PB 5%–19% or Auer rods	Any
MDS, unclassifiable (MDS-U) with 1% blood blasts	1–3	1–3	None or any	BM <5%, PB = 1% (PB blasts must be recorded on at least 2 separate occasions) no Auer rods	Any
MDS with single-lineage dysplasia and pancytopenia	1	3	None or any	BM <5%, PB <1%, no Auer rods	Any
MDS based on defining cytogenetic abnormality	0	1–3	<15%	BM <5%, PB <1%, no Auer rods	MDS-defining abnormality
Refractory cytopenia of childhood	1–3	1–3	None	BM <5%, PB <2%	Any

BM, Bone marrow; MDS, myelodysplastic syndrome; PB, peripheral blood.

\*Cytopenias are defined as Hgb <10 g/dL, pLT <100 × 10<sup>9</sup>/L, and ANC <1.8 × 10<sup>9</sup>/L.

**TABLE 2** International Prognostic Scoring System for Myelodysplastic Syndromes

PROGNOSTIC VARIABLE	SCORE VALUE				
	0	0.5	1.0	1.5	2.0
Marrow blasts (%)	<5	5–10	11–20	—	21–30
Karyotype*	Good	Intermediate		Poor	
Cytopenia†	0/1	2/3			

\*Cytogenetics: Good = normal, –Y alone, del(5q) alone, del(20q) alone; Poor = complex (≥3 abnormalities) or chromosome 7 anomalies; Intermediate = other abnormalities. This excludes karyotypes t(8;21), inv16, and t(15;17), which are considered to be AML, not MDS.

†Cytopenias: neutrophil count <1800/μL, platelets <100,000/μL, Hb <10 g/dL.

**TABLE 3** Survival and Progression by International Prognostic Scoring System Risk Category

RISK CATEGORY	% IPSS POP.	OVERALL SCORE	MEDIAN SURVIVAL (Y) IN THE ABSENCE OF THERAPY	25% AML PROGRESSION (Y) IN THE ABSENCE OF THERAPY
Low	33	0	5.7	9.4
Intermediate 1	38	0.5–1.0	3.5	3.3
Intermediate 2	22	1.5–2.0	1.2	1.1
High	7	≥2.5	0.4	0.2

AML, Acute myelogenous leukemia; IPSS, International Prognostic Scoring System.

**TABLE 4** The Risk Score International Prognostic Scoring System—Revised

PROGNOSTIC VARIABLE	0	0.5	1	1.5	2	3	4
Cytogenetics	Very good	—	Good	—	Intermediate	Poor	Very poor
Blasts BM, %	≤2	—	2%–5%	—	5%–10%	>10%	—
Hb	≥10	—	8–10	<8	—	—	—

The treating physician should consider the ultimate goal of therapy and whether it is intended to cure, extend survival, or merely palliate symptoms. In the first decade of the 21st century, several novel therapeutic options for MDS emerged. Clinical trials evaluating novel agents are being conducted to help identify effective agents for patients who have relapsed or failed to respond to standard therapies.

### Supportive Care

Supportive care has been the cornerstone of MDS therapy for decades; it includes red blood cell transfusion for symptomatic anemia, platelet transfusion to reduce the risk of bleeding or to treat bleeding, and use of hematopoietic growth factors such as erythropoiesis stimulating agents (ESAs) and colony-stimulating factors such as granulocyte colony-stimulating factor (G-CSF),

filgrastim (Neupogen)<sup>1</sup>, and granulocyte-macrophage colony-stimulating factor (GM-CSF) sargramostim (Leukine)<sup>1</sup>. The last two cytokines have limited efficacy and are not routinely recommended for the treatment of MDS-related neutropenia.

Two ESAs are currently available: a recombinant human erythropoietin (rhu-EPO; epoetin alfa [Epogen, Procrit])<sup>1</sup> and a super-sialylated form of EPO (darbepoetin alfa [Aranesp])<sup>1</sup>. These are considered the standard of care for the treatment of anemia in patients with low-risk MDS. A predictive model for response to such treatment has been developed by the Nordic MDS study group to guide patient selection. In general, patients with a serum EPO level less than 500 mU/mL and low transfusion burden are

<sup>1</sup>Not FDA approved for this indication.

likely to respond by improving their hemoglobin level and reducing their need for transfusions.

Thrombopoietin agonists such as romiplostim (N-Plate)<sup>1</sup> and eltrombopag (Promacta)<sup>1</sup> are in clinical trials to evaluate their safety and efficacy in low-risk MDS patients with thrombocytopenia.

### Immunomodulatory Drugs

The novel class of immunomodulatory drugs includes thalidomide (Thalomid)<sup>1</sup> and lenalidomide (Revlimid). Thalidomide was investigated initially with some success in patients with low-risk disease. However, its use was compromised because of poor tolerability. Lenalidomide has been approved for the treatment of patients with low-risk MDS who harbor deletion 5q cytogenetic abnormality because it was shown in clinical trials to result in transfusion independence in about two-thirds of such patients.

### Luspatercept (Reblozyl)

A recombinant fusion protein that acts as a ligand trap for TGF- $\beta$  super family has shown positive results in early phase trials in ameliorating anemia in transfusion-dependent MDS patients. The pivotal MEDALIST trial was a randomized, double-blind, placebo-controlled trial that evaluated the efficacy of luspatercept as defined by the proportion of patients who achieved red blood cell (RBC) transfusion independence during any consecutive 8-week period between weeks 1 and 24 of therapy and enrolled 229 transfusion-dependent patients with low-risk MDS with ring sideroblasts who were randomized at 2:1 to either luspatercept or placebo. The trial demonstrated that 37.9% of those who were randomized to luspatercept achieved the primary efficacy endpoint compared with 13.2% who received placebo ( $P < .0001$ ). Subsequently, the drug was approved by the FDA on April 3, 2020, for the treatment of anemia in transfusion-dependent patients with MDS with ring sideroblasts (MDS-RS), and MDS-RS-T.

### Hypomethylating Agents

Two parenteral hypomethylating agents are currently approved for the treatment of MDS: 5-azacitidine (Vidaza) and decitabine (Dacogen). These agents are cytosine analogues known to inhibit and deplete DNA methyltransferase, which adds a methyl group to cytosine residues in newly formed DNA, resulting in the formation of a hypomethylated DNA in vitro. The exact mechanism of action in vivo has not yet been identified. Results of randomized clinical trials comparing these agents to best supportive care in patients with MDS have demonstrated a statistically significant improvement in response rate and hematologic improvement. It has been shown for the first time that treatment with 5-azacitidine was reported to result in prolongation of survival in patients with Int-2 and high-risk disease. Both drugs have myelosuppressive properties and comparable response rates.

More recently, in 2020, an oral hypomethylating agent (Inqovi) combining decitabine and cedazuridine was approved by the FDA for MDS.

### Immunosuppressive Therapy

Immunosuppressive therapy with antithymocyte globulin (Thymoglobulin)<sup>1</sup> or cyclosporine (Neoral)<sup>1</sup> or both was evaluated in several clinical trials and was shown to result in durable hematologic responses in a subset of MDS patients—specifically, younger patients with low-risk disease, hypocellular marrows, PNH clone, human leukocyte antigen (HLA)-DR 15 phenotype, and low transfusion need.

### Hematopoietic Stem Cell Transplantation

Allogeneic stem cell transplantation is the only curative therapy for MDS patients; this option is feasible for a small subset: typically younger patients with good performance status and an available HLA-matched donor. Approximately 40% of patients can be cured with this modality. The recent introduction of reduced-intensity conditioning regimens and nonmyeloablative transplants has resulted in expanding the age limit for performing the procedure, thus reducing transplant-related complications and mortality. However, it has been associated with a higher risk of relapse.

Because stem cell transplantation is associated with a high rate of treatment-related death—estimated at 39% at 1 year—and the development of acute and chronic graft versus host disease, such treatment is recommended only to patients with high-risk disease. Patients with low-risk MDS may be considered for transplant at disease progression.

### Conclusion and Future Direction

MDS is a chronic disease characterized by features reminiscent of bone marrow failure states with a variable propensity for leukemic evolution. It is curable only by allogeneic stem cell transplantation, which is feasible in only a small subset of patients. For all others, the treatment goal is aimed at improving quality of life and prolonging survival. A variety of ongoing clinical trials are evaluating novel agents and combinations of drugs to further optimize the outcome of patients with this disease. Meanwhile, a great deal of research is focused on understanding the molecular underpinning of this heterogeneous disorder so as to enhance our understanding of its biology.

## NON-HODGKIN LYMPHOMA

Method of

Kevin A. David, MD; and Andrew M. Evens, DO, MSc

### CURRENT DIAGNOSIS

- The etiology of non-Hodgkin lymphoma (NHL) is not known, although several risk factors and conditions are associated with an increased risk of developing lymphoma, including congenital immunosuppression conditions (ataxia-telangiectasia, Wiskott-Aldrich syndrome, and X-linked lymphoproliferative syndrome), acquired immunodeficiency states (e.g., human immunodeficiency virus [HIV] and after solid organ transplantation), viruses (e.g., human T-lymphotropic virus [HTLV]-1 and hepatitis C virus [HCV]), and autoimmune disorders (e.g., Sjögren syndrome, celiac sprue, and systemic lupus erythematosus).
- Patients most commonly present clinically with enlarged, painless lymph nodes, splenomegaly, and bone marrow involvement, but they may also present with other extranodal disease sites (e.g., stomach, skin, liver, bone, brain).
- NHL has many different clinicopathologic subtypes—more than 65 types are included in the World Health Organization (WHO) classification of lymphoid neoplasms. The natural history and prognosis of these vary greatly from indolent and slow-growing types (over many years) to highly aggressive (within weeks) types.

Excisional lymph node biopsy is the gold standard procedure in establishing the precise NHL histology. Expert hematopathology review incorporating morphologic, immunophenotypic, and genetic features is essential for an accurate diagnosis.

### CURRENT THERAPY

- Indolent lymphomas are low-grade and represent slow-growing NHL that may remain stable with low tumor burden, not warranting therapy for several years. The disease is highly responsive to treatment with a variety of treatment options (remission rates exceeding 90% with combined rituximab (Rituxan)/chemotherapy), although the clinical course is characterized by repetitive relapses. Outside of early-stage disease and therapy with allogeneic stem cell transplantation, low-grade NHLs are not curable.
- Transformation of follicular lymphoma to a high-grade NHL occurs in 2% to 3% of patients each year; it is less common in other indolent subtypes. Transformation is typically heralded by an aggressive change in the patient's clinical condition.
- Diffuse large B-cell lymphoma (DLBCL), the most common aggressive NHL, is curable in all stages in a majority of patients with rituximab (Rituxan)-based chemotherapy. A variety of primary extranodal DLBCL clinical subtypes warrant specialized therapy, such as primary central nervous system (CNS) lymphoma and testicular lymphoma.
- Long-term survivors are at increased risk for second cancers. The highest relative risk of developing a secondary malignancy occurs more than 21 to 30 years after original diagnosis. Patients who received an anthracycline (e.g., doxorubicin [Adriamycin]) as part of therapy are at a long-term increased risk for cardiovascular disease.

The term *malignant lymphoma* was originally introduced by Billroth in 1871 to describe neoplasms of lymphoid tissue. Generally speaking, lymphomas are neoplasms of the immune system. Traditionally, lymphomas are divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).

There are many different clinicopathologic subtypes of NHL (>60). By cell of origin, the majority of NHLs are of B-cell origin (85%–90%); T-cell NHLs account for 10% to 15% of lymphomas in the United States, whereas natural killer cell or histiocytic lymphomas are rare (<1%). The NHL subtypes for lymphoid, histiocytic, and dendritic neoplasms as classified by the WHO were updated in 2016.

NHLs manifest most commonly clinically with involvement of lymph nodes, spleen, and bone marrow, but they can involve other extranodal sites (stomach, skin, liver, bone, brain, etc.). Peripheral blood involvement uncommonly occurs (leukemic phase of lymphoma). The natural history and prognosis vary greatly among the different subtypes of NHL, from indolent subtypes that are often slow-growing (i.e., therapy not warranted for years) to very aggressive and rapidly fatal types (within weeks) if not treated. Most NHL subtypes are highly treatable with initial remission rates greater than 90% using combined rituximab (Rituxan)/chemotherapy; however, indolent NHLs are generally incurable, whereas the goal of treating most aggressive NHLs is cure.

### Epidemiology

Currently, NHL represents approximately 5% of all cancer diagnoses, being the seventh most common cancer in women and men. Estimates from the American Cancer Society indicate that in 2021 approximately 90,000 new cases of NHL will be diagnosed in the United States and approximately 22,000 people will die of the disease. In addition, there are approximately 900,000 people living with NHL in the United States.

### Geographic Distribution

The incidence of NHL varies throughout the world, in general being more common in developed countries, with rates in the United States of more than 15 per 100,000 compared with 1.2 per 100,000 in China. In the United States the incidence rates of NHL more than doubled between 1975 and 1995, representing one of the largest increases of any cancer. The increases have been more pronounced in White populations, males, older adults, and those with NHL diagnosed at extranodal sites. Similar findings have been reported in other developed countries. The incidence rates of NHL began to stabilize in the late 1990s, although the temporal trends vary by histologic subtype, as well as by race and sex (Figure 1). Some of the increase may be related to improved diagnostic techniques and access to medical care and the increased risk of NHL attributable to human immunodeficiency virus (HIV) infection. However, additional factors are likely responsible for this unexpected increase in incidence.

### Age

Overall, NHL incidence rises exponentially with increasing age. In persons older than 65 years, the incidence is 90.9 per 100,000 population compared with 7.1 per 100,000 population for persons aged 20 to 49 years. Except for high-grade lymphoblastic and Burkitt lymphomas (the most common types of NHL seen in children and young adults), the median age at presentation for most subtypes of NHL exceeds 60 years.

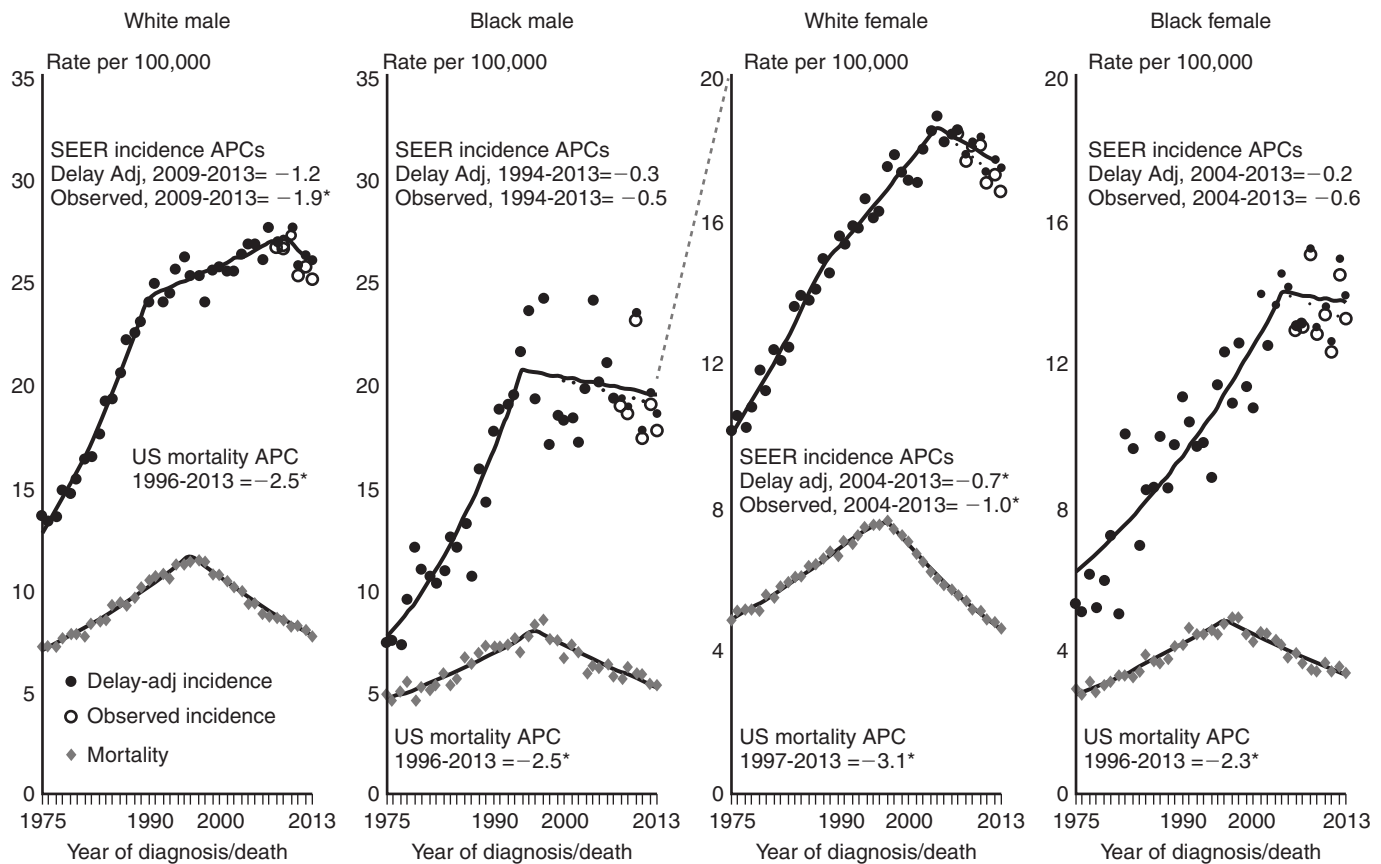

### Race and Ethnicity

Incidence varies by race and ethnicity, with White people overall having a higher risk than Black people and Asians (incidence rates increased 50%–60% in White people compared with Black people). Most NHL subtypes are more common in White people than in Black people; however, peripheral T-cell lymphoma (PTCL), mycosis fungoides, and Sézary syndrome occur more often in Black people than in White people.

### Etiology and Risk Factors

#### Chromosomal Translocations and Molecular Rearrangements

Nonrandom chromosomal and molecular rearrangements play an important role in the pathogenesis of many lymphomas and often correlate with histology and immunophenotype. These

Source: SEER 9 areas and US mortality files (National Center for Health Statistics, CDC).

<sup>a</sup>Rates are age-adjusted to the 2000 US Std population (19 age groups - census P25-1103).

Regression lines and APCs are calculated using the joinpoint regression program version 4.3.0.0. April 2016, National cancer institute.

The APC is the annual percent change for the regression line segments. The APC shown on the graph is for the most recent trend.

\*The APC is significantly different from zero  $P < .05$ .

**Figure 1** Surveillance, epidemiology, and end results (SEER) observed incidence, SEER delay adjusted incidence, and US death rates for non-Hodgkin lymphoma, by race and sex.

chromosomal changes often result in oncogenic gene products; for example, t(11;14)(q13;q32) translocation results in overexpression of *bcl-1* (cyclin D1) in mantle cell lymphoma (MCL), whereas translocation with 8q24 leads to *c-myc* overexpression in nearly all Burkitt lymphomas and in 10% to 15% of patients with diffuse large B-cell lymphoma (DLBCL). Research to discover more information regarding the prognostic and pathogenic importance of these oncogenes continues, although they are currently used primarily in clinical practice for diagnostic purposes. In addition, these genes serve as potential targets for novel therapeutics.

### Environmental Factors

Environmental factors may also play a role in the development of NHL, including particular occupations (e.g., chemists, painters, mechanics, machinists) and chemicals (solvents and pesticides). Patients who receive chemotherapy or radiation therapy for any indication are also at increased risk for developing NHL as a secondary cancer as discussed later.

### Viruses

Several viruses have been implicated in the pathogenesis of NHL, including Epstein-Barr virus, human T-lymphotropic virus (HTLV-1), Kaposi sarcoma-associated herpesvirus (KSHV, also known as human herpesvirus 8 [HHV-8]), and hepatitis C virus (HCV). Meta-analyses have shown 13% to 15% seroprevalence of HCV in certain geographic regions among persons with B-cell NHL. Furthermore, HCV infection is associated with the development of clonal B-cell expansions and certain subtypes of NHL, particularly in the setting of essential (type II) mixed cryoglobulinemia.

HTLV-1 is a human retrovirus that establishes a latent infection through reverse transcription in activated T-helper cells. A minority (5%) of carriers will develop adult T-cell leukemia lymphoma. KSHV-like DNA sequences are often detected in primary effusion lymphomas in patients with HIV infection and in those with multicentric (plasma cell variant) Castleman disease.

### Bacterial Infections

Gastric mucosa-associated lymphoid tissue (MALT) lymphoma is seen most often, but not exclusively, in association with *Helicobacter pylori* infection. Infection with *Borrelia burgdorferi* has been detected in approximately 35% of patients with primary cutaneous B-cell lymphoma in Scotland. Studies indicate that *Campylobacter jejuni* and immunoproliferative small intestinal disease are related. European reports have noted an association between infection with *Chlamydia psittaci* and ocular adnexal lymphoma. The infection was found to be highly specific and does not reflect a subclinical infection among the general population. Furthermore, remission of NHL to antibiotics has been reported. Attempts to confirm this association in the Western hemisphere have been unsuccessful.

### Immunodeficiency

Patients with congenital conditions of immunosuppression are at increased risk of NHL. These conditions include ataxia-telangiectasia; Wiskott-Aldrich syndrome; X-linked lymphoproliferative syndrome; severe combined immunodeficiency; acquired immunodeficiency states, such as HIV infection; and iatrogenic immunosuppression. Relative risk of NHL is increased 150- to 250-fold among patients with acquired immunodeficiency syndrome (AIDS); patients usually

develop high-grade NHLs, such as Burkitt lymphoma or DLBCL. The incidence of posttransplantation lymphoproliferative disorders (PTLDs) after solid organ transplantation ranges from 1% to 3% in kidney transplant recipients to 10% to 12% in heart and multiorgan transplant recipients, the latter who require more potent immunosuppressive therapy.

### Autoimmunity

An increased incidence of gastrointestinal lymphomas is seen in patients with celiac (nontropical) sprue and inflammatory bowel disease, particularly Crohn disease. An aberrant clonal intraepithelial T-cell population can be found in up to 75% of patients with refractory celiac sprue before overt T-cell lymphoma develops. Sjögren disease is associated with a sixfold increased risk of NHL overall, with risk varying in part on severity of disease (5–200 times); moreover, the risk specifically of parotid marginal zone lymphoma is increased 1000-fold. In addition, systemic lupus erythematosus and rheumatoid arthritis have been associated with a slightly increased risk of B-cell lymphoma.

### Genetic Susceptibility

Several studies have implicated a role for genetic variants in the risk of NHL, including genes that influence DNA integrity and methylation, genes that alter B-cell survival and growth, and genes that involve innate immunity, oxidative stress, and xenobiotic metabolism.

### Signs and Symptoms

Fever, weight loss, and night sweats, referred to as B symptoms, are more common in advanced and aggressive subtype NHLs, but they may be present at all stages and in any histologic subtype.

### Low-Grade or Indolent Lymphomas

Painless, slowly progressive peripheral adenopathy is the most common clinical presentation in patients with low-grade lymphomas. Patients sometimes report a history of waxing and waning adenopathy before seeking medical attention. Spontaneous regression of enlarged lymph nodes can occur, which may cause a low-grade lymphoma to be confused with an infectious condition. Primary extranodal involvement and B symptoms are uncommon at presentation; however, both are more common in advanced or end-stage disease and in particular indolent NHL subtypes (e.g., gastric MALT and nongastric extranodal MALT). Bone marrow is frequently involved, sometimes in association with cytopenias. Splenomegaly is seen in approximately 40% of patients, but the spleen is rarely the only involved site besides the specific subtype of splenic marginal zone lymphoma.

### High-Grade or Aggressive Lymphomas

The clinical presentation of high-grade lymphomas is more varied. Although the majority of patients present with adenopathy, more than one-third present with extranodal involvement alone or with adenopathy, the most common sites being the gastrointestinal tract (including Waldeyer ring), skin, bone marrow, sinuses, genitourinary tract, bone, and central nervous system (CNS). B symptoms are more common, occurring in approximately 30% to 40% of patients. Lymphoblastic lymphoma often manifests with an anterior mediastinal mass, superior vena cava syndrome, and leptomeningeal disease. American patients with Burkitt lymphoma often present with a large abdominal mass and symptoms of bowel obstruction. In addition, certain histologic NHL subtypes manifest with symptoms unique to that particular lymphoma subtype; for example, angioimmunoblastic T-cell lymphoma (AITL) in addition to lymphadenopathy presents with disease features including organomegaly, skin rash, pleural effusions, arthritis, eosinophilia, and varied immunologic abnormalities such as positive Coombs test, cold agglutinins, hemolytic anemia, antinuclear antibodies, and polyclonal hypergammaglobulinemia.

### Screening

No effective methods are currently available for screening patients or populations for NHL.

### Diagnosis

A definitive diagnosis can be made only by biopsy of pathologic lymph nodes or tumor tissue. It is critical in most cases to perform an *excisional* lymph node resection to avoid false-negative results and inaccurate histologic classification; fine-needle aspirations or core biopsies are often insufficient for diagnostic purposes. When clinical circumstances make surgical biopsy of involved lymph nodes or extranodal sites prohibitive, a core biopsy obtained under computed tomography (CT) or ultrasonographic guidance may suffice, but it often requires the integration of histologic examination and immunophenotypic and molecular studies for accurate diagnosis. A formal review by an expert hematopathologist is mandatory. In addition to morphologic review and immunostaining of tissue, other studies such as detailed cellular immunophenotyping and genotyping for relevant oncogenes are often needed to complete the diagnosis.

In addition to a detailed history and physical examination, baseline staging studies are warranted. These consist of blood tests (complete blood count with differential, complete metabolic panel including liver function tests, and lactate dehydrogenase [LDH]); CT of chest, abdomen, and pelvis; and bone marrow biopsy and aspirate (Box 1). For aggressive NHL histologies, functional imaging is advocated (i.e., fluorodeoxyglucose [<sup>18</sup>F] positron emission tomography [FDG-PET]), as is assessment of ejection fraction in anticipation of anthracycline-based chemotherapy. Testing for history of hepatitis B virus (HBV) is recommended, especially before starting anti-CD20 antibody therapy; evidence suggests that anti-CD20 antibody therapy (e.g., rituximab [Rituxan]) increases the risk of HBV reactivation above the known rate of chemotherapy-associated reactivation. HIV serology should be obtained in patients with relevant risk factors, especially for DLBCL and Burkitt lymphoma. HTLV-1 serology is recommended in patients who present with cutaneous T-cell lymphoma lesions, especially if they have hypercalcemia.

Examination of cerebrospinal fluid and consideration of intrathecal chemotherapy prophylaxis or integration of intravenous high-dose methotrexate are applicable for patients with DLBCL with bone marrow, epidural, testicular, paranasal sinus, breast, or multiple extranodal sites (especially when in conjunction with elevated LDH). Testing is mandatory for high-grade lymphoblastic lymphoma and Burkitt lymphoma and its variants and primary CNS lymphoma if there is no evidence of increased intracranial pressure. Upper gastrointestinal endoscopy or gastrointestinal series with small bowel follow-through is recommended in patients with head and neck involvement (tonsil, base of tongue, nasopharynx) and those with primary gastrointestinal disease. MCL is associated with a high incidence of occult gastrointestinal involvement. In addition, magnetic resonance imaging (MRI) of the complete craniospinal axis and ocular examination is advocated with any brain or leptomeningeal disease involvement to rule out multifocal disease.

### Classification

The 1965 Rappaport Classification of malignant lymphomas was based solely on architecture and cytology. Since then, with the help of advanced cellular and genetic technologies, numerous new unique NHL entities have emerged. The WHO classification was revised in 2016, which continues to emphasize immunophenotyping, genotyping, and clinical features. Another way to group the many different lymphoma histologies is by clinical presentation and prognosis (Table 1).

### Prognosis

#### International Prognostic Index

The International Prognostic Index (IPI) was developed as a prognostic factor model for aggressive NHLs treated with doxorubicin (Adriamycin)-containing regimens (Box 2). In the pre-rituximab (Rituxan) era, persons with no risk factors or one risk factor had a predicted 5-year overall survival (OS) rate of 73%, compared with 26% for high-risk patients with

**BOX 1** Initial Assessment and Workup for Non-Hodgkin Lymphoma

- Excisional tissue biopsy
- Detailed history and physical examination
- CBC with differential, metabolic panel (including liver function), and LDH
- CT scans (chest, abdomen, pelvis)
- Nuclear functional imaging (i.e., FDG-PET)\*
- Bone marrow biopsy and aspirate
- Heart function (e.g., MUGA) if anthracycline therapy anticipated
- EGD, colonoscopy, or both†
- HIV and HBV testing (with risk factors and/or if monoclonal antibody therapy planned)
- Consider TB testing (i.e., PPD with energy panel) with history of exposure
- Assessment of CSF (when applicable or with risk factors)‡
- Consider early institution of TLS prophylaxis (e.g., intravenous fluids, allopurinol [Zyloprim])\*,†,‡

CBC, Complete blood count; CSF, cerebrospinal fluid; CT, computed tomography; EGD, esophagogastroduodenoscopy; FDG-PET, fluorodeoxyglucose (<sup>18</sup>F) positron emission tomography; HBV, hepatitis B virus; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; MCL, mantle cell lymphoma; MUGA, multigated acquisition [scan]; NHL, non-Hodgkin lymphoma; PPD, purified protein derivative [tuberculin test]; TB, tuberculosis; TLS, tumor lysis syndrome.

\*Primarily for aggressive NHL subtypes.

†With clinical suspicion of involvement; EGD for NHL head and neck involvement (e.g., tonsil, base of tongue, nasopharynx), and consider colonoscopy for MCL (if symptomatic).

‡Consider for aggressive histologies with less than 1 extranodal site and elevated LDH and for particular unique lymphoma locations (e.g., testicular, sinus, breast, adrenal, paraspinal).

**TABLE 1** Clinical Prognostic Classification of Adult Immunocompetent Non-Hodgkin Lymphomas

LYMPHOMA TYPE	PERCENTAGE OF ALL NON-HODGKIN LYMPHOMAS
<b>Indolent or Low-Grade Non-Hodgkin Lymphomas</b>	
Follicular lymphoma	20–25
Small lymphocytic lymphoma	7
MALT-type marginal zone lymphoma	7
Nodal-type marginal zone lymphoma	<2
Lymphoplasmacytic lymphoma	<2
<b>Aggressive or High-Grade Non-Hodgkin Lymphomas</b>	
Diffuse large B-cell lymphoma	30–35
T-cell lymphomas: peripheral or systemic (multiple subtypes)	10–12
Mantle cell lymphoma	6
Lymphoblastic lymphoma	<2
Burkitt lymphoma	<1

Subtypes are listed in order of most to least common. MALT, Mucosa-associated lymphoid tissue.

four or five risk factors. In the postrituximab era, the survival rates have improved (see [Box 2](#)). A variant of the IPI is also useful in predicting outcome in patients with follicular low-grade lymphoma (FLIPI), MCL (MIPI), and most recently in Burkitt lymphoma.

**Molecular Profiling**

DNA microarray technology for gene expression profiling has identified distinct prognostic subgroups in many NHL subtypes including DLBCL and follicular NHL. Patients with germinal center B-like DLBCL have an improved OS compared with other molecular profiles. Studies in follicular NHL have identified gene expression signatures that also predicted survival. Interestingly, the genes that defined the prognostic signatures were not expressed in the tumor cells but were expressed by the nonmalignant tumor-infiltrating cells—primarily T cells, macrophages, and dendritic cells.

**Treatment**

The therapeutic approach for NHL differs for each clinicopathologic subtype. Chemotherapy remains an important modality. However, in some instances, radiation therapy or, rarely, surgical resection plays a role. Biologic approaches, including monoclonal antibodies and antibody-drug conjugates, have shown significant activity and are currently incorporated into many treatment paradigms. In addition, other novel therapeutics targeting the cell surface of lymphoma cells or varied transcription factors continue to be incorporated into treatment paradigms. Autologous and allogeneic stem cell transplantation are mostly reserved for patients with recurrent or refractory disease, although there are some subtypes in which consolidative autologous transplantation after frontline therapy is considered (e.g., MCL and PTCLs).

**Indolent B-Cell Non-Hodgkin Lymphomas**

Indolent lymphomas are low-grade and represent slow-growing NHLs that may be stable with low tumor burden that may not warrant therapy for several years. The disease is responsive to treatment (remission rates greater than 90% with combined rituximab/chemotherapy), although the clinical course is characterized by repetitive relapses. Outside of early-stage disease and therapy with an allogeneic stem cell transplant, low-grade NHLs are not curable. The median survival of patients with advanced-stage follicular lymphoma in the prirituximab era was 9 to 10 years, although that is currently significantly longer (≈16–18 years). Transformation to a high-grade NHL occurs in 2% to 3% of patients each year with follicular lymphoma (less common in other indolent subtypes) and is typically heralded by an aggressive change in the patient’s clinical condition (e.g., B symptoms, rapidly rising LDH).

### General Principles

Only a minority of patients present with early-stage disease (i.e., stage I or II). Low-dose involved field radiotherapy is a valid treatment option for these patients (especially stage I without central sites of disease), and associated 20-year disease-free survival rates are greater than 50%. Treatment for patients with advanced-stage disease ranges from observation (i.e., watchful waiting) to anti-CD20 monoclonal antibody therapy (rituximab [Rituxan] or obinutuzumab [Gazyva]) with or without chemotherapy. Treatment choice depends in part on tumor burden and the patient's individual disease characteristics and baseline functional status. Treatment with frontline anti-CD20 monoclonal antibody with chemotherapy (outpatient therapy given once every 3–4 weeks typically for 6–8 cycles) followed by 2 years of maintenance therapy with anti-CD20 monoclonal antibody for patients with high tumor burden is associated with median progression-free survival (PFS) rates of approximately 9 to 10 years.

Treatment options for relapsed indolent lymphoma include repeating rituximab with or without a different chemotherapy regimen, radioimmunotherapy, oral lenalidomide (Revlimid) immunomodulatory therapy, or stem cell transplantation. There is a small subset of follicular lymphoma patients who experience early progression to first line therapy (i.e., within 2 years), and survival rates are significantly inferior with conventional therapies. Autologous stem cell transplantation is an option for patients with relapsed disease, especially early progressors, although an improvement in OS is debated. Allogeneic stem cell transplantation is a potential curative modality for patients with relapsed or refractory disease, although patient selection is critical owing to potential morbidity and mortality related to this therapeutic option.

### Special Considerations

Localized gastric MALT lymphoma cases often may be managed with therapy for *H. pylori* infection; radiation is typically reserved for failure to eradicate *H. pylori*. Patients with lymphoplasmacytic lymphoma (Waldenström macroglobulinemia) can present clinically with hyperviscosity or cryoglobulinemia, which may be managed acutely with plasmapheresis, but ultimately systemic therapy similar to that for other indolent NHLs is warranted. More recently, the Bruton tyrosine kinase (BTK) inhibitor, ibrutinib (Imbruvica), was approved by the US Food and Drug Administration (FDA) for the treatment of relapsed or refractory marginal zone lymphoma patients who require systemic therapy after at least one anti-CD20–based therapy.

### Aggressive or High-Grade Non-Hodgkin Lymphomas

High-grade B- and T-cell NHLs are typically aggressive lymphomas that are fatal in weeks to a few months if not treated. However, many of these NHLs are curable with multiagent chemotherapy.

### General Principles

DLBCL, the most common aggressive NHL, is curable in all stages in the majority of patients (60%–70%). A common treatment is anti-CD20 monoclonal antibody combined with anthracycline-based chemotherapy: rituximab–cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (Oncovin), prednisone (R-CHOP). The number of treatment cycles depends on stage of disease and response to treatment. Standard therapy for advanced-stage disease is six R-CHOP cycles, whereas patients with early-stage disease may receive three or four cycles with or without involved field radiation. There are emerging data regarding the prognostic importance of *MYC* rearrangement (from tumor testing) as a single finding and especially in conjunction with *BCL-2* and/or *BCL6* (i.e., double or triple hit) by molecular studies as well as with immunohistochemical staining. Outcomes with R-CHOP for DLBCL patients with a molecular double hit (e.g., presence of *MYC* and *BCL-2* rearrangements) are modest; more intensive and novel therapeutic options should be considered.

Therapy for relapsed DLBCL typically includes abbreviated salvage non-cross-resistant chemotherapy followed by autologous stem cell transplantation for patients who have chemotherapy-sensitive disease, which is curative in approximately 35% to 45% of patients.

MCL is a B-cell NHL with initial high remission rates (>90%–95%), but it has more modest long-term outcomes, and it is difficult to cure. With standard chemotherapy regimens (e.g., R-CHOP), the median PFS rates are only 18 to 20 months. With more-intensive chemotherapy regimens, especially ones incorporating high-dose cytarabine as a component of induction therapy, 5-year PFS rates are near 70%. Some groups advocate induction therapy with aggressive high-dose cytarabine (Cytosar)<sup>1</sup>-based chemotherapy followed by consolidative autologous stem cell transplantation in first remission. As noted later, there has been the integration of several novel therapeutic agents into the treatment paradigm of MCL. Bendamustine (Bendeka, Treanda) in combination with rituximab has also become a widely used and more tolerable induction regimen, especially in older patients with MCL.

Burkitt lymphoma and related high-grade NHLs (e.g., lymphoblastic lymphomas) are often rapidly growing malignancies with a doubling time of 24 hours. Prompt initiation of therapy, including aggressive supportive care measures, is often warranted. With aggressive chemotherapy regimens, including prophylactic intrathecal chemotherapy, the majority of Burkitt patients younger than age 40 years are cured (>70%–80%). In addition, there are data showing high efficacy using lower-intensity treatment consisting of infused etoposide (Toposar),<sup>1</sup> doxorubicin, and cyclophosphamide with vincristine, prednisone, and rituximab (EPOCH-R), especially for patients untreated Burkitt lymphoma without CNS involvement, including HIV related.

Systemic (i.e., noncutaneous) PTCLs are mostly aggressive malignancies. They are treatable; however, cure rates are lower compared with most aggressive B-cell NHLs. Standard therapy had consisted of CHOP-based chemotherapy with or without autologous stem cell transplantation in first remission as consolidation. Recently published data from the ECHELON-2 trial combining the antibody drug conjugate, brentuximab vedotin (Adcetris), with cyclophosphamide, doxorubicin, and prednisone (CHP) chemotherapy versus standard CHOP for untreated CD30+ PTCLs was associated with significantly improved PFS and OS. This regimen (i.e., brentuximab vedotin + CHP) was subsequently FDA approved for this indication. Several additional novel targeted agents have also been FDA approved over the past several years for the treatment of T-cell NHL (see later).

### Special Considerations

There are several clinical subtypes of DLBCL that present as primary extranodal manifestations such as primary testicular DLBCL and primary gastric DLBCL. If these lymphomas are localized, treatment typically consists of abbreviated cycles (3–4) of R-CHOP followed by involved field radiation. In addition, CNS prophylaxis with either intrathecal chemotherapy or agents such as intravenous high-dose methotrexate<sup>1</sup> is warranted for testicular DLBCL given the relatively high risk of CNS involvement or relapse.

Primary CNS lymphoma is typically DLBCL; high-dose methotrexate chemotherapy is a key component of therapy.

A long-standing therapeutic maneuver for solid organ transplant-related PTLDs has been reduction of immunosuppression, although, using this approach alone, mortality rates have ranged from 50% to 60% in most series. Evidence with use of initial rituximab-based therapy suggests significantly improved outcomes in the modern era.

The majority of AIDS-related NHLs are aggressive or high-grade types: DLBCL or Burkitt lymphoma. Similar therapy as immunocompetent NHL is often recommended. Response to

<sup>1</sup>Not FDA approved for this indication.

therapy, including cure rate, has improved significantly with better control of opportunistic infections and highly active antiretroviral therapy (HAART).

Mycosis fungoides and Sézary syndrome are cutaneous T-cell lymphomas that initially might show eczematous lesions. It is often difficult to establish the diagnosis, but eventually the lesions develop into plaques and tumors. Lymph nodes, spleen, and visceral organs may be involved. Sézary syndrome is a variant of mycosis fungoides and shows peripheral blood involvement; patients usually have diffuse erythroderma. Skin-targeted modalities for treatment of early-stage mycosis fungoides include psoralens with ultraviolet A (PUVA) light, narrowband-ultraviolet light, skin electron-beam radiation, and topical steroids, retinoids, carmustine (BiCNU) and nitrogen mustard (Mustargen).<sup>1</sup> Treatment goals in advanced stages are to reduce tumor burden and to relieve symptoms. Treatment options also include monochemotherapy or polychemotherapy including CHOP, extracorporeal photopheresis, interferons, retinoids, monoclonal antibodies, recombinant toxins, histone deacetylase inhibitors, and most recently, the antibody drug conjugate brentuximab vedotin (Adcetris) and humanized antibody against CCR4, mogamulizumab (Poteligeo) (Study of KW-0761).

During therapy for aggressive/high-grade NHLs, attention should be paid to preventing tumor lysis syndrome. Measures to prevent this complication include aggressive hydration, allopurinol (Zyloprim), and frequent monitoring of electrolytes, uric acid, and creatinine. Rasburicase (Elitek), a recombinant urate oxidase enzyme, is an expensive but potent agent for treating hyperuricemia.

#### Novel Treatment Options and Modalities

Many new agents targeting specific molecular targets have become available for the treatment of lymphoma (Tables 2 and 3). Novel agents in lymphoma include bortezomib (Velcade) and lenalidomide (Revlimid), which are FDA approved for relapsed or refractory MCL (and lenalidomide also for relapsed follicular lymphoma), and histone deacetylase inhibitors, which are approved for cutaneous T-cell lymphoma and peripheral T-cell NHLs as well. In addition, bortezomib is FDA approved for untreated MCL patients in combination with immunochemotherapy. Other newer agents that are FDA approved for the treatment of patients with chronic lymphocytic leukemia (CLL), including in higher-risk patient populations (e.g., p53 mutated), are idelalisib (Zydeliq), an inhibitor of PI3K delta; the BTK inhibitor ibrutinib (Imbruvica), which is also FDA approved for patients with CLL and MCL; and venetoclax (Venclexta), a BH3 mimetic acting as an inhibitor of BCL2. There are several recently published and a number of ongoing clinical studies to evaluate the optimal sequence and varied combinations for patients with CLL, especially vis-à-vis harnessing frontline targeted therapeutics.

The BTK inhibitor acalabrutinib (Calquence) is FDA approved for relapsed or refractory MCL patients who have received at least one prior therapy. Two other PI3K inhibitors (i.e., copanlisib [Aliqopa] and duvelisib [Copiktra]) are approved for adult patients with relapsed or refractory follicular lymphoma. New anti-CD20 antibodies have also been approved for the treatment of CLL (e.g., obinutuzumab [Gazyva]) as well as antibody drug conjugates, which contain potent drugs that are conjugated to an antibody. These include brentuximab vedotin (Adcetris), which is FDA approved for newly diagnosed CD30-positive T-cell lymphomas and relapsed anaplastic (T-cell) large-cell lymphoma, and the anti-CD79b monoclonal antibody drug complex, polatuzumab vedotin (Polivy), that the FDA approved in combination with rituximab and bendamustine for relapsed/refractory DLBCL.

These novel therapeutic agents are mostly FDA approved for patients with relapsed or refractory disease; however, there are a multitude of ongoing studies in the frontline/untreated setting and in varied sequences and combinations.

There is also great excitement in the continued application of new immunotherapy approaches in NHL such as checkpoint inhibitors (e.g., programmed death-1 [PD-1] inhibitors) as well as chimeric antigen receptor (CAR) T-cell therapy, which involve removal of T cells from patients followed by bioengineered CARs (e.g., CD19) that facilitate T-cell expansion and antigen/tumor recognition when reinfused into the patient. Axicabtagene ciloleucel (Yescarta), tisagenlecleucel (Kymriah), and lisocabtagene maraleucel (Breyanzi) are anti-CD19 CAR T-cell therapies the FDA approved for patients with relapsed or refractory DLBCL. Overall response rates range from 50% to 72%, with complete remission rates of 32% to 51%. Furthermore, 25% to 35% of patients appear to experience longer-term disease remission. There are a multitude of other CAR T-cell and natural killer-based constructs being studied across several lymphoma subtypes.

#### Follow-Up of Long-Term Survivors Relapse

Among patients with aggressive lymphomas, such as DLBCL, most recurrences are seen within the first 2 years after the completion of therapy, although later relapses occur uncommonly. Physical examination and laboratory testing at 2- to 3-month intervals and follow-up CT scans at 6-month intervals for the first 2 years after diagnosis are recommended; however, there is ongoing debate regarding the impact that postsurveillance scans have on disease outcomes. Detection of recurrent disease is important in part because these patients may be candidates for potentially curative therapy (e.g., stem cell transplantation). Patients with advanced low-grade NHL are at a constant risk for relapse, as discussed before.

#### Secondary Malignancies

Long-term NHL survivors are at an increased risk for second cancers. In general, the risk is increased with history of radiation use, but it is also seen with chemotherapy. In a survey of 28,131 Dutch registry patients with NHL who survived 2 years or longer, significant excesses of second cancers were seen for nearly all solid tumors as well as acute myelogenous leukemia (AML) and HL. The standardized incidence ratio (SIR) for solid tumors after NHL was 1.65. The SIRs for solid tumors are increased for up to 30 years after NHL diagnosis, with the highest relative risk of developing a secondary malignancy occurring more than 21 to 30 years after original diagnosis.

#### Late Treatment Complications

There has been more selective use of radiation as part of therapy for NHL. Thus the risk of certain radiation-induced complications has been reduced in patients treated more recently. Nevertheless, the risk still exists. Transplant recipients are at increased risk for secondary myelodysplasia and AML, regardless of whether they received radiation. All chemotherapy agents may cause long-term morbidity; in particular, patients who received an anthracycline (e.g., doxorubicin [Adriamycin]) are at a long-term increased risk of cardiovascular disease. Among Dutch and Belgian NHL patients treated with at least six cycles of doxorubicin-based chemotherapy, cumulative incidence of cardiovascular disease was 12% at 5 years and 22% at 10 years. Risk of coronary artery disease matched that of the general population; however, risk of chronic heart failure was significantly increased (SIR, 5.4), as was stroke (SIR, 1.8). Risk factors associated with excess risk included younger age at start of NHL treatment (<55 years), preexisting hypertension, any salvage treatment, and use of radiotherapy; risk relating to radiotherapy was dose-dependent. Continued studies are needed to develop optimal secondary prevention strategies.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Targeted Therapeutics FDA Approved for the Treatment of B-Cell Non-Hodgkin Lymphoma<sup>1</sup>

<b>BTK inhibitors</b>	<b>Mechanism:</b> Small molecule binds Bruton tyrosine kinase (BTK) and inhibits downstream signaling pathways initiated by B-cell receptor
	<b>Notable toxicities:</b> atrial fibrillation, myelosuppression, rash, arthralgias, headache, bleeding, and impaired wound healing (should be held perioperatively and prior to other invasive procedures)
	<i>Drug Name</i>
	<i>Indication and Year Approved</i>
Ibrutinib (Imbruvica)	Mantle cell lymphoma (2013) CLL/SLL (2014) Waldenström macroglobulinemia (2015) Marginal zone lymphoma (2017)
Acalabrutinib (Calquence)	Mantle cell lymphoma (2017) CLL/SLL (2019)
Zanubrutinib (Brukinsa)	Mantle cell lymphoma (2019)
<b>Anti-CD20 monoclonal antibodies</b>	<b>Mechanism:</b> Bind to CD20 molecule on B lymphocytes and induce a variety of responses, including antibody-mediated cytotoxicity, complement-mediated cytotoxicity, and apoptosis.
	<b>Notable toxicities:</b> infusion reactions, hypogammaglobulinemia, hepatitis B virus reactivation, progressive multifocal leukoencephalopathy (rare)
	<i>Drug Name</i>
	<i>Indication and Year Approved</i>
	Rituximab (Rituxan)
Obinutuzumab (Gazyva)	Untreated CLL with chlorambucil (Leukeran) (2013) Relapsed rituximab refractory follicular lymphoma with bendamustine (Bendeka) (2016) Untreated follicular lymphoma with bendamustine (2017) Untreated CLL with ibrutinib (2019)
Ofatumumab (Arzerra)	Relapsed CLL (2016)
<b>Anti-CD79b monoclonal antibody</b>	<b>Mechanism:</b> Binds to CD79b molecule on B lymphocytes. Conjugated monomethyl auristatin E (MMAE) is then internalized by lymphocyte. MMAE binds tubulin, resulting in cell cycle arrest.
	<b>Notable toxicities:</b> neuropathy, immunosuppression, fatigue, diarrhea
	<i>Drug Name</i>
Polatuzumab vedotin (Polivy)	Relapsed DLBCL with bendamustine and rituximab (2019)
<b>Immunomodulators</b>	<b>Mechanism:</b> affects T-cell stimulatory pathways, angiogenesis, and cell proliferation
	<b>Notable toxicities:</b> myelosuppression, fatigue, rash, thrombosis (prophylactic aspirin or anticoagulants typically advised)
	<i>Drug Name</i>
Lenalidomide (Revlimid)	Relapsed mantle cell lymphoma (2013) Relapsed follicular lymphoma and marginal zone lymphoma (2019)
<b>Anti-CD19 monoclonal antibody</b>	<b>Mechanism:</b> monoclonal antibody that binds to CD19 antigen and mediates B-cell lysis through apoptosis and immune effector mechanisms, including antibody-dependent cellular cytotoxicity (ADCC) and antibody-dependent cellular phagocytosis
	<b>Notable toxicities:</b> neutropenia, fatigue, anemia, diarrhea, thrombocytopenia, cough, pyrexia, and peripheral edema
	<i>Drug Name</i>
Tafasitamab-cxix (Monjuvi) in combination with lenalidomide	Relapsed DLBCL
<b>Phosphatidylinositol-3-kinase (PI3Kδ) inhibitors</b>	<b>Mechanism:</b> small molecule inhibitors of PI3 kinase, resulting in inhibition of various cellular processes, such as cellular growth, proliferation, and intracellular trafficking
	<b>Notable toxicities:</b> pneumonitis, colitis, transaminitis, hypertension, hyperglycemia (copanlisib)
	<i>Drug Name</i>
	<i>Indication and Year Approved</i>
	Idealisib (Zydelig)
Copanlisib (Aliqopa)	Relapsed follicular lymphoma (2017)
Duvelisib (Copiktra)	Relapsed CLL/SLL and follicular lymphoma (2018)
<b>PD-1 (programmed cell death-1) inhibitors</b>	<b>Mechanism:</b> blocks PD-1 on cellular surface, facilitating T-cell-mediated immune killing
	<b>Notable toxicities:</b> pneumonitis, colitis, dermatitis, endocrinopathies (hypothyroidism)
	<i>Drug Name</i>
Pembrolizumab (Keytruda)	Relapsed primary mediastinal large B-cell lymphoma (2018)

**TABLE 2** Targeted Therapeutics FDA Approved for the Treatment of B-Cell Non-Hodgkin Lymphoma<sup>1</sup>—cont'd

<b>Chimeric antigen receptor (CAR) T-cell therapy</b>	<b>Mechanism:</b> CD19-directed genetically modified autologous T cells target CD19-expressing lymphoma cells	
	<b>Notable toxicities:</b> cytokine release syndrome (fever, hypotension, organ dysfunction), neurotoxicity (mental status changes, confusion, seizures), cytopenias	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
	Axicabtagene ciloleucel (Yescarta)	Relapsed DLBCL (2017) Relapsed follicular lymphoma (2021)
	Tisagenlecleucel (Kymriah) Brexucabtagene autoleucel (Tecartus)	Relapsed DLBCL (2018) Relapsed mantle cell lymphoma (2020)
Lisocabtagene maraleucel (Breyanzi)	Relapsed DLBCL (2021)	
<b>BCL-2 inhibitors</b>	<b>Mechanism:</b> small molecule inhibits antiapoptotic activities of protein BCL2	
	<b>Notable toxicities:</b> tumor lysis syndrome, myelosuppression, fever, diarrhea	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Venetoclax (Venclexta)	Relapsed CLL/SLL (2016) Untreated CLL/SLL in combination with obinutuzumab (2019)	
<b>Proteasome inhibitors</b>	<b>Mechanism:</b> inhibits proteasomal clearance of multiple molecules, including proapoptotic molecules	
	<b>Notable toxicities:</b> peripheral neuropathy, fatigue, diarrhea	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Bortezomib (Velcade)	Relapsed mantle cell lymphoma (2006) Untreated mantle cell lymphoma with chemotherapy (2014)	
<b>Nuclear export inhibitor</b>	<b>Mechanism:</b> actively binds to export protein 1 (XPO1 or CRM1) inhibiting the nuclear export of tumor suppressors, growth regulators, and antiinflammatory proteins	
	<b>Notable toxicities:</b> fatigue, nausea, diarrhea, appetite decrease, weight decrease, constipation, vomiting, pyrexia; dizziness and mental status changes; thrombocytopenia, neutropenia, anemia, and hyponatremia	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Selinexor (Xpovio)	Relapsed DLBCL	
<b>Radioimmunotherapy</b>	<b>Mechanism:</b> monoclonal antibodies deliver targeted radiation to lymphoma cells	
	<b>Notable toxicities:</b> cytopenias (delayed), fatigue, MDS	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Ibritumomab tiuxetan (Zevalin)	Relapsed follicular lymphoma (2002) Consolidation for follicular lymphoma after initial chemotherapy (2009)	

CHOP, Cyclophosphamide, doxorubicin, Oncovin, prednisone; CLL/SLL, chronic lymphocytic leukemia/small lymphocytic lymphoma; DLBCL, diffuse large B-cell lymphoma; MDS, myelodysplastic syndrome.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Targeted Therapeutics FDA Approved for the Treatment of T-Cell Non-Hodgkin Lymphoma

<b>Histone Deacetylase Inhibitors</b>	<b>Mechanism:</b> modulates acetylation of key targets, including genes involved in cancer-related cellular pathways	
	<b>Notable toxicities:</b> QT prolongation, electrolyte abnormalities, cytopenias (especially thrombocytopenia), nausea, fatigue	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
	Romidepsin (Istodax)	Relapsed CTCL (2009) Relapsed PTCL (2011)
	Vorinostat (Zolinza)	Relapsed CTCL (2006)
Belinostat (Beleodaq)	Relapsed PTCL (2014)	
<b>Anti-CD30 monoclonal antibody</b>	<b>Mechanism:</b> Binds to CD30 molecule on T lymphocytes. Conjugated monomethyl auristatin E (MMAE) is then internalized by lymphocyte. MMAE binds tubulin, resulting in cell cycle arrest.	
	<b>Notable toxicities:</b> peripheral neuropathy, diarrhea, cytopenias, fatigue, pancreatitis	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Brentuximab vedotin (Adcetris)	CD30-positive mycosis fungoides and cutaneous anaplastic large cell lymphoma (2017) Untreated CD30-expressing PTCL (2018)	
<b>Anti-CCR4 monoclonal antibody</b>	<b>Mechanism:</b> binds CCR4 (CC chemokine receptor type 4) and inhibits downstream signal transduction pathways and chemokine-mediated cellular migration and T-cell proliferation	
	<b>Notable toxicities:</b> infusion reactions, infection, rash, fever, edema, nausea, headache, cytopenias	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Mogamulizumab (Poteligeo)	Mycosis fungoides (2018) Approved outside US for adult T-cell leukemia/lymphoma	
<b>Folate antagonists</b>	<b>Mechanism:</b> folate analog that accumulates in lymphoma cells and impairs DNA synthesis	
	<b>Notable toxicities:</b> mucositis, myelosuppression, nausea, fatigue	
	<i>Drug Name</i>	<i>Indication and Year Approved</i>
Pralatrexate (Folotyn)	Relapsed PTCL (2009)	

CTCL, Cutaneous T-cell lymphoma; PTCL, peripheral T-cell lymphoma.

## PERNICIOUS ANEMIA/MEGALOBlastic ANEMIA

Method of

Anusha Vallurupalli, MBBS

### CURRENT DIAGNOSIS

- Megaloblastic anemia is defined as macrocytic anemia with large, structurally and functionally abnormal red blood cells in the bone marrow and peripheral blood and is most commonly associated with folate or B12 deficiencies.
- In adults, folate deficiency is most commonly due to inadequate dietary intake. Vitamin B12 deficiency is mainly due to cobalamin malabsorption from food due to pernicious anemia, an autoimmune disorder, and gastrointestinal malabsorption.
- Megaloblastic anemia often presents with macrocytosis and hypersegmented neutrophils on peripheral smear.

### CURRENT TREATMENT

- Prompt recognition and diagnosis are essential to prevent both short-term and long-term complications.
- Recognition of the underlying etiology for megaloblastic anemia is essential for a long-term treatment plan.
- Vitamin B12 deficiency can be treated with both oral and parenteral therapy and the route and duration of treatment is usually based on underlying etiology.
- If vitamin B12 deficiency is untreated, folate repletion will correct the megaloblastic anemia but not the associated neuropathic changes that occur with B12 deficiency.
- Folate replacement is generally accomplished through the oral route.
- Preventive B12 and folate dosing is warranted in certain high risk patients.
- Both B12 and folate replacements are generally well tolerated.

### Introduction

Anemia is one of the most common hematologic disorders encountered on a regular basis in various clinical settings. In 2010, the global prevalence of anemia was 32.9%; that is, more than 2.2 billion people were affected. The World Health Organization (WHO) defines anemia as a hemoglobin (Hb) count of less than 13 g/L in men, less than 12 g/L in nonpregnant women, and less than 11 g/L in pregnant women and the elderly. A Hb of less than 10 g/L in any patient should trigger an evaluation. The etiology of anemia is oftentimes multifactorial, especially in elderly patients. In elderly patients, anemia can exacerbate comorbid cardiac complications such as cardiac ischemia and congestive heart failure. Most of the causes of anemia, especially nutritional causes, can usually be treated efficiently. Therefore, the cause of anemia should be identified and treated promptly to decrease the risk of complications.

Megaloblastic anemia, in general, is defined as macrocytic anemia with large, structurally and functionally abnormal red blood cells in the bone marrow and peripheral blood. Hypersegmented neutrophils are also commonly seen on the peripheral smear. The mean corpuscular volume (MCV) is elevated. Megaloblastic anemia is most commonly associated with nutritional deficiencies, specifically B12 and folate. In most cases, diagnosis is made by blood testing.

### Epidemiology

The incidence and prevalence of anemia is highly variable and depends on age, sex, ethnicity, country of origin, socioeconomic status, and multifactorial comorbid conditions.

A retrospective study of 1784 randomly selected older adults living at home found macrocytosis in 6.3% of men and 3.3% of women. Folate and B12 deficiencies are the most common causes of megaloblastic anemia. Folate and B12 nutritional deficiencies are often easily treated.

### Etiology

#### Folate Deficiency

Deficiency of folate is the most common cause of megaloblastic anemia. Folate is abundant in green leafy vegetables and approximately 60% of dietary folate is absorbed in the small intestine. However, folate is not stored in the body for a long duration and needs to be constantly replaced. Body stores of folate only last for approximately 6 months. Other causes include malabsorption and factors affecting folate metabolism (Table 1).

#### Vitamin B12 Deficiency

Deficiency of vitamin B12 can occur due to insufficient capture of the vitamin B12 from dietary sources because of inadequate intake, as seen in vegetarians and vegans or in patients who are malnourished. Malabsorption, as seen in patients with pernicious anemia, atrophic gastritis, or following gastric surgery, is another major cause (Table 2).

**TABLE 1** Causes of Folate Deficiency**Dietary Deficiency**

Malabsorption due to abnormalities of the jejunum

- Celiac disease
- Jejunal resection
- Tropical sprue

Drug-induced malabsorption

- Sulfasalazine (Azulfidine)

Increased requirement

- Pregnancy
- Prematurity
- Chronic hemolytic anemias (sickle cell anemia and autoimmune hemolytic anemias)
- Malignant diseases
- Chronic inflammatory disease

Increased loss

- Some skin diseases
- Long-term dialysis

Acquired abnormality of folate metabolism: dihydrofolate reductase inhibitors (methotrexate and sulfamethoxazole/trimethoprim [Bactrim])

Complex or uncertain mechanism

- Ethanol abuse (some cases)
- Anticonvulsant drugs (some cases)
- Oral contraceptive drugs, glutethimide, and cycloserine

Inherited abnormalities of folate absorption and metabolism

- Hereditary folate malabsorption
- Glutamate formiminotransferase-cycloaminase deficiency

Adapted from Wickramasinghe SN. Diagnosis of megaloblastic anemias. *Blood Rev.* 2006;20(6):299–318.

**TABLE 2** Causes of B12 Deficiency**Dietary Deficiency**

Impaired release of B<sub>12</sub> from food—food cobalamin malabsorption

Inadequate secretion of intrinsic factor

- Pernicious anemia
- Total or partial gastrectomy
- Congenital intrinsic factor deficiency
- Congenitally abnormal intrinsic factor

Impaired release of B<sub>12</sub> from B<sub>12</sub>-R binder complex

- Pancreatic insufficiency
- Zollinger-Ellison syndrome

Diversion of dietary B<sub>12</sub>

- Abnormal intestinal bacterial flora—jejunal diverticula, small intestinal strictures, and stagnant intestinal loops (blind loop syndrome)
- Fish tapeworm infestation

Malabsorption due to abnormalities in the terminal ileum

- Ileal resection
- Crohn disease
- Chronic tropical sprue
- Other acquired diseases
- Imerslund-Gräsbeck syndrome (selective malabsorption with proteinuria)

Drug-induced malabsorption (amino salicylic acid, neomycin, colchicine, slow-release potassium chloride, metformin, phenformin, biguanides, and cholestyramine)

Inactivation of methyl cobalamin by nitrous oxide

Inherited abnormalities of B<sub>12</sub> transport or intracellular B<sub>12</sub> metabolism

- Deficiency or abnormality of transcobalamin II
- Defective methyl cobalamin synthesis (hyper homocysteinemia)
- Defective synthesis of both methyl cobalamin and adenosyl cobalamin (hyper homocysteinemia and methylmalonic acidemia)

Adapted from Wickramasinghe SN. Diagnosis of megaloblastic anemias. *Blood Rev.* 2006;20(6):299–318.

**TABLE 3** Laboratory Findings in Megaloblastic Anemia

Common for both B12 and folate deficiencies:

- Macrocytosis with elevated MCV, often greater than 100
- Megaloblasts and hypersegmented neutrophils on peripheral smear
- Anemia
- Elevated homocysteine levels

Specific for B12 deficiency:

- Elevated MMA levels
- Elevated LDH, indirect bilirubin, and low haptoglobin in the setting of intravascular hemolysis, which can be seen in severe B12 deficiency.
- Positive intrinsic factor antibodies in patients with pernicious anemia.

LDH, Lactate dehydrogenase; MCV, mean corpuscular volume; MMA, methylmalonic acid.

**TABLE 4** Signs and Symptoms of B12 Deficiency**Neurological Symptoms/Signs**

- Dysesthesia and hypoesthesia
- Subacute combined degeneration presenting with ataxia, decreased proprioception, and vibratory sensation
- Extrapyramidal signs (e.g., dystonia, dysarthria, and rigidity)
- Abnormal deep tendon reflexes
- Ataxia or positive Romberg test

**Gastrointestinal Symptoms/Signs**

- Glossitis
- Abdominal pain
- Dyspepsia likely related to atrophic gastritis or *H. pylori* infection

**Psychiatric Symptoms**

- Depression or mood impairment
- Psychosis
- Dementia

**Rare Manifestations**

- Skin hyperpigmentation
- Grey hair

**Anemia Symptoms**

- Fatigue
- Palpitations
- Exertional dyspnea
- Chest pain
- Lightheadedness

**Pernicious Anemia**

Pernicious anemia is characterized by malabsorption of B12 due to a deficiency of intrinsic factor. It is often associated with other co-existing autoimmune disorders such as celiac disease, Hashimoto thyroiditis, and Sjögren syndrome. Pernicious anemia is usually diagnosed by checking for intrinsic factor antibodies in the blood or by biopsy-proven immune atrophic gastritis. Intrinsic factor neutralizing antibodies are found in the setting of atrophic immune gastritis. *Helicobacter pylori*-related atrophic gastritis is in the differential and, if there is a clinical suspicion, should be evaluated by gastric biopsy. Intrinsic factor antibodies should not be checked after parenteral B12 administration for at least 2 weeks, as it will result in a false negative result.

**Clinical Manifestations**

Symptoms of anemia and laboratory findings (Table 3) from folate deficiency and B12 deficiency are essentially indistinguishable. B12 deficiency can manifest without anemia and is also characterized by neuropsychiatric symptoms (Table 4). The cause of neurological symptoms is thought to be secondary to the role that vitamin B12 plays in neuronal myelination, although the exact mechanism is not known.

**Diagnosis**

The diagnosis of pernicious anemia is based on laboratory testing (see Table 3). Complete blood count with differential, peripheral

**TABLE 5** Differential Diagnosis of Macrocytic Anemia

- Chronic alcohol abuse
- Myelodysplastic syndromes
- Hypothyroidism
- Chronic lung disease with hypoxia
- Heavy smoking
- Chronic liver disease
- Chronic hemolytic anemia
- Therapy with certain anticonvulsant drugs
- Myeloma (some cases)
- Hypoplastic and aplastic anemia
- Physiologic
- Normal neonates
- Normal pregnancy (some cases)

Adapted from Wickramasinghe SN. Diagnosis of megaloblastic anemias. *Blood Rev.* 2006;20(6):299–318.

blood smear, complete metabolic profile including total and indirect bilirubin, lactate dehydrogenase, and serum folate and B12 levels are all included in the initial diagnostic testing. Methylmalonic acid (MMA) and homocysteine levels in indeterminate situations where the B12 or folate serum levels are borderline low may be helpful. MMA levels are increased in B12 deficiency, whereas MMA levels are normal in folate deficiency. Homocysteine levels are increased in both folate and B12 deficiencies. There may be fluctuations in MMA and homocysteine levels due to underlying concurrent conditions such as renal insufficiency (increased MMA levels), methylmalonic aciduria (increased MMA levels) and hereditary homocystinemia (increased homocysteine levels), and additional bacterial overgrowth in the small intestine (increased MMA levels), in addition to other rare conditions. Intrinsic factor antibody testing should be ordered prior to initiation of parenteral B12 replacement in patients with pernicious anemia.

Bone marrow aspiration and biopsy are not routinely recommended and should be reserved for cases in which there is persistent anemia despite replacement of both B12 and folate with resultant normalized levels. Patients with pernicious anemia should be evaluated for underlying gastric cancer with esophagogastroduodenoscopy. A systematic meta-analysis of 27 studies revealed a pooled gastric cancer incidence rate in patients with pernicious anemia of 0.3/100 person-years and an estimated sevenfold relative risk of gastric cancer.

### Differential Diagnosis

The differential diagnosis for macrocytic anemia includes anemia related to chronic alcohol use (with or without liver disease), thyroid failure, and myelodysplastic syndromes (Table 5). Symptoms of copper deficiency can mimic B12 deficiency, can occasionally present with macrocytosis and should be ruled out with serum copper level testing if the patient does not respond to B12 supplementation.

### Prevention

Providing food sources with nutrients rich in folic acid and/or B12 is best for preventing megaloblastic anemia. Therapeutic supplementation may be necessary, especially for the very old. The Institute of Medicine (United States) Standing Committee on the Scientific Evaluation of Dietary Reference Intakes has recommended fortification of cereals with multiple B vitamins, including B12. Prophylactic folate treatment should be administered to patients with increased requirements such as those with chronic hemolytic anemias and women who are pregnant. Preventive therapeutic replacement should be offered to all patients who have undergone bariatric gastric surgery or patients with compromised small intestine absorption due to various causes.

### Treatment

#### General Principles

All patients who are identified as having B12 deficiency and/or folate deficiency should be treated. Replacement of the nutrients usually corrects the anemia. Blood transfusions are generally

reserved for emergency situations such as severe symptomatic anemia and in patients with cardiac complications (i.e., chest pain, heart failure) associated with anemia. Oral replacement is generally well tolerated and is the first line treatment of choice. Parenteral replacement, especially for B12 deficiency, should be considered in patients with severe B12 deficiency who present with symptomatic anemia, severe neurologic symptoms, pernicious anemia, as well as in patients who are at risk for malabsorption and in women who are pregnant. Replacement with oral folate in a patient with undiagnosed B12 deficiency will improve the anemia but will not reverse the neurological symptoms.

The underlying cause for B12 deficiency and/or folate deficiency should be identified and treated. The duration of therapy depends on the underlying cause of the deficiency. Lifelong replacement is recommended for patients with irreversible causes (e.g., gastric bypass surgery and pernicious anemia). Short term treatment is recommended for patients with reversible causes (e.g., drug induced, reversible causes of malabsorption, inadequate dietary intake, and alcoholism). Both B12 and folate are water soluble vitamins and do not generally cause any major adverse effects.

#### Treatment of B12 Deficiency

Vitamin B12 is available in oral, sublingual, intramuscular (IM), subcutaneous (SC), and intranasal formulations. Cyanocobalamin is the most available formulation in United States. The oral formulation is generally effective in patients with a reversible cause and is administered at a dosage of 1000 µg daily for at least 1 month followed by either continuation of the same dose for maintenance or the dose can be decreased to 100 to 500 µg daily in patients with mild reversible deficiencies. The parenteral formulation is preferably administered IM at a dose of 1000 µg daily for 1 week followed by 1000 µg once a week for 1 month. The maintenance dose for IM or parenteral deep SC injection is 1000 µg monthly and indefinitely, depending on the etiology. Patients are usually taught to self-administer the injections to minimize the inconvenience of travel, improve compliance, and decrease costs.

#### Treatment of Folate Deficiency

The replacement dose for folic acid varies between 1 and 5 mg/day. Usually, therapy is continued for at least 3 to 6 months, provided that the underlying causes of the deficiency have been corrected.

#### Complications and Long-Term Monitoring

Patients with undiagnosed megaloblastic anemia can develop severe anemia and cardiac comorbidities. Neuropsychiatric changes can become irreversible if the B12 deficiency is not treated promptly. Patients may also develop long-term complications from undiagnosed underlying etiologies.

There is no need for frequent monitoring of B12 and folate levels once the underlying cause of the deficiency has been identified and appropriate treatment has been started.

### CURRENT DIAGNOSIS

- Platelet-mediated bleeding disorders commonly present with bleeding from mucosal surfaces or skin. Bleeding caused by reduced platelet counts may present with petechiae or purpura, whereas abnormalities of function are more likely to present with bleeding after injury or menstruation.
- Evaluation of platelet function used to be measured by the bleeding time. However, it is now more commonly evaluated by the platelet function analysis (PFA)-100 or platelet aggregation studies.
- Thrombocytopenia is most commonly caused by deficient production of platelets from the bone marrow, decreased platelet survival in the circulation, or sequestration of platelets by an enlarged spleen.
- Patients may bleed after trauma at platelet counts less than 50,000/ $\mu\text{L}$  and develop petechiae or purpura at platelet counts less than 20,000/ $\mu\text{L}$ , but they usually do not have severe bleeding unless platelet counts drop to less than 10,000/ $\mu\text{L}$ .
- The most common causes of new thrombocytopenia in the hospitalized patient are drugs or infection, whereas the usual cause of new platelet function abnormalities are medications.
- Patients in the hospital and placed on heparin should have their platelet counts monitored, and a reduction of 50% should be evaluated for heparin-induced thrombocytopenia (HIT).
- Immune thrombocytopenic purpura (ITP) usually presents in outpatients as new-onset mucocutaneous bleeding associated with only a reduced platelet count or unexplained asymptomatic isolated thrombocytopenia.
- Drugs that inhibit platelet activation and aggregation, such as aspirin, clopidogrel (Plavix), and dipyridamole (Persantine) can lead to significant bleeding, especially after surgery or procedures. This effect may last for 7 to 10 days.
- Patients presenting with a lifetime history of easy bruising and or heavy menses should have careful evaluation of their bleeding history and family history of bleeding. If positive, studies to rule out von Willebrand disease or hereditary disorders of platelet granules such as storage pool disorder should be done.

### CURRENT THERAPY

- Patients with severe thrombocytopenia (platelet counts <10,000/ $\mu\text{L}$ ) that is due to impaired production are at risk of severe bleeding and should be considered for platelet transfusions. The benefit of transfusing platelets when the platelet count reaches this level and the patient is not bleeding has been demonstrated as reducing bleeding in some patients in a recent study.
- Standard practice for platelet transfusions is to maintain platelet counts greater than 50,000/ $\mu\text{L}$  for patients with gastrointestinal bleeding and 75,000 to 100,000/ $\mu\text{L}$  for neurosurgical procedures. Platelet transfusions should be considered for certain other invasive procedures.
- Patients with immune thrombocytopenia should not receive platelet transfusions unless they are having significant bleeding because response to platelet transfusion occurs in less than 10% of patients and is short lasting.
- Patients with immune thrombocytopenic purpura (ITP) who have no bleeding and platelet counts greater than 30,000/ $\mu\text{L}$  can be followed without treatment because the risk of bleeding is low.

- In patients with ITP and thrombocytopenia less than 10,000/ $\mu\text{L}$ , initial treatment with high doses of corticosteroids in combination with intravenous immunoglobulin (IVIg; Gamunex) induces a rapid rise in platelets, usually within 24 hours.
- Current treatment for patients with ITP who fail prednisone treatment include splenectomy, rituximab (Rituxan),<sup>1</sup> or thrombopoietin agonists (romiplostim [Nplate] or eltrombopag [Promacta]).
- Patients with chronic renal failure can develop severe bleeding diathesis, which appears to be multifactorial including platelet dysfunction. Dialysis can reduce bleeding but not completely correct it. Other treatment that may help to include desmopressin (DDAVP)<sup>1</sup>, tranexamic acid (Lysteda)<sup>1</sup>, and synthetic erythropoietin (Epoen)<sup>1</sup>.
- Patients with drug induced platelet dysfunction who may need to undergo surgery or who are bleeding may require platelet transfusions.
- Patients with inherited platelet disorders and mild bleeding can be treated with DDAVP but, if severe, may require platelet transfusions.

<sup>1</sup>Not FDA approved for this indication.

Platelets are small nonnucleated blood cells that are derived from bone marrow megakaryocytes. Their production is controlled by the hormone thrombopoietin produced in the liver, and they survive in the circulation for 8 to 10 days. On blood vessel injury, they form a seal or plug at the site of injury to limit bleeding. This initial event, termed *primary hemostasis*, occurs after endothelial injury when the subendothelial surface is exposed to circulating blood. Platelets are drawn to the site via von Willebrand factor (VWF), which, in combination with other proteins including fibrillar collagen, fibronectin, and laminin, leads to platelet adhesion. After platelets adhere to the vessel wall, they are activated, undergo a shape change, and release products from their granules. These platelet granule products, including adenosine diphosphate (ADP) and thromboxane A<sub>2</sub>, further potentiate this process. Fibrinogen then binds to platelets via GPIIb/IIIa on the platelet surface causing firm platelet aggregation. The platelet secretory release reaction and aggregation recruits other platelets forming a firm hemostatic plug. Platelets also support the coagulation phase by interacting with circulating clotting factors and providing a surface for generation of thrombin. Secondary hemostasis occurs and thrombin-mediated fibrin mesh stabilizes the platelet plug.

### Clinical Manifestations

The hallmark of platelet-mediated bleeding disorders is mucocutaneous bleeding such as nose bleeds, prolonged bleeding after tooth extractions, and heavy menstrual bleeding. When the platelet count drops to less than 30,000/ $\mu\text{L}$ , one may also see petechiae or purpuric lesions, especially on lower extremities.

### Quantitative Platelet Disorders (Thrombocytopenia)

Primary hemostasis depends on an adequate number of platelets to prevent bleeding. A significant reduction in platelets or thrombocytopenia is usually defined as less than 100,000/ $\mu\text{L}$ . However, bleeding usually does not occur until the platelet count drops much lower. For example, spontaneous bleeding may only occur when the platelet count is less than 20,000/ $\mu\text{L}$  and severe life-threatening bleeding occurs only less than 10,000/ $\mu\text{L}$ . Thrombocytopenia can develop due to inadequate platelet production from the bone marrow, reduced platelet survival in the circulation, or sequestration of platelets in the spleen. Differentiating the cause requires evaluation of the patient's associated medical problems, physical findings, drug history, blood chemistry analysis, and possibly bone-marrow sampling.

Decreased platelet production is often the result of chemotherapeutic drugs for cancer, some antibiotics and antivirals (Table 1),

**TABLE 1** Drugs Commonly Implicated as Causes of Drug-Induced Thrombocytopenia

CATEGORY	IMPLICATED IN SEVERAL REPORTS
Heparin	Unfractionated and low-molecular-weight heparin
Cinchona alkaloids	Quinidine, quinine
Platelet inhibitors	Abciximab (RepPro), eptifibatid (Integrilin), tirofiban (Aggrastat)
Antirheumatic agents	Gold salts
Antimicrobial agents	Linezolid (Zyvox), rifampin, sulfonamides, vancomycin
Sedatives and anticonvulsants	Valproic acid, phenytoin, carbamazepine
Histamine receptor antagonists	Cimetidine
Diuretic agents	Chlorothiazide
Analgesic agents	Acetaminophen, naproxen, diclofenac
Chemotherapy agents	Oxaliplatin (Eloxatin), fludarabine (Fludara), and others

or radiation therapy. These drugs may cause bone marrow injury, including damage to the megakaryocytes. Complete recovery may occur after stopping the offending agent. One common agent that can induce thrombocytopenia is alcohol. Thrombocytopenia associated with reduction in the white blood cell count and or red blood cell count should alert physicians to the possibility of a bone marrow disorder such as forms of leukemia or aplastic anemia. In cases where the cause is not evident, a bone marrow biopsy may be necessary to demonstrate whether there is a malignancy that may require urgent treatment.

Patients with reduced platelet production can often be observed without intervention depending on the severity of the thrombocytopenia, presence of bleeding, or the need to perform invasive procedures. Guidelines for transfusion of platelets to prevent bleeding (prophylactic transfusion) have changed in the last few years. With evidence that severe bleeding may not occur in most patients until the platelet count is less than 10,000/ $\mu\text{L}$ , limited platelet resources, and potential for development of alloimmunization to platelets, transfusions are not usually given unless sustained platelet counts are less than 10,000/ $\mu\text{L}$ . When platelets are transfused, it is appropriate to measure the response with a platelet count 1 hour post transfusion. The platelet count should rise 30,000 to 40,000/ $\mu\text{L}$  for the usual four-pack of platelet transfusion. Patients requiring frequent transfusions may require single-donor apheresis or human leukocyte antigen-matched platelets to obtain a good response.

### Thrombocytopenia Resulting from Increased Platelet Destruction

Normally, platelets live in the circulation for 10 days, and the bone marrow replenishes them at the same rate that they are destroyed. Platelet survival may be altered by both nonimmune and immune processes. Severe infections will often lead to increased platelet destruction, and the platelet count returns to normal when the infection is adequately treated. Consumption of platelets also can occur in association with microangiopathic hemolytic anemia, as seen in disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP/HUS). It is important to review the blood smear to document fragmented red blood cells and evaluate coagulation parameters to help differentiate DIC from TTP/HUS and other causes of consumption. TTP/HUS may require specific and urgent treatment to prevent life-threatening complications.

Platelet transfusions are not usually given for TTP because there are reports of patients deteriorating after transfusions.

Immune-mediated platelet destruction is seen in response to several common drugs, including the sulfonamides and vancomycin. The characteristic pattern of immune-mediated platelet destruction is a sharp drop in the platelet count 7 to 10 days after starting the drug. The platelet count may drop to 5000/ $\mu\text{L}$  or less. Recognition is important because significant bleeding may occur, and the platelet count will only improve after discontinuation of the drug. Glycoprotein IIa/IIIb inhibitors, which are often used after cardiac stent placement, may cause a dramatic drop in the platelet count to as low as 1000/ $\mu\text{L}$  within hours of administration. This is important to recognize because this is one case where platelet transfusions may be necessary to prevent severe bleeding and it can be easily confused with other causes of low platelet counts.

Heparin-induced thrombocytopenia (HIT) is a unique drug reaction for several reasons. First, although thrombocytopenia is the initial sign of this entity, the major and feared complication is arterial and venous thromboses. It appears to affect 4% to 5% of patients exposed to unfractionated heparin and approximately 0.5% of patients exposed to low-molecular-weight heparin. Those at highest risk are female surgical patients who receive a minimum of 4 days of either type of heparin. The classic pattern is exposure to heparin at any dose with development of antibodies to heparin at day 4 and a 50% reduction in platelet count by day 6. The antibodies responsible are to the heparin-platelet factor 4 complex (IgG-PF4). A suspicious clinical pattern and a high antibody titer measured by an enzyme-linked immunosorbent assay are often diagnostic. Patients suspected of having HIT are at a high risk of thromboembolic disease within the first 24 hours of the drop in platelet count, and the heparin should be immediately stopped. However, despite the reduced platelet count, bleeding is unusual. Patients should be placed on an alternative anticoagulant, usually a direct thrombin inhibitor. The platelet count takes approximately 2 weeks to return to normal, and warfarin (Coumadin) should not be started until the platelet count returns to normal to avoid warfarin-associated necrosis. By reducing protein C and protein S, warfarin creates a temporary hypercoagulable state and places the patient at risk for warfarin-associated necrosis during the time when patients are most susceptible to thrombosis from HIT.

Immune thrombocytopenic purpura (ITP), previously termed *idiopathic thrombocytopenic purpura* affects 1 to 3 people per 100,000 but is probably the most common cause of severe isolated thrombocytopenia seen in the outpatient setting. It affects all ages, although ITP in childhood has a unique natural history. Childhood ITP is often associated with viral illness, is commonly transient, and may not need treatment. In adults, 40% of patients may have protracted or recurrent episodes of ITP, and the majority of patients need treatment. It was demonstrated in the 1950s that ITP is caused by circulating antiplatelet antibodies, and, like many autoimmune diseases, it is more common in women. When ITP presents in association with other diseases such as systemic lupus erythematosus or chronic lymphatic leukemia, or in patients with HIV, management of the underlying disease is important. The clinical presentation of ITP depends on the degree of thrombocytopenia. Mild thrombocytopenia of 20,000 to 80,000/ $\mu\text{L}$  is often asymptomatic, whereas platelet counts less than 20,000/ $\mu\text{L}$  may present with mucocutaneous bleeding and diffuse petechiae and purpura. Thrombocytopenia, an otherwise normal blood count, and peripheral blood smear without evidence of splenomegaly in a patient with no other illness helps to make a tentative diagnosis. A bone marrow biopsy is no longer considered necessary to confirm the diagnosis.

Treatment of ITP has changed over the past several years, and initial treatment after the diagnosis requires evaluation of the platelet count, whether it is increasing or decreasing, and the presence or absence of bleeding. Patients who have counts greater than 20,000/ $\mu\text{L}$  without bleeding and who are not in need of an invasive procedure can be observed without intervention. Patients

with counts between 10,000 and 20,000/ $\mu\text{L}$  may be started on oral prednisone at 1 mg/kg. Patients with severe thrombocytopenia less than 10,000/ $\mu\text{L}$  and those who are bleeding can receive high-dose dexamethasone (Decadron) at 40 mg daily for 4 days and intravenous immunoglobulin (IVIG; Gamunex). There is usually a response to treatment within 24 hours. Although usually not helpful or required, approximately 10% of patients will have a response to platelet transfusion, and this can be considered for patients presenting with low platelet counts and bleeding. Refractory or recurrent ITP is a common problem in these patients, and recommendations for treatment include splenectomy, rituximab (Rituxan)<sup>1</sup>, or thrombopoietin agonists. The choice of which to use depends on the patient and his or her clinical condition.

### Thrombocytopenia Due to Hypersplenism

The platelet mass is distributed 70% in the circulation and 30% in the spleen. Enlargement of the spleen and/or alteration of blood flow in portal hypertension may increase platelet sequestration in the spleen and reduce the platelet count in the peripheral blood circulation. Patients' counts rarely drop to less than 20,000/ $\mu\text{L}$ . Thus thrombocytopenia caused by hypersplenism does not usually need any intervention. Patients with hepatitis C and cirrhosis may present with low platelet counts, and this may represent both hypersplenism and secondary immune thrombocytopenia. A trial of steroids may be used if these patients' clinical situation requires therapy.

## Qualitative Platelet Function Disorders

### Acquired Qualitative Platelet Function Disorders

Acquired disorders of platelet function are commonly seen, because platelets are the target of medications used to prevent arterial and cardiac stent thrombosis. Spontaneous bleeding is not common, but bleeding resulting from trauma or surgery can be a significant clinical problem. Because many patients may be on multiple antiplatelet agents or anticoagulants at the same time, the risk of bleeding needs to be recognized. Acquired qualitative disorders of platelet function may be due to drugs, hematologic diseases, or medical illnesses.

Drugs are the most common cause of acquired platelet dysfunction with differing risks of bleeding due to different targets. Aspirin causes irreversible acetylation of cyclooxygenase I (COX-1) and inhibits generation of prostaglandin A<sub>2</sub>. Although it is considered a weak antiplatelet agent with up to 25% resistance, aspirin increases the risk of bleeding in otherwise normal patients. Major bleeding was seen in up to 3.7% of patients and, when aspirin is used in combination with other antiplatelet agents or in patients with underlying bleeding disorders, the bleeding risk is higher. Clopidogrel (Plavix) is a thienopyridine prodrug, and the active metabolite irreversibly inhibits the surface receptor P2Y<sub>12</sub> on platelets. In clinical trials the risk of major bleeding in patients taking clopidogrel was similar to what is described with aspirin. Clopidogrel may significantly increase bleeding after surgery. GPIIb/IIIa receptor antagonists used after cardiac stent placement inhibit platelet aggregation and can induce severe thrombocytopenia.

Malignancies of the bone marrow may produce abnormally functioning platelets or alter platelet function by affecting VWF. The myeloproliferative and myelodysplastic disorders may produce platelets with reduced numbers of granules and may have associated increased risk of gastrointestinal bleeding and bleeding after invasive procedures. Acquired von Willebrand disease, an infrequent cause of abnormal bleeding, can be seen in patients with lymphoproliferative disease, multiple myeloma, and Waldenström macroglobulinemia.

Systemic illness can alter platelets and increase the bleeding risk. Acute and chronic renal failure are common causes of platelet-function abnormalities. In uremia, hemorrhagic complications

include upper gastrointestinal bleeding, pericardial bleeding, and intracranial bleeding. Bleeding in renal failure is believed to be multifactorial and includes impaired release of platelet granules, decreased prostaglandin formation, VWF dysfunction, and presence of severe anemia. Effective treatment includes improvement of the anemia with erythropoietin (Epoen)<sup>1</sup> or DDAVP<sup>1</sup> or conjugated estrogens (Premarin).<sup>1</sup>

### Hereditary Qualitative Platelet Function Disorders

Inherited abnormalities of platelet function are infrequent disorders that give rise to bleeding of varying severity. Inherited abnormalities of platelet function are often classified according to the type of genetic defect. Bernard-Soulier syndrome (BSS) is a severe bleeding disorder with autosomal recessive inheritance characterized by thrombocytopenia, decreased platelet adhesion, reduced platelet survival, and giant platelets on blood smear. Patients with BSS have defects in the GPIb-IX-V complex leading to reduced binding to VWF. Glanzmann thrombasthenia is an autosomal recessive disorder with defects of integrin  $\alpha\text{IIb}\beta_3$ , a receptor on activated platelets that normally binds platelets during aggregation. Platelet aggregation to ADP and thrombin is abnormal. Patients with BSS and Glanzmann thrombasthenia who need treatment require platelet transfusions.

Hereditary disorders of platelet secretion are common reasons patients present to clinicians for evaluation of mucocutaneous bleeding. Defects in platelet dense granules ( $\delta$  storage pool disease) are suspected in patients with bleeding and a negative work-up for von Willebrand disease. Diagnosis is made by platelet electron microscopy and or platelet aggregation studies. Granule deficiency associated with abnormalities of other lysosome-related organelles may lead to specific phenotypes such as Hermansky-Pudlak and Chediak-Higashi disease. Gray platelet syndrome (GPS), or alpha granule deficiency, is an autosomal recessive disorder with mild bleeding. GPS patients may also be thrombocytopenic. Treatment for bleeding or in preparation for surgery includes DDAVP<sup>1</sup> or platelet transfusions.

## POLYCYTHEMIA VERA

Method of

Peter R. Duggan, MD; and Sonia Cerquozzi, MD

### CURRENT DIAGNOSIS

- Polycythemia vera (PV) should be considered when there is persistent elevation of hemoglobin (> 165 g/L in men and > 160 g/L in women) or hematocrit (> 49% in men and > 48% in women).
- *JAK2V617F* mutation testing and erythropoietin levels should be performed when PV is suspected.
- Bone marrow biopsy and aspiration may be necessary in some cases to confirm the diagnosis of PV and to distinguish PV from other myeloproliferative neoplasms (MPNs).
- PV is highly likely when *JAK2V617F* mutation is present and erythropoietin level is subnormal. When *JAK2V617F* mutation is seen with normal erythropoietin level, PV is possible; bone marrow biopsy is recommended to differentiate PV from other MPNs. When *JAK2V617F* is normal and erythropoietin is low, consider *JAK2* exon 12 mutational analysis or alternative diagnosis of congenital polycythemia. Wildtype *JAK2V617F* with normal or high erythropoietin level makes PV very unlikely, and patients should be investigated for secondary causes of polycythemia.
- Investigations for secondary polycythemia that may be indicated include:
  - Chest x-ray
  - Pulse oximetry
  - Arterial blood gas including carboxyhemoglobin and methemoglobin levels
  - Kidney and liver function tests
  - Abdominal imaging studies (ultrasound or computed tomography [CT] scan)
  - Oxyhemoglobin dissociation curve
  - Nocturnal polysomnography

### CURRENT THERAPY

- All patients should be treated with phlebotomy and/or cytoreductive therapy to target hematocrit less than 45%.
- Low-dose aspirin<sup>1</sup> (acetylsalicylic acid [ASA]) should be used in *all patients* without a contraindication.
- In *high-risk* patients with PV (age ≥ 60 years and/or history of thrombosis), cytoreductive therapy should be used in combination with ASA.
- Alkylating agents should be avoided as cytoreductive therapy owing to the risk of acute leukemia.
- Conventional cardiovascular risk factors (diabetes, hypertension, hyperlipidemia) should be aggressively managed, and cigarette smoking should be discouraged.
- Thromboembolic events should be managed according to accepted management guidelines. Thromboprophylaxis should be used after surgery and in other high-risk situations.

<sup>1</sup>Not US Food and Drug Administration (FDA) approved for this indication.

Polycythemia vera is a clonal stem cell disorder characterized by an increase in red cell production independent of the stimulation by erythropoietin. PV is the most common of the chronic myeloproliferative neoplasms (MPNs), occurring in approximately 2 to 3 people per 100,000 annually. The median age at diagnosis is 70 years, and it is rare in patients younger than 40 years.

A mutation of the tyrosine kinase Janus kinase 2 (*JAK2*) is consistently found in PV. This sheds some light on the pathogenesis

of the disease and is useful in the diagnosis of PV and other MPNs. A single acquired mutation (*V617F*) of the gene for the JH-2 domain of *JAK2* can be found in 90% to 95% of patients with PV. The JH-2 domain functions to inhibit *JAK2* activity. In normal erythropoiesis, binding of erythropoietin to its receptor lifts this inhibition and allows *JAK2* stimulation of cell division and differentiation. In mutated *JAK2*, this inhibitory function is absent, leading to constitutive activity of the tyrosine kinase. This mutation is also present in about half of patients with essential thrombocytosis and primary myelofibrosis. The small number of patients with PV who are negative for the common *JAK2V617F* mutation have another functionally similar mutation within *exon 12*.

### Presentation

Many patients with PV are asymptomatic, and PV is diagnosed after the incidental finding of an elevated hemoglobin or hematocrit on routine complete blood count. Splenomegaly is present in 30% to 40% of patients. Up to half of patients experience nonspecific symptoms such as weight loss, sweating, headache, fatigue, epigastric discomfort, visual disturbances, and dizziness. Many of these symptoms are likely caused by decreased blood flow due to an increased blood viscosity from polycythemia.

Generalized pruritus is often described, often after a warm bath or shower (aquagenic pruritus). Although the cause of this is unknown, it is thought to be due to the degranulation of increased numbers of mast cells in the skin of patients, releasing histamine and other inflammatory mediators. However, the symptom responds poorly to antihistamines, and it does not always resolve with treatment of PV.

Venous and arterial thromboembolic events are a major cause of morbidity and mortality in PV. Thrombosis at presentation occurs in up to 40% of patients. Ischemic stroke, transient ischemic attack, and myocardial infarction are common, especially among elderly patients. These, along with deep venous thrombosis and pulmonary embolus, are the most common thrombotic events and often result in serious morbidity, disability, and even death. Thrombotic events that are considered unusual in the general population, such as Budd-Chiari syndrome; portal, mesenteric, and other abdominal vein thrombosis; and cerebral venous thrombosis, occur more commonly among patients with PV. The possibility of an underlying MPN should be considered when a patient presents with such an event.

PV can manifest with symptoms of peripheral vascular disease. Patients with erythromelalgia describe a painful burning sensation of the hands and feet; pallor, erythema, or cyanosis of the extremities; and sometimes cutaneous ulceration. Erythromelalgia results from microvascular thrombosis and ischemia due to platelet activation and aggregation and responds well to platelet reduction and antiplatelet agents such as aspirin (ASA).<sup>1</sup>

Almost all patients with PV are iron deficient at diagnosis, even before the onset of therapeutic phlebotomy. Other manifestations of PV include acute gouty arthritis, peptic ulcer disease, erosive gastritis, and hypertension.

### Diagnosis and Differential Diagnosis

The 2016 World Health Organization (WHO) diagnostic criteria for PV are shown in [Box 1](#). The *JAK2V617F* mutation is present in about 95% of cases of PV. Erythropoietin level is decreased in more than 90% and is rarely elevated. Few patients with PV carry a mutation of exon 12 (~4%) of the *JAK2* gene instead of the more common *JAK2V617F* mutation. A *JAK2* mutation can also be found in about half of patients with essential thrombocytosis and primary myelofibrosis.

Leukocytosis and thrombocytosis are present in the majority of cases of PV. Red cell mass is increased. A nuclear medicine study measuring red cell mass and plasma volume is rarely required with the availability of *JAK2* testing, but it may be useful when

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** 2016 World Health Organization Diagnostic Criteria for Polycythemia Vera

Diagnosis requires three major criteria or first two major criteria and minor criterion.\*

**Major Criteria**

1. Hemoglobin > 165 g/L in men, 160 g/L in women, or  
Hematocrit > 49% in men, > 48% in women, or  
Other evidence of increased red cell volume<sup>†</sup>
2. Bone marrow biopsy: hypercellular for age with trilineage growth (panmyelosis)
3. Presence of *JAK2V617F* or *JAK2* exon 12 mutation

**Minor Criterion**

1. Subnormal serum erythropoietin level

\*Bone marrow biopsy may not be required in sustained erythrocytosis—hemoglobin > 185 g/L (hematocrit > 55.5%) in men or > 165 g/L (hematocrit > 49.5%) in women—if major criterion 3 and minor criterion are present.

<sup>†</sup>> 25% above mean normal predicted value.

relative polycythemia is suspected. Bone marrow biopsy and aspiration are not often needed for a diagnosis of PV but have been included as a major criterion within the revised WHO classification. Bone marrow examination can be important for diagnosing PV in the rare cases where *JAK2* is negative and to differentiate PV from other *JAK2*-positive MPNs when the distinction cannot be made based on peripheral blood counts.

Erythrocytosis can occur as a result of a number of other conditions in the absence of PV (Box 2). A careful history and physical examination with selected investigations can usually distinguish PV from secondary polycythemia and relative polycythemia (see Current Diagnosis). In relative (apparent, spurious) polycythemia, there is usually only a modest increase in the hematocrit, because of a decrease in plasma volume rather than a true increase in red cell mass. Thrombocytosis, leukocytosis, and splenomegaly should be absent. Causes include smoking, dehydration, and use of diuretics, and it is also described in middle-aged, obese, hypertensive men (Gaisböck syndrome).

Red cell mass can be elevated owing to increased stimulation of erythropoiesis by high levels of erythropoietin. Erythropoietin can be increased as an appropriate response to chronic hypoxia (sleep apnea, right-to-left cardiac shunts, chronic lung disease, high altitude, smoking, methemoglobinemia), and it can be inappropriately elevated owing to erythropoietin-secreting tumors (renal cell carcinoma, hepatocellular carcinoma, cerebellar hemangioma, uterine fibroids) or decreased kidney perfusion (renal artery stenosis). Familial causes of polycythemia include high-affinity hemoglobins, erythropoietin receptor mutations, and Chuvash polycythemia. Polycythemia occurs in 10% to 15% of patients following kidney transplantation, and this may be due to erythropoietin secretion by the native kidneys or increased sensitivity to erythropoietin. Polycythemia can be drug induced, such as with the use of performance-enhancing drugs (erythropoietin [Epogen], androgens) in athletes and testosterone replacement in men.

**Prognosis**

Patients with PV have a reduced life expectancy compared with the general population, with a median survival of approximately 14 years, or 24 years if younger than age 60 at diagnosis.

Despite therapy, thrombosis remains an important cause of mortality. Cardiac disease, ischemic stroke, pulmonary embolus, and other thrombotic events account for 40% of deaths among patients with PV. Nonfatal thrombosis is common, occurring in almost 4% of patients annually. Age and a history of prior thromboembolic events are independent risk factors for thrombosis and

**BOX 2** Differential Diagnosis of Polycythemia**Normal Red Cell Mass**

**Elevated Red Cell Mass****Primary Polycythemia**

Polycythemia vera

**Secondary Polycythemia**

- Congenital EPO receptor mutations
  - Chuvash polycythemia
  - High-affinity hemoglobin
- Appropriately elevated EPO (hypoxia driven)
- Chronic hypoxic lung disease
  - Cardiac shunts or cyanotic heart disease

• Sleep apnea

• Methemoglobinemia

• High altitude

• Chronic carbon monoxide poisoning

• Cigarette smoking

• Renal artery stenosis

Inappropriately elevated EPO

• Renal cell carcinoma

• Hepatocellular carcinoma

• Hemangioblastoma

• Uterine fibroids

Other causes:

• Erythropoietin stimulating agents (ESA)

• Androgens (testosterone)

• Kidney transplant

Abbreviation: EPO = erythropoietin.

**BOX 3** Thrombotic Risk in Polycythemia Vera**Low Risk**

Age < 60 years and no history of thrombosis

**High Risk**

Age ≥ 60 years and/or history of thrombosis

can be used to predict a patient's risk of future events (Box 3). Low-risk patients are younger than 60 years and have no history of thrombosis. They experience new events at a rate of 2% per year. For patients older than 60 years or with a past history of thrombosis, this rate is 5% annually, but it can be as high as 11% when both risk factors are present.

The contribution of other cardiovascular risk factors (smoking, diabetes, hypertension, hyperlipidemia) to thrombotic risk in PV has been studied, with inconclusive results. However, because these are major contributors to the development of cardiovascular disease in the general population, they should also be considered when assessing risk in patients with PV. Leukocytosis (white blood cell count >  $15 \times 10^9/L$ ) has been associated with a higher risk of arterial thrombosis.

Conversely, the risk of major hemorrhage is low, with fatal bleeding responsible for less than 5% of all deaths. However, there is considerable excess mortality from malignancy, in particular transformation to a myelodysplastic syndrome, myelofibrosis, or acute leukemia. The rate of leukemic transformation is less than 10% at 20 years. Risk factors for leukemic transformation include advanced age, leukocytosis, and abnormal karyotype. Approximately 10% of patients transform to myelofibrosis (post-PV myelofibrosis). Risk factors for post-PV myelofibrosis include leukocytosis and *JAK2V617F* allele burden of greater than 50%.

## Treatment

The goals of treatment in PV are to lower the risk of thrombosis while minimizing toxicity. This is achieved by a combination of phlebotomy, aspirin,<sup>1</sup> and hydroxyurea (Hydrea)<sup>1</sup> or other cytoreductive agents. The use of these therapies can be individualized based on a patient's risk of developing future thromboembolic events. Risk stratification (Box 3) aims at identifying patients with PV at higher risk of thrombotic events who require cytoreductive therapy. Because cerebrovascular and cardiovascular disease are among the main causes of morbidity and mortality for these patients, careful attention should be paid to the management of conventional cardiovascular risk factors. Hypertension, diabetes, and hyperlipidemia should be controlled with standard measures based on current guidelines, and patients should be encouraged to stop smoking. As the hematocrit increases in PV, there is a dramatic increase in blood viscosity. Phlebotomy is the fastest, most effective way to normalize a patient's hematocrit, and it should be initiated immediately in those with newly diagnosed PV. Blood volume should be reduced as rapidly as possible. Usually, 500 mL of blood is removed every 1 or 2 days until the hematocrit is less than 45%. The frequency of phlebotomy or volume of blood removed can be decreased in elderly patients, those with cardiovascular disease, or others who do not tolerate this schedule. The optimal target in patients with PV is to maintain a hematocrit less than 45% to lower the risk of major thrombotic events and death from cardiovascular causes. Regular phlebotomy eventually results in iron deficiency, at which point most patients' phlebotomy needs decrease dramatically. Iron replacement should be avoided.

### Aspirin

Previous studies did not support the routine use of aspirin to prevent thrombosis in PV. However, high doses of aspirin were used in these early studies, resulting in excess bleeding in the treatment arm. The results of a recent large randomized trial show that low-dose aspirin (100 mg/day) reduces major thrombotic events (nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis). This was accomplished without an increase in bleeding risk. Although there was a trend suggesting more minor bleeding events in those receiving aspirin, the rates of major bleeding were identical for those receiving aspirin or placebo. The benefit from aspirin was seen, even though this study included many low-risk patients without a prior history of thromboembolism. Low-dose aspirin (75–100 mg daily)<sup>1</sup> should be started in all patients without a contraindication to the drug (history of bleeding or intolerance). Because of the risk of bleeding from acquired von Willebrand disease that can occur with extreme thrombocytosis, aspirin should be held when platelets are more than  $1500 \times 10^9/L$  until the count can be lowered by cytoreduction.

### Cytoreductive Therapy

Cytoreductive therapy is recommended for high-risk patients with PV (Box 3). Hydroxyurea (HU)<sup>1</sup> is the cytoreductive agent most commonly used to treat PV. Hydroxyurea can safely control blood counts and decreases spleen size in PV and other MPNs. Randomized data are limited, but hydroxyurea also appears to reduce thrombotic complications. A starting dosage of 15 to 20 mg/kg daily (1000–1500 mg daily) is used. Occasional phlebotomy is still required to maintain hematocrit less than 45%, but the frequency usually decreases. Myelosuppression is the main toxicity. The lowest dosage that provides therapeutic effect should be used, and excess myelosuppression should be avoided. The dosage can be titrated to ensure that the white cell count

remains higher than  $3.0 \times 10^9/L$ , neutrophils are higher than  $2.0 \times 10^9/L$ , and platelets are in the normal range.

Hydroxyurea has been associated with leg ulcers and other skin changes, especially after long-term use. There is growing evidence that hydroxyurea does not contribute to the excess rates of acute leukemia seen in PV; rates are no different than in those treated with phlebotomy alone. However, transformation is clearly associated with the use of other chemotherapeutic agents such as chlorambucil (Leukeran)<sup>1</sup>, busulfan (Myleran)<sup>1</sup>, and pipobroman (Vercyte),<sup>2</sup> accounting for one-third of the deaths among patients with PV treated with these agents. The use of these agents should be avoided. Hydroxyurea resistance can occur in up to 11% of patients and is associated with increased risk of death. Both hydroxyurea resistance and intolerance are defined according to the European Leukemia Net (ELN) criteria.

Interferon- $\alpha 2b$  (IFN- $\alpha 2b$ ) (Intron A)<sup>1</sup> is an alternative treatment option in the setting of hydroxyurea resistance and/or intolerance and often is considered in young patients with PV. IFN- $\alpha 2b$  is available in both short-acting and controlled-release (pegylated) formulations. IFN- $\alpha 2b$  is commonly administered subcutaneously with a starting dose of 3 million units daily, or pegylated IFN- $\alpha 2b$  (Peg-Intron)<sup>1</sup> is given at 45 to 90  $\mu g$  weekly. Studies have shown its efficacy in controlling blood counts in addition to achieving complete hematologic and molecular responses. The inconvenience of its administration and its side effects including mood disturbances and flu-like illness make it a less desirable therapy. Controlled studies are comparing hydroxyurea with pegylated forms of IFN- $\alpha 2b$ . At present, both are first-line cytoreductive treatment options with recommendations that IFN- $\alpha 2b$  be used in females with childbearing potential.

Ropeginterferon alfa-2b (Besremi; Ropeg [Europe]) is a monopegylated, long-acting interferon, aimed to be administered once every 2 weeks or longer. It was FDA approved for PV at the end of 2021 based on results from the phase 3 PROUD/CONTINUATION-PV clinical trials. In the CONTINUATION-PV trial, which included 171 patients, 61% of patients on ropeginterferon alfa-2b met complete hematologic response (CHR) (defined as hematocrit  $<45\%$  without phlebotomy for at least 2 months since last phlebotomy, platelets  $\leq 400 \times 10^9/L$ , leukocytes  $\leq 10 \times 10^9/L$ , normal spleen size with improved disease burden markers). A total of 71% of patients had a CHR compared with 58% on the standard of care. Ropeginterferon alfa-2b was well tolerated, with serious adverse reactions (incidence  $>4\%$ ) being urinary tract infection, transient ischemic attack, and depression.

### JAK Inhibitors

Ruxolitinib (Jakafi), a *JAK1/2* inhibitor, was originally approved in patients with myelofibrosis, including myelofibrosis evolving from PV. There was a significant reduction in spleen size and constitutional symptoms in almost half of these patients. In the phase III RESPONSE trial, ruxolitinib illustrated its effectiveness in controlling hematocrit ( $<45\%$ ), reducing spleen size ( $\geq 35\%$ ), and improving symptoms in patients with PV who had hydroxyurea intolerance or resistance, resulting in its approval as a second-line cytoreductive agent in PV. The most common side effects are anemia, thrombocytopenia, and atypical infection risk.

### Other Treatment Issues

Hyperuricemia is common in myeloproliferative neoplasms and occasionally results in kidney stones or gout. Allopurinol (Zyloprim) 300 mg daily can be used to reduce uric acid levels in patients with these complications. For those with intractable

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

pruritus, several agents have been used with variable success. Some patients respond to aspirin,<sup>1</sup> hydroxyurea<sup>1</sup>, cimetidine (Tagamet)<sup>1</sup>, cyproheptadine (Periactin)<sup>1</sup>, and paroxetine (Paxil)<sup>1</sup> 20mg daily. Both IFN- $\alpha$ 2b<sup>1</sup> and ruxolitinib have been successful in the majority of cases.

Less than 60% of pregnancies occurring in patients with PV are successful. First-trimester fetal loss is the most common complication, and third-trimester fetal loss, preterm birth, and intrauterine growth restriction are also common. Phlebotomy should be used to keep the hematocrit at less than 45%. Interferon- $\alpha$ 2b<sup>1</sup> is recommended for those requiring cytoreductive therapy during pregnancy; other cytoreductive agents are contraindicated owing to possible teratogenic effects. There is some evidence that the use of low-dose aspirin<sup>1</sup> throughout pregnancy improves live birth rate. It is recommended that prophylactic low-molecular-weight heparin (LMWH) be used for 6 weeks postpartum.

Surgery in patients with PV has a high risk of both operative bleeding and postoperative thromboembolism. Elective surgeries should be delayed until cytoreductive measures and phlebotomy can be used to achieve good control of blood counts. Aspirin should be held for 1 week before surgery to reduce the risk of hemorrhage. LMWH should be given after surgery to prevent deep venous thrombosis. Mechanical compression stockings are an option for patients with bleeding that prevents the use of anticoagulation. When thromboembolic events do occur, treatment should be according to current management guidelines. Venous thromboembolism is treated with LMWH and warfarin (Coumadin). Indefinite anticoagulation should be considered because of the high risk of recurrent events. Low-dose aspirin is indicated in those with a history of arterial events such as stroke and myocardial infarction.

## PORPHYRIAS

Method of

Marshall Mazepa, MD; and Gregory Vercellotti, MD

### CURRENT DIAGNOSIS

- Making the diagnosis relies on, first, an awareness and index of suspicion for these rare conditions, which manifest as either unexplained abdominal pain and neurologic symptoms, photosensitive skin lesions (some blistering and some not), or both.
- Patients with inexplicable recurrent abdominal pain may request an evaluation for acute intermittent porphyria (AIP), which can be excluded with a spot urine aminolevulinic acid (ALA) and porphobilinogen (PBG) test. Urine ALA and PGB will be extremely elevated at the time of acute attack, which is the ideal time to make the diagnosis, but levels *will remain elevated* (many times the upper limit of normal) for many weeks to months afterward, which can facilitate making the diagnosis in the nonacute setting.
- Porphyria cutanea tarda (PCT), the most common form of porphyria, is typically acquired, concurrent with iron overload, hepatitis C infection, and/or smoking. It classically presents with blistering skin lesions on the backs of the hands due to sun exposure.

### CURRENT THERAPY

- Patients should avoid alcohol consumption, smoking, hormone therapy, and drugs known to trigger attacks.
- Treatment of acute neurovisceral pain attacks includes outpatient oral carbohydrate loading or intravenous hemin (Panhematin) for treatment of severe attacks that require hospitalization.
- For patients with an acute hepatic porphyria (AHP) and recurrent severe neurovisceral attacks, givosiran (Givlaari), a small interfering RNA targeting aminolevulinic acid synthase-1 (ALAS-1), was recently US Food and Drug Administration (FDA) approved as a preventive therapy to reduce the frequency of attacks.
- For patients with erythropoietic protoporphyria (EPP), afamelanotide (Scenesse), an analogue of human  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) that stimulates melanin production, was recently FDA approved for reduction in EPP-related photosensitivity.

The porphyrias refer to a family of metabolic disorders of heme synthesis, where symptoms occur due to abnormal accumulation of metabolites, and most are congenital. Porphyria cutanea tarda (PCT) is the exception, which is caused by the acquired inhibition of hepatic uroporphyrinogen decarboxylase (UROD), commonly associated with hepatitis C virus (HCV) infection and iron overload. The porphyrias can be classified by the organ of heme precursor overproduction and acuity—the acute and chronic hepatic porphyrias and the acute erythropoietic porphyrias. This new system of classification has largely been driven by the development of new therapies that specifically target the metabolic driver of disease in the acute hepatic porphyrias (AHPs), including the recent FDA approval of givosiran (Givlaari) for AHPs. From a more practical standpoint, we recommend considering classifying the patient's symptoms

**TABLE 1** Heme Synthesis Pathway

METABOLITES	ENZYME	DISEASE	PATHOLOGY
Succinyl coenzyme A (CoA) and glycine			
Delta aminolevulinic acid (ALA)	ALA synthase (ALAS-1)	X-linked protoporphyria (XLP)	Gain-of-function mutation in ALA synthase Mimics EPP <10% of erythropoietic porphyrias (EPs) Males > females
Porphobilinogen (PBG)	ALA dehydratase	ALA dehydratase deficiency porphyria (ADP)	Elevated urine ALA
Hydroxymethylbilane	Porphobilinogen deaminase	<b>Acute intermittent porphyria (AIP)</b>	Elevated urine ALA and PBG
Uroporphyrinogen III	Uroporphyrinogen synthase	Congenital erythropoietic porphyria (CEP)	Excess erythrocyte, plasma porphyrins, urinary and fecal porphyrins; hemolytic anemia
Coproporphyrinogen III	Uroporphyrinogen decarboxylase (UROD)	<b>Porphyria cutanea tarda (PCT)</b>	Elevated plasma and urine uroporphyrins Normal urine ALA and PBG
Protoporphyrinogen IX	Coproporphyrinogen oxidase (CPOX)	Hereditary coproporphyria (HCP)	Elevated urine ALA and PBG Plasma and stool porphyrins to differentiate VP
Protoporphyrin IX	Protoporphyrinogen oxidase (PPOX)	Variegate porphyria (VP)	Elevated urine ALA and PBG Plasma and stool porphyrins to differentiate HCP

as either neurovisceral alone, neurovisceral plus dermatologic, or dermatologic alone, because the symptoms inform potential diagnoses and requisite testing.

While there are at least nine porphyrias, from a therapy perspective, three porphyrias are the most important to recognize. Acute intermittent porphyria (AIP) is likely the most common AHP. Patients with unexplained recurrent abdominal pain may request an evaluation for this disorder from their primary care doctor or consultant. PCT is likely overall the most common porphyria, and treatment with phlebotomy and avoidance of alcohol and other triggers can lead to profound relief of symptoms. Erythropoietic protoporphyria (EPP) is a very rare porphyria with dermatologic findings only, and a new FDA-approved therapy increases melanocyte melanogenesis, which is protective against ultraviolet (UV) light-associated painful skin manifestations, the first of its kind. Given that these conditions are rare, we suggest coordinating diagnosis and management with an expert. The American Porphyria Foundation (APF) website ([porphyriafoundation.org](http://porphyriafoundation.org)) provides an important resource for patients and providers alike, including US experts in the field.

### Pathophysiology and Clinical Manifestations

The heme synthetic pathway includes eight enzymes (Table 1). Heme is primarily synthesized in bone marrow (giving rise to hemoglobin in erythroblasts) and about 20% in the liver. While the pathways to synthesize heme are similar in the two organs, regulation of the two pathways differs. Aminolevulinic acid synthase-1 (ALAS-1) regulates heme synthesis in the liver and other organs; ALAS-2 regulates heme synthesis in the bone marrow. Both heme (the end product of the pathway) and glucose down-regulate ALAS-1 activity through negative feedback, observations which inform treatment. Conversely, demand for ALAS-1 activity can be increased by many inducers of cytochrome P450 because heme is central to the function of these enzymes. Hence, drugs that induce cytochrome P450 should be avoided in patients with porphyria.

Clinical manifestations of the porphyrias include neurovisceral and/or dermatologic symptoms. The term *neurovisceral* refers to unexplained generalized abdominal pain plus neurologic

symptoms ranging from mild neurologic manifestations (e.g., paresthesias and weakness) to, rarely, severe manifestations, including seizures and respiratory failure. Patients commonly describe a prodrome they recognize over time. Some patients can abort severe attacks with home measures such as carbohydrate consumption, rest, and hydration. They may also recognize extreme alcohol intolerance, triggers of attacks from new medications, herbs, or supplements, and, in women, onset of symptoms after puberty and during the luteal (premenstrual) stage of their menstrual cycle when progesterone levels are highest. Women are more commonly diagnosed with AHPs than men (estimated 4:1). Due to a delay in diagnosis, many patients have had multiple non-diagnostic evaluations or surgical interventions. Hyponatremia may occur during episodes and prompt treatment should be given to avoid precipitating seizures. Dark or reddish-tinged urine may also be present during an acute episode.

The dermatologic manifestations of the porphyrias include photosensitivity and either blistering or nonblistering skin lesions on sun-exposed areas. By far the most common manifestation is PCT, which has isolated blistering skin findings, classically on the backs of hands and other sun-exposed areas. In erythropoietic porphyria, skin lesions are nonblistering, but extremely painful and have a prodrome of escalating pain with light exposure. Coordination of care and management with a dermatologist is frequently necessary for diagnosis because there are many other blistering skin lesions and causes of photosensitivity. Liver damage in the form of cholestatic hepatitis is an uncommon complication, as well as are porphyrin-containing gallstones.

### Diagnosis

The diagnosis of the porphyrias relies on the presence of symptoms (neurovisceral and/or dermatologic) consistent with the diagnosis and biochemical abnormalities to confirm the diagnosis. A careful history shows painful episodes, prodrome, exacerbating, and alleviating factors, including alcohol tolerance, skin rashes or dermatologic evaluations, and neurologic manifestations (most commonly weakness). In addition to alcohol and tobacco histories, a careful review of all current and past medications and their associations with attacks should be evaluated. Among the more common

**TABLE 2** Diagnosis and Treatment of Porphyrrias

	SPECIFIC PORPHYRIAS	NEURO-VISCERAL	DERMATOLOGIC	TREATMENT	TREATMENT MECHANISM
Acute hepatic porphyrias	AIP (most common), ADP, HCP, VP	Yes	AIP, ADP—none VP and HCP photosensitive blistering	Hemin (Panhematin)— acute Givosiran (Givlaari)— prophylaxis	Hemin—negative feedback on ALAS-1 Givosiran—direct inhibition of transcription of ALAS-1

ADP, ALA dehydratase deficiency porphyria; AIP, Acute intermittent porphyria; ALAS-1, aminolevulinic acid synthase-1; CEP, congenital erythropoietic porphyria; EPP, erythropoietic protoporphyria; HCP, hereditary coproporphyria; HCV, hepatitis C virus; PCT, porphyria cutanea tarda; VP, variegate porphyria; XLP, X-linked protoporphyria.

inducers of attacks include oral contraceptives and many anticonvulsants. An excellent resource on drug safety in the porphyrias is provided at the APF website ([porphyriafoundation.org](http://porphyriafoundation.org)). An account of the most recent painful episode and timing from testing may also be helpful when considering testing.

The linchpin to the diagnosis of the AHPs, AIP in particular, is the spot urine ALA, porphobilinogen (PBG), and urine creatinine test (creatinine normalizes the measurement and negates the need for a 24-hour urine collection). While the likeliest time to find extreme elevations in heme metabolites will be during an attack, because testing is now done exclusively at reference laboratories, it is often impractical to base a diagnosis and treatment plan on acute testing. However, testing should be sent if the diagnosis is being considered during an episode of acute abdominal pain. In the outpatient setting, often there is confusion about the utility of testing outside of an acute episode. Because this is a congenital metabolic disorder, for most porphyrias, including AIP, a spot ALA, PBG, and urine creatinine test is sufficient to make the diagnosis. The levels of ALA and PBG outside of an acute episode will often remain high for many weeks. Hence, even without acute abdominal pain, levels greater than four to five times the upper limit of normal will make the diagnosis. Conversely, a common error in diagnosis is to measure levels of *all* porphyrins in the urine. Drugs whose metabolism induces cytochrome P450 (and hence heme synthesis), excess alcohol, and other chronic illnesses can result in relatively minor elevations in downstream porphyrins and lead to confusion about the diagnosis.

The APF website ([porphyriafoundation.org](http://porphyriafoundation.org)) is an excellent resource for providers and patients alike. There are a limited number of reference laboratories with the proficiency to perform the diagnostic assays for these disorders, which are listed on the APF website. Most helpful to a specialist is for the patient to be given the spot urine ALA, PBG, and urine creatinine test prior to referral for evaluation of the AHPs.

For PCT, the diagnosis can be suspected by visual inspection of blistering skin lesions, aided by the evaluation of a dermatologist, including a skin biopsy and confirmation with biochemical testing. The first step in diagnosis is to measure plasma porphyrins. If elevated, then typically laboratories will reflexively fractionate the different porphyrins, which reveals elevated uroporphyrin and heptacarboxyl porphyrins. Given that blistering skin lesions are not specific to PCT, a spot urine porphyrin test should also be done concurrently. In PCT, urine ALA and PBG will be normal, in contrast to the hereditary coproporphyrias (HCPs) that have blistering skin lesions. After the diagnosis of PCT is made, evaluation for susceptibility factors that could lead to the finding of PCT (given

that 80% are acquired) should also be done, including HCV and HIV infections, alcoholic liver disease, and iron overload. Genetic predisposition to iron overload due to mutations in the HFE gene (pathogenic in hereditary hemochromatosis) is frequently found.

For the very rare erythropoietic porphyrias, including EPP, a more specialized approach is needed, including evaluation by a dermatologist. EPP in particular is diagnosed by elevated protoporphyrin in red blood cells (erythrocyte protoporphyrin), plasma, and stool (normal in urine), which shares a phenotype with the very rare X-linked protoporphyria (XLP) but differs in the genetic lesion.

Given that these metabolic disorders are genetic in origin (PCT is the exception), there may be a temptation to perform genetic testing over biochemical testing to make the diagnosis. However, genetic testing should only be performed to confirm the diagnosis *after* discovery of biochemical evidence to support the diagnosis. The incomplete penetrance in these disorders has been well established so that to begin with genetic testing would likely falsely assign the diagnosis to patients whose symptoms should not be attributed to the disorder.

## Management

### Acute Hepatic Porphyrrias

The main principle of management of all AHPs is *avoidance* of inducers of heme biosynthesis to reduce production of excess toxic metabolites that drive the clinical disease manifestations (Table 2). In AHPs, where neurovisceral and/or skin symptoms are hallmarks, patients should be counseled to avoid alcohol use, smoking, oral contraceptives (both estrogen and progestins have been associated with attacks), and physicians should carefully prescribe drugs that induce cytochrome P450. The APF website ([porphyriafoundation.org](http://porphyriafoundation.org)) has an excellently curated and searchable drug database that should be consulted before starting any new medication. Patients should also be counseled about the risks of over-the-counter medications, herbal medicines, and supplements as potential inducers of attacks. Patients should also be counseled about environmental or situational inducers of attacks that in general would be considered metabolic stressors, such as physical or emotional stress, infection, fasting (e.g., as with fad diets), pregnancy (also a high progesterone state), and surgery. For women with attacks that are regularly triggered by menstrual cycles, ovarian suppression with gonadotropin-releasing hormone analogue can be used as a preventive measure as well.

When patients experience the prodrome of an acute attack (neurologic symptoms, tachycardia, vague abdominal pain), some are able to abort attacks by oral carbohydrate loading (at least 300 g/

day). For patients who present for medical attention, in addition to withdrawal of any identifiable precipitants of the attack (new medications, supplements, or alcohol), IV dextrose (10% dextrose in 0.45% normal saline) can be used as a temporizing measure if hemin is not available or for treatment of mild attacks. Carbohydrates directly but weakly inhibit ALAS1, so hemin is preferred for treatment of attacks that require more than therapy at home.

Intravenous hemin (Panhematin) rapidly reduces plasma PBG and ALA by reducing ALAS-1 activity through negative feedback. The primary acute toxicity from this therapy is phlebitis so it is strongly recommended to deliver this therapy by a central catheter. The drug is dosed once per day for 4 consecutive days at a dose of 3 to 4 mg/kg and reconstituted in albumin for better stability. Other supportive measures for an acute attack include antiemetics and analgesics (opioids commonly required for pain control). While seizures are highly uncommon, management is quite challenging given that the most common anticonvulsants are also strong precipitants of porphyric attacks. Thus, electrolyte abnormalities and other precipitants of seizures should be carefully managed.

Some patients with frequent attacks require regular treatment with hemin or preventive hemin infusions. However, because the effect of this therapy is short lived, this can lead to iron overload and poor quality of life. Givosiran (Givlaari) was recently approved exclusively as a preventive therapy for AHPs. This novel therapy is a small interfering RNA therapy that inhibits ALAS-1, and hence is a potent inhibitor of hepatic heme synthesis. The most commonly reported toxicities in the trials included injection-site reactions, nausea, rash, and elevated transaminases. The phase 3 clinical trial found a significant reduction in attacks when this therapy was given as a once-monthly subcutaneous injection overall by about 70% over placebo and nearly half had no attacks. Hemin (see Treatment of Acute Attacks) was still effective as a rescue therapy for acute attacks.

### Porphyria Cutanea Tarda

Blistering skin lesions are attributed to the presence of iron overload in addition to other predisposing factors that cause UROD deficiency. By treating iron overload with phlebotomy, plus removing or treating underlying triggers such as alcohol and tobacco use, hepatitis C (HCV) infection, or HIV infection, PCT can be effectively managed. Phlebotomy can be initiated on an every 2-weeks schedule with careful attention to the patient's hemoglobin and symptoms of anemia. While ideally iron deficiency is the target (ferritin <20), a careful balance between symptoms of PCT and symptoms of iron deficiency should be considered. In addition to phlebotomy, skin protection from sun exposure is the other important management strategy, along with supportive care of blistering lesions, including treatment of secondary bacterial infections.

If phlebotomy is poorly tolerated, then hydroxychloroquine (Plaquenil)<sup>1</sup> 100 mg twice weekly is another effective treatment. In a randomized trial, this therapy has been shown to reduce PCT symptoms and plasma porphyrin levels as quickly as phlebotomy (≈6 months).

Patients with HCV infection should be considered for eradication therapy and/or screened for cirrhosis and hepatocellular carcinoma. It is not known whether HCV eradication alone will cause remission in PCT, but certainly it is beneficial to reduce the patient's risk of HCV-related complications such as cirrhosis. HIV infection should be treated and smoking cessation should be pursued. Patients often avoid alcohol because they recognize its deleterious effects, but for those with alcohol use disorder, cutting back on use or abstinence is much more challenging and management should be coordinated with an addiction specialist. Similarly, tobacco cessation is strongly encouraged.

### Erythropoietic Porphyrias

In treatment of erythropoietic porphyrias, where EPP is the more common of these rare diseases, trigger avoidance is the mainstay

of treatment. From a young age, patients can identify the prodrome of an attack during sunlight exposure. Thus, avoidance of sunlight exposure is the primary preventive strategy. It should be noted that UV light exposure still occurs through glass. When necessary, precautions should be made and a physician letter may be necessary to allow window tinting in the patient's car. In addition, exposure from other sources of UV light such as fluorescent lights can cause photosensitivity. For any patient with EPP who is undergoing surgery, particular attention needs to be paid to avoid excess UV exposure from operating room lights. Transparent sunscreens block UV light only and are not effective for prevention of symptoms in EPP. Regular use of protective clothing and hats was the only treatment for EPP until recently. Avoidance of sunlight also frequently leads to vitamin D deficiency.

Afamelanotide (Scenesse) is a synthetic analogue of alpha-melanocyte stimulating hormone. This recently approved drug, the first drug approved for EPP, increases melanin and skin pigmentation, and hence, improves sunlight tolerability. The drug is administered, as a monthly controlled-release implant. Overall, this new therapy is well tolerated and though it improves sunlight tolerability it does not affect the underlying cause.

## SICKLE CELL DISEASE

Method of

Enrico M. Novelli, MD; Mark T. Gladwin, MD; and Lakshmanan Krishnamurti, MD

### CURRENT DIAGNOSIS

- Sickle cell disease (SCD) is diagnosed by neonatal screening in the United States.
- Persons with congenital hemolytic anemia should be tested for SCD by hemoglobin electrophoresis regardless of their ethnic background.
- Infection with parvovirus B19 should be suspected in children presenting with acute anemia and reticulocytopenia.
- Human leukocyte antigen (HLA) class I and II testing should be performed in all patients with SCD and unaffected siblings to identify candidates for hematopoietic stem cell transplant.
- Transcranial Doppler screening for primary prevention of stroke is indicated in children with homozygous SCD.
- Acute chest syndrome is diagnosed in patients presenting with fever, hypoxemia, and a radiographic pulmonary infiltrate.
- Screening for kidney disease should be performed by obtaining a spot urine sample for microalbuminuria
- Screening for iron overload by ferritin, quantitative liver magnetic resonance imaging (MRI), cardiac MRI, or liver biopsy is indicated in all patients who have received more than 10 lifetime transfusions.
- Pulmonary hypertension screening by transthoracic echocardiogram is indicated in all patients with homozygous SCD.

<sup>1</sup>Not FDA-approved for this indication.

## CURRENT THERAPY

- All children with sickle cell disease (SCD) should receive penicillin prophylaxis.
- High fever should be treated empirically with coverage for *Streptococcus pneumoniae* pending results of blood cultures.
- Children with high transcranial Doppler velocity need to be placed on a chronic transfusion regimen to keep the hemoglobin (Hb) S less than 30%.
- Painful vasoocclusive episodes warrant prompt treatment with an individualized intravenous opiate regimen, as well as supportive care and incentive spirometry.
- Preoperative transfusion should aim at a target hemoglobin level of 10 g/dL regardless of the HbS percentage and is indicated in all patients with SCD undergoing major surgery.
- Therapy with hydroxyurea (Droxia, Siklos) is indicated in all patients at all ages with HbSS disease and HbS $\beta$ -thalassemia, and in patients with HbSC with a severe phenotype on a case-by-case basis.
- Erythropoietin-stimulating agents can be used in conjunction with hydroxyurea to prevent or ameliorate reticulocytopenia and in patients with underlying renal insufficiency.
- Iron chelation is indicated in all patients with findings of iron overload.
- Treatment of acute chest syndrome includes parenteral antibiotics to cover atypical microorganisms and transfusion, with exchange transfusion reserved for the most severe cases.
- Patients with pulmonary hypertension should receive optimal hematologic care (maximal hydroxyurea and/or chronic transfusion therapy) and specific therapy for pulmonary hypertension in severe cases, with coordination and referral to a pulmonary hypertension specialist.
- Stem cell transplantation should be offered to all patients who have a matched donor and display a severe phenotype.

## Epidemiology

Sickle cell disease (SCD) affects 70,000 to 100,000 persons in the United States and millions worldwide. The hemoglobin S (HbS) mutation arose in West-Central Africa approximately 7300 years ago and then propagated to vast tropical and subtropical areas due to the selective pressure of malaria infection. It is predominantly found in persons of African, Mediterranean, Arab, or Indian ancestry. In the United States, approximately 1 in 15 African Americans harbors the HbS (sickle hemoglobin) mutation and 1 in 400 is affected by the disease. Most patients with SCD in the United States are homozygous for HbS (SS), with heterozygous HbSC being the second most common abnormality. Conversely, in Mediterranean countries, HbS/ $\beta$ -thalassemia is the most common SCD syndrome, and in the Arab peninsula HbSS in combination with hereditary persistence of fetal hemoglobin (HPFH) is particularly prevalent.

## Pathophysiology

SCD consists of a group of inherited hemoglobinopathies characterized by a qualitatively abnormal hemoglobin molecule that affects the structure and integrity of the red blood cells (RBCs). SCD is an autosomal recessive disease due to homozygosity for HbS, characterized by a single base substitution in the  $\beta$ -globin gene of the hemoglobin tetramer, leading to an amino acid substitution (valine to glutamic acid), or coinheritance of HbS with other abnormal hemoglobins such as hemoglobin C, D, E, and O or  $\beta$ -thalassemia.

HbS is less soluble than normal hemoglobin (HbA) in the deoxygenated state and polymerizes when sickle RBCs are exposed to hypoxic conditions in the microcirculation. In the classic pathophysiologic explanation of SCD, sickled RBCs containing HbS polymers are less deformable and remain trapped in the

microcirculation, causing end-organ ischemia and necrosis. Compounding this mechanism, more recent literature has emphasized the role of cellular adhesion, abnormal cytokine levels, ischemia-reperfusion injury, oxidative damage, sterile inflammation, and an abnormal endothelial milieu (Figures 1 and 2). HbS polymers also lead to deformity and fragility of the RBC membrane, with resulting intravascular and extravascular hemolysis.

Patients with SCD suffer from severe chronic hemolytic anemia and acute episodes of RBC trapping and destruction in the microvasculature (vasoocclusive episodes). Vasoocclusive episodes are the hallmark of SCD and are characterized by more intense episodic vasoocclusion, often with increasing hemolysis, and are due to exogenous or endogenous factors that acutely alter the rheologic properties of the RBCs. The main determinants of RBC sickling and vasoocclusion are hypoxemia, RBC dehydration, RBC concentration, high HbS relative to fetal hemoglobin (HbF), and blood viscosity; these can occur in a multitude of clinical settings. Most common clinical inciting events leading to vasoocclusive episodes are dehydration due to inadequate replacement of fluid losses, thermal changes, surgical stress, exposure to low oxygen tension, infections, and psychological stressors.

Epidemiologic studies indicate that the risk of vasoocclusive episodes and acute chest syndrome is related to high steady-state hemoglobin levels, leukocytosis, and low HbF levels. These findings are consistent with pathogenic mechanisms of altered red cell rheology, higher viscosity, HbS polymerization, and inflammatory cellular adhesion. Interestingly, the epidemiologic risk factors associated with chronic vascular complications such as pulmonary hypertension (PH), cutaneous leg ulceration, priapism, systemic systolic hypertension, renal failure with proteinuria, and possibly stroke are different and include a low steady-state hemoglobin level, increased hemolytic intensity, iron overload, and markers of low nitric oxide (NO) bioavailability. One hypothesis is that SCD is driven by two overlapping but different mechanisms of disease: on one hand, vasoocclusion causes vasoocclusive episodes and acute chest syndrome, and on the other hand, hemolytic anemia leads to endothelial dysfunction and chronic vasculopathy. Both are caused fundamentally by HbS polymerization.

## Prevention

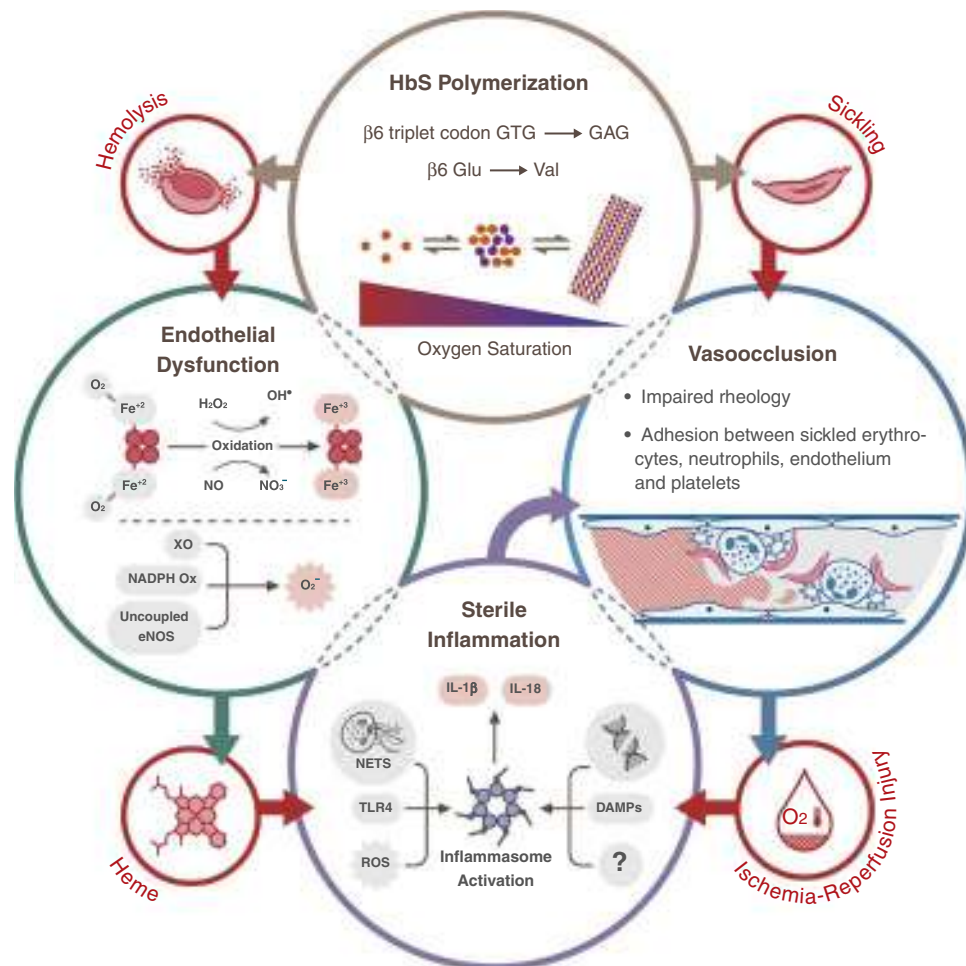

See “Evidence-Based Management of Sickle Cell Disease: Expert Panel Report, 2014” at <http://www.nhlbi.nih.gov/health-pro/guidelines/sickle-cell-disease-guidelines> for detailed, consensus guidelines on prevention and treatment.

## Bacterial Infections

Before the antibiotic era, most patients with SCD succumbed to bacterial sepsis from encapsulated organisms. A landmark multicenter, randomized, double-blind, placebo-controlled clinical trial of prophylaxis with oral penicillin in children with sickle cell anemia published in 1986 showed that bacterial prophylaxis started at birth reduced by approximately 80% the incidence of infection in the penicillin group, as compared with the group given placebo. This study became the foundation for universal screening of SCD. Results of the Penicillin Prophylaxis in Sickle Cell Study II (PROPS 2) trial show that prophylaxis can be safely discontinued at age 5 years as long as there is no history of prior serious pneumococcal infection or surgical splenectomy and in the setting of appropriate comprehensive care. All children should also receive both the 13-valent pneumococcal conjugate (Pneumovax 13) and 23-valent pneumococcal polysaccharide (Pneumovax) vaccines, and adults should receive Pneumovax. Vaccinations for *Haemophilus influenzae* and *Neisseria meningitidis* are also indicated.

## Neurologic Events

Stroke is a devastating complication of SCD and affects predominantly children with HbSS and abnormal transcranial Doppler (TCD) results. Silent cerebral infarcts are magnetic resonance imaging (MRI)-detectable abnormalities that also

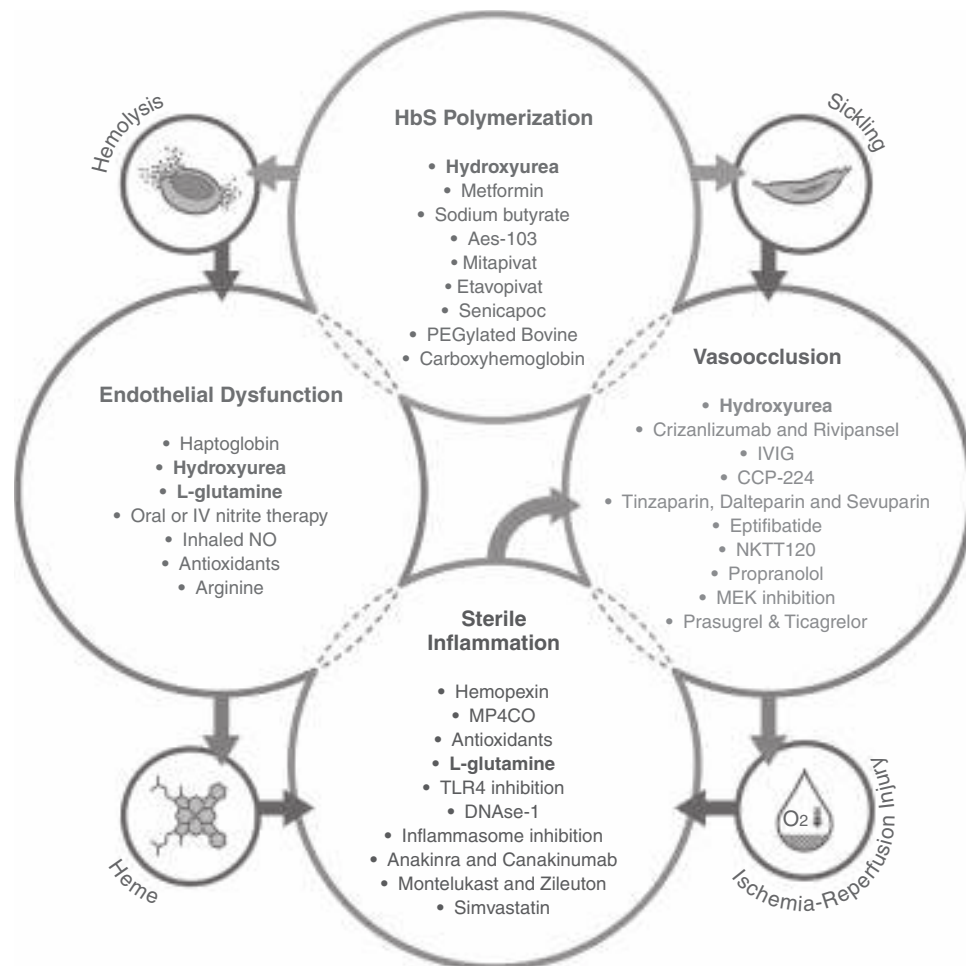

**Figure 1** Molecular pathophysiology of SCD. A mutation in the  $\beta$ -globin gene leads to substitution of valine for glutamic acid at the 6th position in the  $\beta$ -globin chain. Following deoxygenation, the mutated hemoglobin (HbS) molecules polymerize to form bundles (top circle). The polymer bundles result in erythrocyte sickling (clockwise), which results in impaired rheology of the blood and aggregation of sickle erythrocytes with neutrophils, platelets and endothelial cells to promote stasis of blood flow referred to as “vaso-occlusion” (right circle). Vaso-occlusion promotes ischemia-reperfusion (I-R) injury (clockwise). Hb polymer bundles (top circle) also promote hemolysis or lysis of erythrocytes (counter-clockwise) that releases cell free Hb into the circulation. Oxygenated Hb ( $\text{Fe}^{2+}$ ) promotes endothelial dysfunction (left circle) by depleting endothelial nitric oxide (NO) reserves to form nitrate ( $\text{NO}_3^-$ ) and methemoglobin. Alternatively, Hb can also react with  $\text{H}_2\text{O}_2$  through the Fenton reaction to form hydroxyl free radical ( $\text{OH}^\bullet$ ) and methemoglobin ( $\text{Fe}^{3+}$ ). Also, NADPH oxidase (NADPH ox), Xanthine oxidase (XO) and uncoupled endothelial NO synthase (eNOS) generate oxygen free radicals to promote endothelial dysfunction. Methemoglobin ( $\text{Fe}^{3+}$ ) degrades to release cell free heme (counter-clockwise), which is a major eDAMP. Reactive oxygen species (ROS) generation, toll-like-receptor-4 (TLR4) activation, neutrophil extracellular traps (NETs) generation, release of tissue or cell derived DAMPs, DNA and other unknown factors (?) triggered by cell free heme or I-R injury can contribute to sterile inflammation by activating inflammasome pathway in vascular and inflammatory cells to release IL-1 $\beta$  (bottom circle). Finally, sterile inflammation further promotes vaso-occlusion through a feed-back loop by promoting adhesiveness of neutrophils, platelets and endothelial cells. (Reproduced with permission from the Annual Review of Pathology: Mechanisms of Disease, Volume 14 © 2019 by Annual Reviews, <http://www.annualreviews.org>.)

carry a high risk of morbidity, including overt stroke and cognitive impairment. There is conclusive evidence that chronic transfusions are effective in the primary and secondary prevention of both overt and silent strokes in SCD. The first landmark trial (STOP) published in 1995 showed that the first stroke can be prevented by placing children with abnormal TCD on prophylactic monthly transfusions with a target HbS of less than 30%. Transfusions were later found to also have a beneficial effect on reducing the incidence of the recurrence of silent cerebral infarcts, as shown by the SIT trial. The importance of continuing transfusions for more than 30 months was underscored by the STOP 2 trial, where TCD abnormalities recurred and the incidence of silent cerebral infarctions on MRI was higher in the transfusion-halted group. The enthusiasm over the beneficial effects of transfusions was tempered by the concerns about the side effects of long-term, possibly indefinite use of this therapeutic strategy. Therefore there has been an interest in exploring whether hydroxyurea (Droxia, Siklos) could represent an alternative to transfusion in high-risk children. Specifically, the SWiTCH trial explored the hypothesis that

hydroxyurea and phlebotomy could maintain an acceptable stroke recurrence rate and significantly reduce the hepatic iron burden as compared with a prophylactic chronic transfusion regimen. Unfortunately, the trial was terminated early because of a significantly higher stroke recurrence rate in the hydroxyurea arm compared with the transfusion arm, with equivalent hepatic iron burden in both groups. Thus the issue of when, if ever, it is safe to discontinue transfusions for the secondary prevention of stroke is still unknown. Conversely, as shown by the results of the TWiTCH trial, another study halted prematurely by the National Institutes of Health, hydroxyurea is not inferior to chronic transfusions in lowering TCD velocities in children at high risk but without a history of stroke, thereby suggesting that this drug may be equally effective in the primary prevention of neurologic complications.

#### Clinical Manifestations

Multiple genetic and epigenetic factors affect the SCD phenotype. Patients homozygous for HbS (SS) or compound heterozygous for HbS and a nonfunctional  $\beta^0$ -thalassemia allele tend

**Figure 2** FDA approved and experimental therapies targeting the molecular pathobiology of sickle cell disease. The FDA approved drugs are in bold. (Modified from the Annual Review of Pathology: Mechanisms of Disease, Volume 14 © 2019 by Annual Reviews, <http://www.annualreviews.org>.)

**TABLE 1** Severity of the Main Sickle Cell Syndromes

GENOTYPE	CLINICAL SEVERITY	HEMOGLOBIN (G/DL)
HbSS	Usually marked	6–10
HbS- $\beta^0$ -thalassemia	Moderate to marked	6–10
HbS- $\beta^+$ -thalassemia	Mild to moderate	9–12
HbSC	Mild to moderate	10–15
HbSS-HPFH	Mild	

HbSC, Heterozygous phenotype; HbSS, homozygous phenotype; HPFH, hereditary persistence of fetal hemoglobin.

to display the most severe manifestations. On the other end of the spectrum, HPFH, particularly common in Saudi Arabia, or coinheritance of  $\beta$ -thalassemia mitigates the phenotype. Although the net effect of high HbF levels on the phenotype of SCD is beneficial, coinheritance of one or two  $\alpha$ -thalassemia alleles has a more complex effect.  $\alpha$ -Thalassemia is present in approximately 30% of patients with SCD and is associated with higher hemoglobin, lower mean corpuscular volume (MCV), and decreased rate of hemolysis. These effects are protective toward stroke and leg ulcers but lead to increased rates of vasoocclusive episodes, osteonecrosis, and acute chest syndrome because of increased blood viscosity related to the higher hemoglobin level. Patients with HbSC and HbS/ $\beta^+$ -thalassemia have an intermediate severity phenotype (Table 1). Haplotypes

of polymorphic sites in the  $\beta$ -globin gene cluster in chromosome 11 have been associated with different disease severity and rates of complications. Other yet unidentified genetic factors predispose certain patients to develop a particularly severe hemolysis with brisk reticulocytosis and a high rate of specific complications that include leg ulcers, priapism, and PH.

### Hematology

This section describes the main clinical manifestations of SCD in each organ system (Figure 3 and Table 2).

#### Baseline or Steady-State Hematologic Abnormalities

Chronic intravascular and extravascular hemolysis causes a chronic anemia of moderate to severe intensity in HbSS and HbS/ $\beta^0$ -thalassemia, with a hemoglobin range of 6 to 9 g/dL. In HbSC and HbS/ $\beta^+$ -thalassemia, the anemia may be mild or absent. The anemia of SCD is usually normocytic in HbSS, with anisocytosis and poikilocytosis and a population of small dehydrated dense cells, irreversibly sickled cells, numerous reticulocytes, and schistocytes. Reticulocytosis is common but not compensatory, and nucleated RBCs are seen in acute exacerbations of the anemia such as in splenic or hepatic sequestration. Baseline leukocytosis with neutrophilia is also common and is a poor prognostic sign associated with acute chest syndrome in adults and frequent vasoocclusive episodes in children. Preclinical studies have shown that leukocytes are not simply a marker of disease activity and acute phase but also have a direct pathogenic role in cellular adhesion and vasoocclusion. The platelet count is commonly elevated in SCD, particularly in patients who are autosplenectomized as a result of

**Figure 3** Acute and chronic complications of sickle cell disease.

**TABLE 2** Landmark Randomized Clinical Trials in Sickle Cell Disease

YEAR OF PUBLICATION	TITLE	MAIN FINDINGS
1986	Prophylaxis with oral penicillin in children with sickle cell anemia: A randomized trial	84% reduction in incidence of infection and no deaths from pneumococcal septicemia in the penicillin group
1995	Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH)	Reduced incidence of painful crises, ACS, and transfusion in the hydroxyurea group Survival benefit in follow-up study
1995	Preoperative Transfusion in Sickle Cell Disease Study	A conservative transfusion regimen was as effective as an aggressive regimen in preventing perioperative complications in patients with sickle cell anemia
1996	Multicenter investigation of bone marrow transplantation for sickle cell disease	HCT is safe in SCD with survival and event-free survival at 4 years of 91% and 73% and can lead to cure
1998	Stroke Prevention Trial in Sickle Cell Anemia (STOP)	Transfusion reduces the risk of a first stroke by 92% in children with sickle cell anemia who have abnormal results on transcranial Doppler ultrasonography
2005	Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP 2)	Discontinuation of transfusion for the prevention of stroke in children with sickle cell disease results in a high rate of reversion to abnormal blood-flow velocities on Doppler studies and stroke
2009	Improving the Results of Bone Marrow Transplantation for Patients with Severe Congenital Anemias	Nine of 10 adults who received nonmyeloablative allogeneic hematopoietic stem cell transplantation for severe sickle cell disease achieved stable, mixed donor–recipient chimerism and reversal of the sickle cell phenotype, without acute or chronic GVHD.
2011	Pediatric Hydroxyurea Phase III Clinical Trial (BABY HUG)	Children ages 9–18 months randomized to receive hydroxyurea irrespective of disease severity for 2 y had decreased pain episodes, dactylitis, ACS, hospitalization, leukocyte count, and transfusion and increased hemoglobin as compared with children receiving placebo.
2014	Silent Infarct Trial (SIT)	Children with silent cerebral infarcts and normal TCD velocity who were randomized to chronic transfusion therapy had a 58% relative risk reduction in the recurrence of silent cerebral infarct or stroke as compared to those in the observation arm.
2017	Sustain Study	Crizanlizumab, a monoclonal antibody that targets P-selectin, reduced the rate of VOE to a median/year of 1.63 compared to 2.98 with placebo and increased the median time to the first and second crisis.
2019	Realizing Effectiveness Across Continents With Hydroxyurea (REACH)	Children 1 to 10 years of age with sickle cell anemia in four sub-Saharan countries had lower rates of vaso-occlusive pain, malaria, transfusion and death on hydroxyurea (Tshilolo, 2019).

ACS, Acute chest syndrome; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; SCD, sickle cell disease; TCD, transcranial Doppler; VOE, vasoocclusive crisis.

repeated splenic infarction, and platelet activation is increased. In the subset of patients with HbSC and HbS/β<sup>+</sup>-thalassemia who retain a functional spleen and develop splenomegaly, features of hypersplenism may instead be observed with resulting mild pancytopenia.

#### **Hematologic Indices During Vasoocclusive Episodes**

In acute vasoocclusive episodes the total Hb decreases as a result of hemolysis (by 1.6 g/dL in acute chest syndrome). The lactate dehydrogenase (LDH), reticulocyte count, and other markers of hemolysis such as aspartate transaminase (AST) and indirect

bilirubin are elevated in steady state, and in many—but not all—patients are further increased during vasoocclusive episodes. Haptoglobin levels are chronically depressed in SCD and typically not measurable, even in steady state, in patients with HbS homozygosity. In patients with HbSC, vasoocclusive episodes may be due to increased blood viscosity and RBC sickling, and worsening hemolysis might not be readily appreciated.

Splenic sequestration crises occur mostly in childhood and are characterized by anemia disproportionate to the degree of hemolysis, reticulocytosis, and acute splenomegaly. Splenic sequestration and repeated episodes of splenic infarction eventually lead to autosplenectomy, although some patients develop splenomegaly. Splenic infarction usually manifests with left upper-quadrant pain and may be massive, involving more than 50% of the splenic tissue.

In severe vasoocclusive episodes, massive bone marrow infarction can also occur. In these instances, the peripheral blood smear reveals a leukoerythroblastic picture with immature neutrophilic forms, nucleated RBCs, and teardrop cells. Fat emboli syndrome, a life-threatening complication of vasoocclusive episodes, can then develop as bone marrow fat embolizes to peripheral capillary beds, leading to multiorgan failure.

#### **Red Blood Cell Alloimmunization**

RBC alloimmunization is a common complication of transfusional therapy in SCD and occurs in approximately 30% of patients. It is primarily due to the disparate expression of RBC antigens in African Americans as compared with the donor pool, which is mostly composed of whites. Alloimmunization complicates RBC matching and leads to delayed hemolytic transfusion reactions. Alloantigens that become undetectable by indirect Coombs test 2 months after exposure to mismatched blood have the potential to result in future false-negative cross-matching results. A subset of heavily alloimmunized patients with SCD undergoes life-threatening hemolytic reactions upon exposure to mismatched RBC units. In these hyperhemolytic crises, there is intense hemolysis of transfused and non-transfused RBCs and acute anemia. Treatment of hyperhemolytic crises is empirical and includes erythropoietin-stimulating agents (ESAs), parenteral steroids, and intravenous immunoglobulins (Gammagard).<sup>1</sup>

#### **Iron Overload**

Hemosiderosis is the other major complication of transfusional therapy in SCD and is characterized by iron deposition in the heart, liver, and endocrine glands, leading to organ failure and significant morbidity and mortality. It commonly occurs in patients who have received more than 10 lifetime transfusions or more than 20 packed RBC units. Liver biopsy is the “gold standard” for diagnosis, but it is an invasive and uncomfortable procedure. Hepatic and myocardial iron quantitation by MRI is supplanting liver biopsy as the preferred test to diagnose iron overload and monitor therapy with iron chelators, although when this is not available diagnosis often rests on the finding of an elevated ferritin and transferrin saturation in the appropriate clinical setting.

#### **Hemostatic Activation and Thrombosis**

Numerous studies have shown that arterial and venous thrombosis are common in SCD and include pulmonary embolism, in situ pulmonary thrombosis, and stroke. In SCD, alterations at all levels of the hemostatic system have been described: patients with SCD exhibit increased basal and stimulated platelet activation, increased markers of thrombin generation and fibrinolysis, increased tissue factor activity, and increased von Willebrand factor (vWF) antigen and thrombogenic ultralarge vWF multimers with depressed ADAMTS13 activity. Interestingly, hemostatic activation is amplified during vasoocclusive episodes, as shown by increases in multiple markers of thrombosis as compared with steady state, suggesting a link between hemolysis and thrombosis.

#### **Neurology**

Ischemic stroke is common in SCD, with the highest incidence between 2 and 5 years of age. Patients may develop overt stroke from large vessel occlusion (5% to 8% of patients with HbSS) or silent infarcts from focal ischemia detectable by MRI without symptoms of acute stroke (20% to 35% of patients with HbSS). The pathophysiology of stroke in SCD is unclear, although genetic factors and an imbalance between oxygen demand and supply have been postulated. Multiple epidemiologic studies have shown that the risk factors for ischemic stroke in adult patients include HbSS genotype, severity of anemia, systolic hypertension, male gender, and increasing age. Patients with repeated strokes are at risk for development of anatomic abnormalities and Moyamoya pattern of vascularization, which predisposes to both ischemic and hemorrhagic stroke later in life. The highest incidence of intracerebral hemorrhages occurs in patients older than 20 years.

Both overt and silent strokes have a negative impact on IQ and cause cognitive impairment measurable by psychometric testing. Children and adults with SCD can develop cognitive impairment and subtle signs of accelerated brain aging and vascular dementia even in the absence of focal ischemia by MRI, with a low hematocrit being a predictor of neuropsychological dysfunction. These abnormalities are probably due to chronic and diffuse, as opposed to focal, cerebral anoxia and may be unmasked by psychometric testing.

#### **Ophthalmology**

Retinal abnormalities are common in SCD and are often asymptomatic until the occurrence of ophthalmologic emergencies. Retinal disease is due to arteriolar occlusion, with subsequent vascular proliferation, neovascularization, retinal hemorrhage (stage IV), and detachment (stage V). Patients with HbSC are more prone to retinal complications, possibly as a result of increased blood viscosity.

#### **Nephrology**

Renal abnormalities are common in SCD and manifest primarily as hematuria, proteinuria, and renal tubular acidosis. Hematuria is usually due to papillary necrosis and is an acute finding that requires supportive care and carries a good prognosis. Rarely, gross hematuria requires urologic consultation. Tubular functional defects include an inability to concentrate the urine (hyposthenuria) and renal tubular acidosis. Hyposthenuria often manifests with enuresis in childhood, and it is clinically relevant because it predisposes patients to an increased risk of dehydration. Renal tubular acidosis similar to type IV renal tubular acidosis is a common finding in SCD and may lead to hyperkalemia, an important consideration in patients already predisposed to hyperkalemia with intravascular hemolysis and whenever therapy with angiotensin-converting enzyme inhibitors is entertained.

Hyperphosphatemia and hyperuricemia are also often observed in SCD. Microalbuminuria may be detected in early adulthood and tends to progress to nephrotic range proteinuria. Focal segmental glomerulosclerosis is the most common glomerular abnormality and it is probably due to glomerular sickling and infarction. There are currently no approved therapies to prevent progression to end-stage renal disease, which occurs in up to 20% of patients and at a median age of 37 years. Renal replacement therapy is often needed in older adults with SCD. Serum creatinine and 24-hour creatinine clearance are not adequate for screening and monitoring of progression of kidney disease, because tubular secretion of creatinine is preserved and glomerular hyperfiltration is common in SCD, leading to a relatively low creatinine and a high glomerular filtration rate even in patients with underlying kidney impairment. Testing for microalbuminuria, plasma cystatin C levels, and hemoglobinuria may instead be used as screening tools for chronic kidney disease.

#### **Leg Ulcers**

Leg ulcers occur in 10% to 20% of patients with HbSS and have been associated with a chronically high hemolytic rate. They are

<sup>1</sup>Not FDA approved for this indication.

usually located over the malleolar areas and are exquisitely painful, debilitating, disfiguring, and nonhealing. Vascular and plastic surgery consultations are recommended and aim at excluding local vascular problems that can complicate management of the ulcers and at providing prompt débridement and skin grafting. Although hydroxyurea is associated with development of leg ulcers in patients with myeloproliferative disorders, there is no such link with leg ulcers in SCD. Although wound healing may be impaired with hydroxyurea use, patients who develop an increase in fetal hemoglobin and have reduced sickling as a result of hydroxyurea therapy might have a net benefit in terms of tissue oxygenation and perfusion. Transfusional therapy, including exchange transfusional therapy, topical nitrates<sup>1</sup>, and nutritional zinc<sup>7</sup> or L-arginine<sup>7</sup> supplementation, have shown benefit in anecdotal reports, but the evidence is inconclusive.

### Gastroenterology

Nausea, vomiting, and dyspepsia in SCD are related to delayed gastric emptying and gastrointestinal motility disorders, autonomic neuropathy, or medical therapy. Opiates are often responsible for acute nausea and vomiting, whereas other medications such as hydroxyurea and deferasirox (Exjade) are occasionally responsible for chronic symptoms. Gastroparesis may be due to damage of the microvasculature of autonomic nerves (vasa vasorum) from repeated episodes of sickling.

The liver may be episodically affected by hepatic sequestration crises, heralded by direct hyperbilirubinemia, right upper quadrant pain from distention of the hepatic capsule, acute anemia, and reticulocytosis or by sinusoidal vasoocclusion leading to severe episodes of intrahepatic cholestasis. Supportive therapy and transfusions are indicated for hepatic vasoocclusive complications. Exchange transfusion may be the preferred modality for hepatic sequestration with the goal of preventing erythrocytosis once the pooled RBCs are released back into the circulation. Elevation of liver injury tests may be drug induced (hydroxyurea, deferasirox) but also related to hepatic sickling, particularly if it occurs during a vasoocclusive episode.

### Infectious Disease

Patients homozygous for HbSS develop functional asplenia during childhood. This is due to repeated episodes of splenic infarction leading to fibrosis and autosplenectomy. As a result, children are susceptible to overwhelming bacterial sepsis from encapsulated organisms such as *Streptococcus pneumoniae*, *H. influenzae*, and *N. meningitidis*. High pediatric mortality from sepsis was therefore common before a landmark study published in 1986 demonstrated the benefit of penicillin prophylaxis instituted at birth. Vaccination for encapsulated organisms is also standard of care in children and adults. In spite of preventive measures, the incidence of life-threatening bacterial infections is increased in SCD, and high fever should be treated empirically as in splenectomized patients, with coverage for penicillin-resistant *S. pneumoniae* pending blood culture results. Patients with indwelling venous catheters are at risk of catheter-related bacteremia.

Viral infections with bone marrow-tropic viruses such as Epstein-Barr virus, cytomegalovirus, and predominantly parvovirus B19 place patients at risk for myelosuppression, which can further worsen chronic anemia. In children, infections with parvovirus B19 are responsible for transient red cell aplasia and severe aplastic crises, characterized by acute anemia and reticulocytopenia due to intramarrow destruction of erythroid precursors. Treatment of these episodes includes transfusion and intravenous immunoglobulins<sup>1</sup>, besides supportive measures.

Individuals with SCD are known to be particularly vulnerable to H1N1 influenza, which has raised concerns about the outcomes of SARS-CoV-2 infection and COVID-19 in SCD. Epidemiological data show that African Americans have been disproportionately

affected during the COVID-19 pandemic, but large studies on the outcomes of COVID-19 in SCD have not yet been published.

### Pulmonology

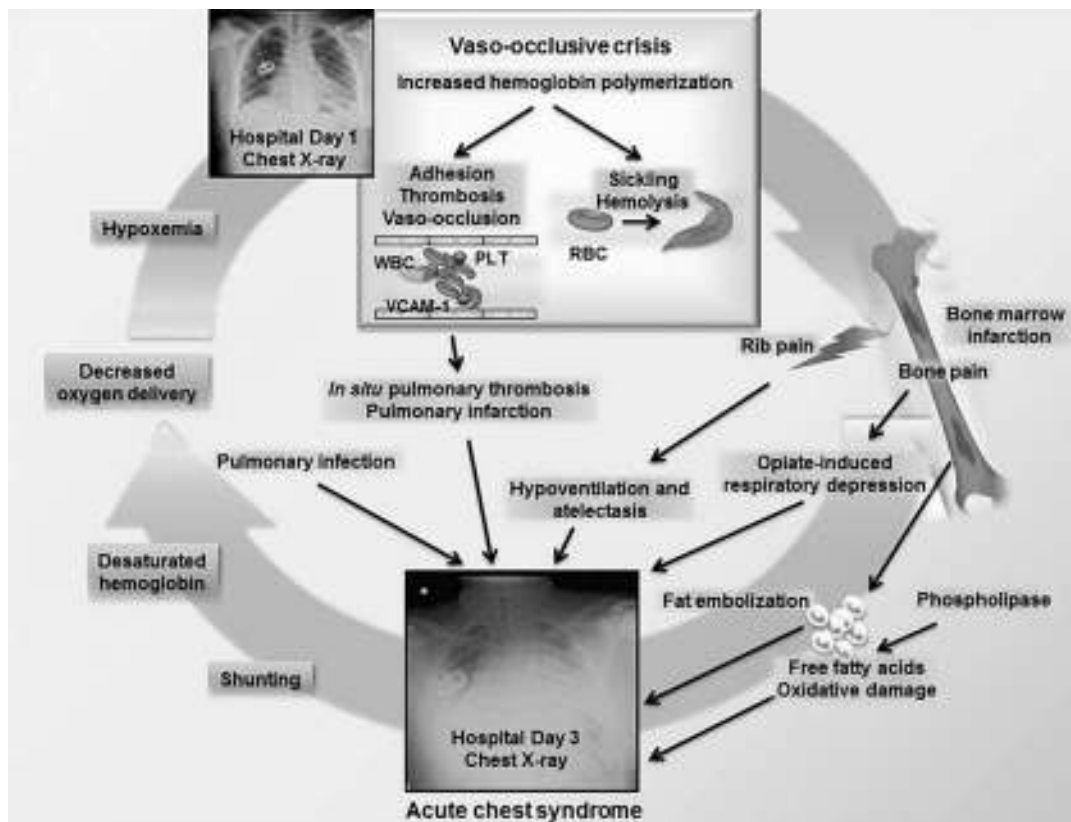

A subset of patients with vasoocclusive episodes develop acute chest syndrome, the major pulmonary complication of SCD. Acute chest syndrome is a lung injury syndrome defined by fever, pleuritic chest pain, oxygen desaturation, and multilobar radiographic infiltrates associated with severe vasoocclusive episodes, infection, and bone marrow fat embolization (Figure 4). It usually develops 2 to 3 days after hospitalization for vasoocclusive episodes and is often misdiagnosed as nosocomial pneumonia or aspiration pneumonia, particularly because it displays a predilection for the lower lobe of the lungs. Although pneumonia often accompanies acute chest syndrome, proper diagnosis is important because acute chest syndrome warrants simple or exchange transfusion in addition to antibiotic therapy and supportive measures. Common infectious pathogens identified in cases of acute chest syndrome include *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella pneumophila*, thus dictating inclusion of a macrolide in the antibiotic cocktail. Pulmonary embolism with resulting infarct is also in the differential diagnosis of acute chest syndrome and may occur concurrently in 17% of patients. If not recognized and treated promptly, acute chest syndrome leads to pulmonary failure and carries a high mortality.

Airway hyperreactivity is common in children with SCD and needs to be actively diagnosed and aggressively treated because it is associated with worse SCD outcomes. Children with chronic respiratory symptoms should be tested for bronchial hyperresponsiveness.

Chronic complications of SCD include pulmonary fibrosis and PH. PH is an emergent complication of SCD and is associated with a high morbidity and mortality. Multiple epidemiologic studies have shown that a high baseline hemolysis rate, low hemoglobin, increasing age, a history of leg ulcers, liver dysfunction, iron overload, and kidney failure are risk factors for the development of PH. Three epidemiologic studies and a randomized clinical trial have shown that an elevated tricuspid regurgitant jet velocity (TRV) measured by Doppler echocardiography is a common occurrence in SCD with 30% of the patients having a TRV of 2.5 m/s (2 standard deviations [SDs] above the normal mean) or higher, and 10% of the patients having a TRV of 3.0 m/s (3 SDs above the normal mean) or higher. These have proven to be valuable cutoff values, as a TRV of less than 2.5 m/s, when combined with an N-terminal pro B-type natriuretic peptide (NT-proBNP) value less than 160 has a high negative predictive value for PH. A TRV of 3.0 m/s or higher confers a positive predictive value for having PH by right heart catheterization (RHC) of 60% to 75% and a relative risk for death of 10.6. Controversy exists on the significance of an intermediate TRV value of 2.5 to 2.9 m/s, because it is unclear how accurately it predicts RHC-diagnosed PH. In three subsequent studies, patients with intermediate or high TRV values had a prevalence of PH by RHC ranging from 25% to 65% depending on what specific cutoff value was used as the criteria to perform an RHC (2.5 vs. 2.8) and on whether patients with evidence of end-organ damage were included or excluded. However, it is worrisome that regardless of the prevalence of PH, patients with an intermediate TRV are as a whole at increased risk of death (relative risk 4.4). One screening approach is to consider RHC in all patients with TRV of 3.0 or higher and in patients with intermediate TRV values of 2.5 to 2.9 m/s if the NT-proBNP is greater than 160 pg/mL or the 6-minute walk is less than 333 m or there is a high clinical pretest probability of having PH (mosaic perfusion pattern on computed tomography [CT] scan, low diffusing capacity of the lung for carbon monoxide (DLCO), significant dyspnea on exertion, etc.). It is likely that intermediate TRV values will need to be combined with other measures of right ventricular function and functional capacity such as NT-proBNP, and 6-minute walk to derive a highly predictive composite biomarker of PH. All studies have been concordant on the high risk of death conferred by PH in SCD whether

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

**Figure 4** Vicious cycle of acute chest syndrome (ACS). Vasoocclusive crises are characterized by increased intraerythrocytic polymerization of deoxygenated hemoglobin S, leading to red blood cell sickling, cellular hyperadhesion, hemolysis, and vasoocclusion in the microvasculature. These processes are responsible for acute pain (pain crisis) and bone marrow necrosis. ACS typically occurs in a subset of patients 2 to 3 days after hospitalization for a vasoocclusive episode, and radiographically may present as new multilobar, basilar infiltrates on a chest x-ray. Fat embolization from the necrotic marrow is a recognized cause of ACS and is diagnosed by identifying lipid-laden macrophages in the bronchoalveolar lavage. However, pulmonary infection is the most common trigger of ACS and may be superimposed over existing pulmonary infarction. Hypoventilation and molecular pathogens such as reactive oxygen species from ischemia-reperfusion injury and by-products of hemolysis may also play a role in inducing or exacerbating lung injury. Finally, in situ pulmonary thrombosis has been frequently identified as a comorbid condition in patients with ACS and may be caused by endothelial and hemostatic activation. As a result of lung injury, ventilation-perfusion mismatches and shunting ensues, with subsequent hemoglobin desaturation and hypoxemia. Tissue hypoxia in turn triggers further hemoglobin S polymerization and sickling in a vicious cycle.

measured by echocardiography, NT-proBNP, or RHC. Noninvasive transthoracic Doppler echocardiography is recommended by the American Thoracic Society as a screening test in homozygous SCD due to its safety, low cost, and availability. However, the definitive diagnosis of PH requires a confirmatory RHC.

RHC studies of patients with SCD and PH reveal a hyperdynamic state similar to the hemodynamics characteristic of portopulmonary hypertension. It is increasingly clear that pulmonary pressures rise acutely in vasoocclusive episodes and even more during acute chest syndrome. This suggests that acute PH and right heart dysfunction represent a major comorbidity during acute chest syndrome, and right heart failure should be considered in patients presenting with acute chest syndrome.

### Cardiology

Similar to other conditions with chronic anemia, SCD is associated with a hyperdynamic state, low peripheral vascular resistance, and normal blood pressure or hypotension. In this setting, even mild elevation of the blood pressure can indicate relative hypertension and represent a risk factor for stroke. Because there are no studies on the treatment of hypertension in SCD, general guidelines on antihypertensive therapy are applied.

Coronary artery disease is rarely observed in SCD, although many patients complain of chest pain during vasoocclusive episodes. In these instances, the usual work-up for acute coronary syndrome is recommended. It is possible that myocardial microvascular occlusions are the predominant ischemic event in SCD.

Left-sided heart disease in SCD is primarily due to diastolic dysfunction (present in approximately 13% of patients), although

systolic dysfunction and mitral or aortic valvular disease (2% of patients) can also occur. The presence of diastolic dysfunction alone in SCD patients is an independent risk factor for mortality. Patients with both pulmonary vascular disease and echocardiographic evidence of diastolic dysfunction are at a particularly high risk for death (odds ratio, 12.0; 95% confidence interval [CI], 3.8 to 38.1;  $P < .001$ ).

Cardiac dysfunction is a late complication and the major cause of death in patients with iron overload. Heart failure and conduction defects are the most common abnormalities and warrant emergent iron chelation treatment. Among the iron chelators, deferoxime (Ferriprox) appears to be particularly apt at reducing cardiac iron content. Chelators may be used in combination for cases of severe cardiac decompensation from hemosiderosis.

Methadone (Dolophine) is associated with a risk of QTc prolongation, which carries a risk of arrhythmias and sudden death, particularly in the setting of PH and iron overload. Frequent electrocardiographic (ECG) monitoring, as well as dosage reduction or discontinuation, are warranted in this group, particularly if the QTc is greater than 500 ms.

### Endocrinology

Iron overload is a common cause of endocrinopathy in SCD and thalassemia, with the hypophysis, gonads, and thyroid glands being particularly affected. Patients with iron overload should therefore undergo screening for endocrine dysfunction as it is mandated in thalassemia.

However, patients with SCD are at risk for specific endocrine problems regardless of their iron status. Delayed growth

and puberty are relatively common, presenting in females with delayed age of menarche by 2 to 3 years and in males with small testicular size and hypospermia. Likely pathogenic factors include increased catabolism, chronic hypoxemia, hospitalizations with prolonged immobility, ischemic insults during vasoocclusive episodes, and chronic use of opiates.

### Priapism

Priapism is the most common urogenital complication in patients with the HbSS genotype. It is a sustained, painful erection in the absence of sexual stimulation from occlusion of the penile blood return. It is defined as stuttering if it lasts from minutes to less than 3 hours and as prolonged if it lasts more than 3 hours. The latter is considered a urologic emergency because of the risk of permanent fibrosis and impotence and requires a urologic consultation. Pseudoephedrine (Sudafed)<sup>1</sup> may lead to detumescence in nonemergency settings, whereas aspiration of the corpus cavernosum is required in the emergency setting and is performed under conscious sedation and local anesthesia. This is usually accompanied by installation of epinephrine. Other supportive measures, such as intravenous fluids and parenteral opiates, are usually indicated.

Penile shunts are used as a last resort to prevent further episodes of priapism by increasing the cavernous blood flow using native vessels or by creating an arteriovenous shunt. They invariably result in erectile dysfunction, which can be ameliorated by implantation of an inflatable penile prosthesis. There are data showing that sildenafil (Viagra)<sup>1</sup> therapy can prevent priapism by altering vascular smooth muscle tone through inhibition of phosphodiesterase 2 activity.

### Diagnosis

The diagnosis of SCD rests on the hemoglobin electrophoresis or high-performance liquid chromatography (HPLC), which allows detection of most hemoglobin variants. In patients with microcytosis  $\alpha$ -globin gene sequencing may reveal coinheritance of an  $\alpha$ -thalassemia trait.

<sup>1</sup>Not FDA approved for this indication.

### Neonatal Screening

Children with SCD have an increased susceptibility to bacteremia due to *S. pneumoniae*, which can occur as early as 4 months of age and carries a case fatality rate as high as 30%. Acute splenic sequestration crises also contribute to mortality in infancy. Diagnosis by newborn screening and immediate entry into programs of comprehensive care, including the provision of effective pneumococcal prophylaxis, can reach infants who might otherwise be lost to the healthcare system and has been demonstrated to decrease morbidity and improve survival. Currently, newborn screening and follow-up of SCD are carried out in all 50 states in the United States, as well as in most developed countries, and initiatives are under way to introduce universal newborn screening in most sub-Saharan African countries.

### Late Diagnoses and Misdiagnoses

Rarely, patients who were born before the adoption of universal screening or who were lost at the time of follow-up of positive neonatal screening results are only diagnosed late in life. This occasionally occurs in patients with HbSC who might have normal hemoglobin and hematocrit and a mild disease phenotype. Alternatively, the disease may be misdiagnosed as iron deficiency in patients with HbS/ $\beta^+$ -thalassemia on account of their microcytosis, which places them at risk of futile and potentially harmful prolonged trials of iron supplementation. Patients who have a low HbS level (< 40%) due to recent transfusion or who have only mildly decreased hemoglobin (HbSC or HbS/ $\beta^+$ -thalassemia) may receive an erroneous diagnosis of sickle cell trait (carrier state).

### Treatment

From the original description of SCD in 1910 to the 1970s, there was no efficacious therapy for SCD, and most patients died within the first 2 decades of life, with infectious complications being responsible for the majority of pediatric fatalities. Several preventive and pharmacologic milestones since then, and the realization that care has to occur in a multidisciplinary setting, have profoundly affected the natural history of the disease (Table 3). Median age at death in resource-rich countries was 42 years in male patients and 48 years in female patients

**TABLE 3** Manifestations of Sickle Cell Disease With Key Prevention and Treatment Strategies

MANIFESTATION	PREVENTION	TREATMENT
Pneumococcal sepsis	Penicillin, Pevnar/Pneumovax vaccination	Antibiotic therapy for penicillin-resistant <i>Streptococcus pneumoniae</i>
Splenic or liver sequestration	—	Exchange transfusion
Painful vasoocclusive episode	Hydroxyurea (Droxia), prevention of exposure to triggers	Intravenous fluids, parenteral opiates, supplemental oxygen
Acute chest syndrome	Incentive spirometry during VOE, hydroxyurea	Transfusion, broad-spectrum antibiotics with atypical coverage
Iron overload	Optimization of transfusion therapy	Iron chelation with deferasirox (Exjade) or deferoxamine (Desferal)
RBC alloimmunization	Transfusion with leukoreduced RBCs	—
CVA	Chronic transfusion in children with high transcranial Doppler velocity	Exchange transfusion and thrombolytics in selected cases
Pulmonary hypertension	Hydroxyurea?, treatment of predisposing conditions such as obstructive sleep apnea, hypoxemia, thromboembolism	Hydroxyurea, chronic transfusion therapy, specific therapy
Kidney disease	Antihypertensive therapy?, hydroxyurea?, ACE inhibitors?	ACE inhibitors?, renal replacement therapy, kidney transplant
Priapism	Hydroxyurea?	Pseudoephedrine (Sudafed) <sup>1</sup> , aspiration of corpus cavernosum, sildenafil (Viagra) <sup>1</sup>
Leg ulcers	Hydroxyurea?, topical sodium nitrite?, voxelotor?	Surgical débridement, surgical grafting

ACE, Angiotensin-converting enzyme; CVA, cerebrovascular accident; RBCs, red blood cells; TCD, transcranial Doppler; VOE, vasoocclusive episode (crisis).

<sup>1</sup>Not FDA approved for this indication.

with HbSS, according to data from the Cooperative Study of Sickle Cell Disease in the 1980s (a prehydroxyurea setting), thereby still lagging approximately 2 to 3 decades behind that of the general African-American population. The following sections summarize the therapeutic approach to the most important complications of SCD.

### Vasoocclusive Episodes

Acute pain from vasoocclusive episodes in SCD is extremely intense, affects both children and adults, and is due to ischemia or necrosis of the vascular beds. Most patients report severe pain in the bones and joints of the extremities, as well as lower back, although acute ischemia and pain can affect unusual sites such as the mandibular area. Infants and young children may experience dactylitis, a painful swelling of the hands from bone marrow infarct in the small bones of the digits. Occasionally, adults may also experience the typical signs of inflammation, such as edema, warmth, and erythema in an affected limb, but a paucity or absence of signs is the norm. Imaging studies such as MRI, positron emission tomography (PET), and bone scan can reveal signs of acute bone marrow infarction in a painful bony area, but they are not routinely used in the work-up of a pain episode, unless osteomyelitis or septic arthritis are suspected.

Intravenous opiates are the mainstay of treatment of a pain episode. Even in opiate-naïve patients with SCD, opioid dosages often exceed those required for other indications. For instance, doses of intravenous hydromorphone (Dilaudid) of 1 to 2 mg are typical in adult patients. However, most patients, are on an oral pain regimen at home and have a history of multiple admissions for vasoocclusive episodes. In these cases, individualized care based on prior effective regimens and the patient's own perception of the intensity of pain are recommended. After an attempt at controlling the pain with three or four closely spaced opiate boluses is made, patients who are in persistent discomfort or have evidence of underlying complications triggering the vasoocclusive episode should be admitted and ideally placed on patient controlled analgesia. Nonsteroidal antiinflammatory drugs such as ketorolac (Toradol) have fallen out of favor due to their risks in patients with renal disease and their questionable efficacy. The American Pain Society and the National Heart, Lung and Blood Institute (NHLBI) have published guidelines for the treatment of acute and chronic pain in SCD, followed by other institutions in the past decade.

Common obstacles to prompt and effective care in SCD are the health professional's fear of overdosing the patient, as well as misconceptions about addiction and pseudoaddiction. In general, healthcare professionals tend to overestimate the prevalence of opioid use disorder in SCD and tend to undertreat patients significantly, leading to patients' frustration and anger when their pain demands are not met (pseudoaddiction).

Nonpharmacologic therapies such as biofeedback, relaxation, and localized heat may be effective and should be incorporated into the management of pain episodes whenever possible. Care for vasoocclusive episodes should also include management of possible precipitating factors: dehydration and hypovolemia should be corrected with hypotonic crystalloids, and an infection work-up should be initiated in patients with fever, hypoxemia, or leukocytosis above baseline. Antiemetics and antipruritus therapy are also usually required.

Prior experiences in multiple institutions have shown that a dedicated facility for effective and rapid management of uncomplicated vasoocclusive episodes reduces hospitalizations and length of stay and facilitates integration of care—psychological, socioeconomic, and nutritional—in a multidisciplinary approach. This experience is the basis of the concept of the day hospital in SCD and relies on the need to provide prompt assessment and treatment of pain, safe dose titration to relief, monitoring of adverse effects, and adequate disposition (emergency department, inpatient admission, home) in a clinical environment familiar with SCD and the individual patient.

### Chronic Pain

Chronic pain is common, and a study using pain diaries compiled by patients shows that most patients with SCD experience pain on an almost daily basis (PiSCES study). Orthopedic problems such as avascular necrosis (AVN) are common and tend to develop early in patients with HbSS disease, thus exposing patients to a lifetime of pain. There is an increasing realization that central sensitization and opiate-induced hyperalgesia also play a significant role in chronic pain in SCD. Unfortunately, there is a dearth of safe and effective strategies to manage chronic pain in SCD. At times, short-acting and long-acting opiates are required to empower the patient to manage pain at home and minimize use of the emergency department. Drugs for neuropathic pain, such as gabapentin (Neurontin)<sup>1</sup>, may also be used in combination with opiates because neuropathic pain may develop as a result of tissue ischemia and necrosis.

Patients who have successfully transitioned from pediatric to adult care, have a good support system, and are distracted by their work or school schedules tend to cope better and require less pharmacologic support.

Because analgesic care is life-long, consultation with pain specialists is often valuable, particularly in patients for whom more-sophisticated pain regimens are needed. For instance, the mu-opioid receptor partial agonist buprenorphine (Buprenex, Butrans), opioid rotation, and methadone used as analgesic can help to reduce the total opiate requirements. Several States in the United States have approved the use of marijuana for medical purposes for several conditions including SCD. Although controlled studies on the benefits and risks of medical marijuana in SCD are lacking, studies in sickle mice and anecdotal reports hold promise. Urine toxicology screens and written "opiate agreements" are indicated in patients receiving opiates to ensure adherence with the therapy and to minimize the risk of use of illicit substances, particularly at a time of heightened surveillance for opiate abuse in the United States. The ASH guidelines published in 2020 emphasized an individualized approach in the management of chronic pain in SCD due to the lack of extensive evidence on the benefits of opioids for chronic pain in this population. In addition, they recommended "against the initiation of chronic opiate therapy unless pain is refractory to multiple other treatment modalities" in children and adults with chronic pain from SCD. All recommendations on opioids for chronic pain were "conditional" based on very low certainty in the evidence about effects, and reflect a more guarded stance on opioids due to the deeper appreciation of the risks of chronic opioids for noncancer pain that has emerged in the past few years.

### Transfusional Therapy

In SCD, the benefits of transfusion in terms of improved hemodynamics and oxygenation need to be balanced with the risks of iron overload, alloimmunization, transfusion reactions, and viral transmission of infectious agents. Leuko-reduced, sickle-negative RBCs with extended phenotypic matching for Rh Cc, Ee, and Kell, which account for 80% of detected antibodies, are required. By using extended phenotypic matching, the rate of alloimmunization decreased from 3% to 0.5% per unit, and the rate of delayed hemolytic transfusion reactions decreased by 90% in the STOP study. In previously immunized patients, a full RBC match also inclusive of matching for the Duffy, Kidd, and S antigens is recommended. Indications for transfusion include hemoglobin less than 5 g/dL or less than 6 g/dL with symptoms and any severe complication such as stroke, aplastic anemia, splenic or hepatic sequestration, or acute chest syndrome.

Prophylactic transfusions have been considered standard of care before surgery (with the exclusion of minor procedures such as intravenous port placement); the benefit of preoperative transfusions in preventing SCD-related complications in HbSS patients has also been confirmed in a small randomized clinical trial (the TAPS study).

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** Indications for Transfusion**No Indication**

Chronic steady-state anemia  
 Uncomplicated painful episode  
 Infections  
 Minor surgery without general anesthesia  
 Aseptic necrosis of hip or shoulder  
 Uncomplicated pregnancy

**Unclear Indication**

Intractable or frequent painful episodes  
 Leg ulcers  
 Before receiving intravenous contrast dye  
 Complicated pregnancy  
 Cerebrovascular accident in adults  
 Chronic organ failure

**Simple Transfusion**

Symptomatic anemia
 

- High output cardiac failure
- Dyspnea
- Angina
- Central nervous system dysfunction

 Sudden decrease in hemoglobin
 

- Aplastic crisis
- Acute splenic sequestration

 Severe anemia (hemoglobin ~5 g/dL) with fatigue or dyspnea  
 Preparation for surgery with general anesthesia

**Exchange Transfusion**

Acute cerebrovascular accident  
 Multiple organ system failure  
 Acute chest syndrome  
 Hepatic sequestration  
 Retinal surgery

As to the type of transfusion strategy to be used, a clinical trial published in 1995 showed that a conservative prophylactic transfusion regimen to achieve a target hemoglobin of 10 g/dL and any HbS value was as effective as an aggressive regimen to achieve a hemoglobin of 10 g/dL and a target HbS value of less than 30% in preventing postsurgical complications such as acute chest syndrome.

Exchange transfusion (erythrocytapheresis with RBC exchange) is usually reserved for the most severe complications, which include acute chest syndrome with impending pulmonary failure, acute stroke and its prevention in children, multiorgan failure, and sepsis. **Box 1** summarizes the main indications for simple and exchange transfusion in SCD, as well as the areas of uncertainty.

**Iron Chelation**

Patients who have received more than 10 transfusions or 20 units of packed RBCs should be screened for iron overload. Most authorities recommend initiation of iron chelation based on a ferritin level consistently greater than 1000 ng/mL, based on data from the thalassemia literature, although liver iron quantitation by MRI or biopsy should be obtained, when available, prior to therapy and to monitor its effectiveness. In the United States, the oral chelating agents deferasirox (Exjade) and deferiprone (Ferriprox) and the parenteral deferoxamine (Desferal) are available and should be administered until the ferritin level is less than 500 ng/mL for three consecutive measurements. Patients on iron chelation with deferasirox and deferoxamine require monitoring of hepatic, renal, auditory, and visual toxicity, and particular caution has to be exercised in the setting of renal disease, because transient, reversible increases in serum creatinine and rare instances of irreversible acute kidney injury have been reported in patients with underlying renal insufficiency. Deferiprone has been associated with agranulocytosis and neutropenia, mandating close monitoring of the absolute neutrophil count during therapy.

**Erythropoietic Stimulating Agents**

Although a brisk reticulocytic response is common in SCD, patients who develop renal failure or aplastic crises or who receive therapy with hydroxyurea may experience a relative or absolute reticulocytopenia (<100,000 reticulocytes/mL) and a worsening of their baseline anemia. In these situations, therapy with ESAs may be beneficial.

Because of bone marrow expansion in patients with HbSS, higher starting doses of erythropoietin (Epogen, (Epogen, Procrit)<sup>1</sup> than in patients without SCD may be considered. For darbepoetin (Aranesp)<sup>1</sup>, a reasonable starting dose is 100 to 200 µg/weekly or every 2 weeks. ESAs can be titrated by 20% to 25% increases in dose per week in patients who do not respond adequately. Weekly monitoring of hematocrit is essential to avoid overdosage and relative erythrocytosis, which can lead to hyperviscosity and vasoocclusive episodes.

**Nutritional Considerations**

Malnutrition, growth retardation, and stunting with findings of low lean and fat body mass are highly prevalent in children and adolescents with SCD, due to their increased caloric demands and a hypermetabolic state. Macronutrient and micronutrient deficiencies are common, and nutritional counseling is warranted. Hypovitaminosis D and low bone mineral density are also prevalent in children and adults. Folic acid<sup>1</sup> is indicated at the dose of 1 mg daily as in other hemolytic diseases, particularly where folate nutritional supplementation programs are absent. Strategies aimed at decreasing iron intake and absorption should be implemented early. There is also growing interest in antioxidant nutraceuticals, particularly in light of the clinical trial showing beneficial effects with L-glutamine (Endari) in SCD; however, evidence on other substances remains limited. The small subset of patients who are overweight or obese is at risk for exacerbating or precipitating common orthopedic problems in SCD such as AVN of the femoral head and its resulting disability. These patients should also receive targeted nutritional counseling.

**Hydroxyurea**

Since the pediatric hematologist Janet Watson suggested in 1948 that the paucity of sickle cells in the peripheral blood of newborns was due to the presence of increased HbF, there has been interest in developing therapies to modulate the hemoglobin switch from fetal to newborn life and prolong HbF production. Several antineoplastic agents, including 5-azacytidine (Vidaza)<sup>1</sup> and hydroxyurea, became the focus of attention after they were found to increase HbF levels in nonhuman primates and individuals with SCD.

The landmark Multicenter Study of Hydroxyurea in Sickle Cell Disease (MSH) showed that the incidence of painful crises was reduced from a median of 4.5 per year to 2.5 per year in hydroxyurea-treated patients with SCD. The rates of acute chest syndrome and blood transfusion were also reduced significantly. A follow-up for up to 9 years of 233 of the original 299 subjects showed a 40% reduction in mortality among those who received hydroxyurea. This study led to the approval of hydroxyurea (Droxia, Siklos) as the first disease-modifying therapy in adults with SCD. More recent studies showed that hydroxyurea is safe and effective in children and adults with SCD. The recently concluded BABY HUG study showed that children 9 to 18 months with HbSS disease randomized to receive 2 years of hydroxyurea therapy, irrespective of the disease severity, had less dactylitis and fewer pain episodes, hospitalizations, and transfusions than children receiving placebo.

On the molecular and cellular levels, the benefits of hydroxyurea are mostly related to increased intracellular HbF, which prevents the formation of HbS polymers and sickling. In addition to this mechanism, some patients on hydroxyurea who do not adequately increase their HbF levels also display clinical benefits,

<sup>1</sup>Not FDA approved for this indication.

**Start therapy** if one or more of the following conditions are present:

- frequent pain episodes
- history of acute chest syndrome
- other severe VOE
- severe symptomatic anemia

**Starting dose:** 15 mg/kg or 7.5 mg/kg if the patient has kidney disease

**Endpoints:**

- less pain
- increase in HbF to 15%–20%
- increased hemoglobin level to 7–9 g/dL
- improved well-being
- acceptable myelotoxicity

**Dose escalation:** increase dose by 500 mg every other day every 8 weeks if no toxicity encountered to a maximum of 35 mg/kg

**Lab monitoring:**

- At time of initiation or escalation: check CBC/differential/reticulocyte count every 2 weeks; serum chemistries every 2–4 weeks, percent HbF every 6–8 weeks
- During maintenance: check CBC/differential/reticulocyte count chemistries monthly, percent HbF every 3 months

**Criteria to hold:**

- ANC <2000
- Hb <9.0 g/dL and reticulocyte count <80,000 (alternatively start Epo)
- Platelet count <80,000
- Raising creatinine
- 2-fold elevation of AST or ALT over baseline
- 2 months prior to planned conception/pregnancy

**Figure 5** Protocol for hydroxyurea treatment.

suggesting that hydroxyurea might have other beneficial rheologic properties.

Although the MSH study only included patients with HbSS, its findings traditionally have been extrapolated to other sickle cell syndromes such as HbSC and HbS/β-thalassemia. A report from Greece, where S/β-thalassemia is highly prevalent, has confirmed that hydroxyurea similarly reduces complications and mortality in patients with HbS/β<sup>0</sup>-thalassemia, with a nonsignificant benefit also observed in HbS/β<sup>+</sup> thalassemia. Existing guidelines also recommend hydroxyurea in patients with HbSC disease, but there is still no high-level evidence to support this practice.

Hydroxyurea has been indicated at a dosage of 15 mg/kg (7.5 mg/kg in patients with renal disease) in patients with frequent pain episodes, history of acute chest syndrome, other severe vasoocclusive episodes, or severe symptomatic anemia, although another sensible approach is to prescribe it to all patients with HbSS regardless of their phenotype. End points are less pain, increase in HbF to 15% to 20%, increased hemoglobin level to 7 to 9 g/dL in severely anemic patients, improved well-being, and acceptable myelotoxicity. The dosage can be increased by 500 mg every other day every 8 weeks to a maximum of 35 mg/kg if no toxicity is encountered. Considering the potential myelotoxicity, hepatotoxicity, and nephrotoxicity of this medication, laboratory monitoring needs to be performed every 2 weeks at the time of initiation or escalation and monthly during maintenance therapy. Laboratory studies should include a complete blood cell (CBC) count, differential and reticulocyte count, and serum chemistries. Measurements of HbF can be performed every 3 months. An elevated MCV is a marker of adherence to the therapy.

Criteria for holding hydroxyurea are listed in [Figure 5](#). Patients need to be counseled on the teratogenic potential, as demonstrated in animal studies, as well as the risks of infertility and leukemogenesis, although a growing body of evidence shows that these risks may have been overestimated in patients with SCD.

Other side effects that can affect compliance include, but are not limited to, weight gain, alopecia, skin and nail

hyperpigmentation (melanonychia), nausea and vomiting, and mucosal ulcerations. Because of the toxicity concerns, as well as factors intrinsic to long-term preventive therapy, hydroxyurea therapy has had low effectiveness in spite of high efficacy, with underprescribing by healthcare professionals and poor patient compliance being major obstacles to its widespread adoption.

### Therapy of Pulmonary Hypertension

Because evidence-based guidelines for managing PH in patients with SCD are not available, recommendations are based upon the pulmonary arterial hypertension literature, case reports, small open-label studies, and expert opinion. For patients with mild PH (tricuspid regurgitant velocity [TRV], 2.5 to 2.9 m/s), it is important to identify and treat risk factors associated with PH such as rest, exercise or nocturnal hypoxemia, sleep apnea, pulmonary thromboembolic disease, restrictive lung disease or fibrosis, left ventricular systolic and diastolic dysfunction, severe anemia, and iron overload. These patients may benefit from aggressive SCD management, including optimization of hydroxyurea dosage and initiation of a chronic transfusion program in those who do not tolerate or respond poorly to hydroxyurea. Consultation with a pulmonologist or cardiologist experienced in PH is also recommended.

For patients with TRV 3 m/s or more, we recommend following the guidelines for TRV 2.5 to 2.9 m/s. In addition, RHC is necessary to confirm diagnosis and to directly assess left ventricular diastolic and systolic function. We would consider specific therapy with selective pulmonary vasodilator and remodeling drugs if the patient has pulmonary arterial hypertension defined by RHC and exercise limitation defined by a low 6-minute walk distance.

US Food and Drug Administration (FDA)-approved drugs for primary pulmonary arterial hypertension include the endothelin receptor antagonists (bosentan [Tracleer] and ambrisentan [Letairis]), prostaglandin-based therapy (epoprostenol [Flolan], treprostinil [Remodulin, Tyvaso, Orenitram], and iloprost [Ventavis]), the phosphodiesterase-5 inhibitors (sildenafil [Revatio]), and riociguat (Adempas), the first member of a new class of drugs, the soluble guanylate cyclase (sGC) stimulators. No published randomized studies in the SCD population exist for any of these agents, although a multicenter placebo-controlled trial of sildenafil for PH of SCD was stopped early because of an unexpected increase in hospitalizations for vasoocclusive crisis in the treatment group receiving sildenafil.

Anticoagulation is indicated in patients who have evidence of pulmonary thromboembolic complications and is supported by evidence of benefit in other populations with PH.

### Hematopoietic Stem Cell Transplantation

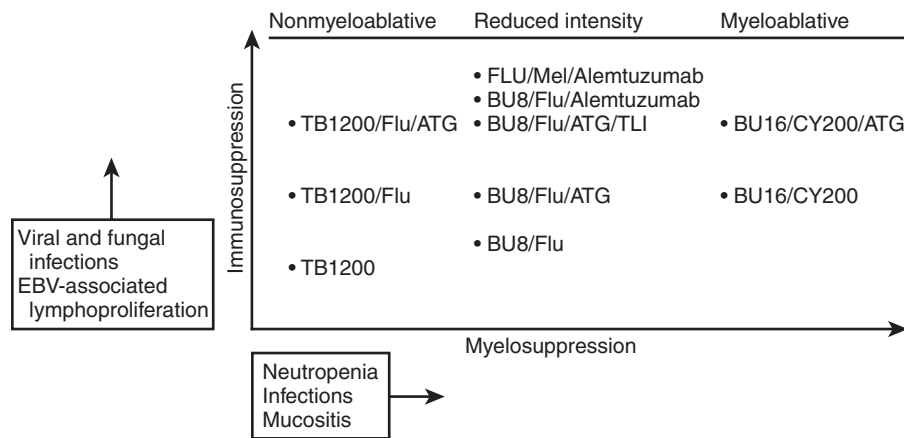

Despite improvement of supportive care in SCD, life expectancy remains lower than for those not affected. In addition, quality of life for patients with SCD is usually significantly impaired. Although hydroxyurea can decrease acute complications of SCD such as vasoocclusive episodes and acute chest syndrome, no satisfactory measures exist to prevent the development of irreversible organ damage in adults. Furthermore, therapy with hydroxyurea is lifelong, and only 20% to 30% of eligible patients are prescribed or actually take the drug.

Currently, allogeneic hematopoietic stem cell transplantation (HCT) remains the only curative treatment. Indications for HCT have been empirically determined from prognostic factors derived from studies of the natural history of SCD. The most common indications for which patients with SCD have undergone HCT are a history of stroke, recurrent acute chest syndrome, or frequent vasoocclusive episodes.

Allogeneic HCT after myeloablative therapy has been performed in hundreds of pediatric and numerous adult patients with SCD. The backbone of the preparative regimens have consisted of busulfan (Busulfex)<sup>1</sup> 14 to 16 mg/kg and cyclophosphamide (Cytoxan)<sup>1</sup> 200 mg/kg. Additional immunosuppressive

<sup>1</sup>Not FDA approved for this indication.

**Figure 6** Spectrum of immunosuppression and myelosuppression in preparative regimens in hematopoietic stem cell transplantation (HCT) in sickle cell disease (SCD). Most preparative regimens for HCT in SCD have used a backbone of busulfan (BU) (Busulfex)<sup>1</sup> and cyclophosphamide (CY) (Cytosan)<sup>1</sup>. Additional immunosuppressive agents include equine antithymocyte globulin (Atgam)<sup>1</sup> or leporine antithymocyte globulin (Thymoglobulin) (ATG)<sup>1</sup>, antilymphocyte globulin, total lymphoid irradiation (TLI) or total body irradiation (TBI), fludarabine (Flu) (Fludara)<sup>1</sup>, and alemtuzumab (Campath)<sup>1</sup>. Attempts to reduce the intensity of preparative regimens for patients with SCD have been based on one of two approaches. The first is the use of reduced-intensity conditioning regimens to produce less myeloablation. These require donor marrow infusion for hematopoietic recovery. The second is the use of nonmyeloablative regimens, which do not eradicate host hematopoiesis and allow hematopoietic recovery even without donor stem cell infusion. <sup>1</sup>Not FDA approved for this indication. Adapted with permission from Krishnamurti L. Hematopoietic cell transplantation: a curative option for sickle cell disease. *Pediatr Hematol Oncol.* 2007;24:569–575.

agents used have included antithymocyte globulin (Atgam)<sup>1</sup>, rabbit antithymocyte globulin (Thymoglobulin)<sup>1</sup>, antilymphocyte globulin, or total lymphoid irradiation (Figure 6). Cyclosporine A (Neoral)<sup>1</sup>, alone or with mercaptopurine (Purinethol)<sup>1</sup> or methotrexate<sup>1</sup>, has been used for posttransplant graft-versus-host disease prophylaxis.

The outcome of HCT for patients with SCD from matched siblings is excellent. Of 1000 recipients of human leukocyte antigen (HLA)-identical sibling transplants performed between 1986 and 2013 and reported to the European Blood and Marrow Transplant, Eurocord, and the Center for International Blood and Marrow Transplant Research, the 5-year event-free and overall survival were 91.4% (95% CI 89.6% to 93.3%) and 92.9% (95% CI 91.1% to 94.6%), respectively. Event-free survival was lower with increasing age at transplantation (hazard ratio [HR] 1.09;  $P < .001$ ) and higher for transplantations performed after 2006 (HR 0.95,  $P = .013$ ). Twenty-three patients experienced graft failure; 70 patients (7%) died, the most common cause of death being infection. Stabilization or reversal of organ damage from SCD has been documented after HCT. In patients who have stable donor engraftment, complications related to SCD resolve, and there are no further episodes of pain, stroke, or acute chest syndrome. Patients who successfully receive allografts do not experience sickle-related central nervous system complications and have evidence of stabilization of central nervous system disease by cerebral MRI. However, the impact of successful HCT on reversal of cerebral vasculopathy has been variable. Current research is focused on improving the applicability of HCT to a greater proportion of patients with SCD by the development of novel conditioning regimens minimizing myeloablation (see Figure 6), the use of novel sources of hematopoietic stem cells such as umbilical cord blood, extending HCT to adult recipients and alternate donors such as matched unrelated donors and haploidentical donors. The aim of these studies is to develop safe and effective alternatives for patients without matched sibling donors, thus increasing the applicability of curative therapy for SCD.

### New and Experimental Therapies

The last few years have witnessed a flourishing of new therapeutic approaches for SCD. Three new drugs have received FDA approval and have been incorporated in the clinical practice

across the United States, and several are in the pipeline or being reviewed in accelerated approval pathways by the FDA. Several decades of preclinical research in sickle mouse models are finally bearing fruit with pathologic pathways identified in sickle mice being harnessed for the development of molecular targeted biologicals. Finally, gene therapy is currently on the horizon with several gene therapy and gene editing approaches being developed simultaneously.

### Antioxidant Strategies

In 2018, pharmacologic *L*-glutamine (Endari) received FDA approval as the second disease-modifying drug in SCD. A randomized, phase III multicenter trial showed that patients in the *L*-glutamine group had significantly fewer pain crises and hospitalizations than those in the placebo group. Of note, two-thirds of the patients in both arms received concomitant hydroxyurea. Reassuringly, the drug had relatively mild side effects including nausea and fatigue. *L*-glutamine presumably acts by reducing oxidant stress in the sickle RBCs, although its effects on major disease parameters such as hemolysis are unclear.

### Modulation of Cellular Adhesion

Adhesive interactions between RBCs, white blood cells, and platelets, and between cells and endothelium are implicated in the pathogenesis of vasoocclusive episodes. Recently, several compounds have been developed to target specific adhesion molecules such as E-selectin and P-selectin. This is a particularly promising area of research that has yielded two compounds in advanced phases of development. The P-selectin inhibitor crizanlizumab has shown significant reduction of the rate of crises per year and longer median time to the first crisis and second crisis when given as intravenous prophylaxis in a double-blind, randomized, phase II clinical trial. FDA approved crizanlizumab (Adakveo) for the prevention of vasoocclusive episodes in SCD in November 2019. As in the case of *L*-glutamine, crizanlizumab can be used with and without concurrent hydroxyurea therapy. The pan-selectin inhibitor rivipansel<sup>5</sup> had shown promising results in a phase II trial of treatment of vaso-occlusive episodes but failed to meet the

<sup>5</sup>Investigational drug in the United States.

primary end point of time to readiness for discharge and other key secondary endpoints in a phase III trial.

### Modulation of Hemoglobin Oxygen Affinity

Deoxygenation of HbS leads to polymerization, sickling, and hemolysis. Thus strategies aimed at increasing the oxygen affinity of HbS may be beneficial. Clinical trials in adults and children have shown reduced hemolysis and improved hemoglobin with voxelotor, a once daily oral drug that increases the oxygen affinity of hemoglobin maintaining it in the oxygenated state and reducing polymerization and sickling. Unfortunately, these changes were not accompanied by a statistically significant reduction in vaso-occlusive episodes. Voxelotor (Oxbryta) was also approved by the FDA for the treatment of SCD in November 2019.

Another promising strategy to reduce HbS polymerization by modulating oxygen affinity involves the use of pyruvate kinase activators. Both mitapivat (Pyrukynd)<sup>1</sup> and etavopivat<sup>5</sup> are promising pyruvate kinase activators that ameliorate the sickling of SCD RBCs by reduction of 2,3-diphosphoglycerate (2,3-DPG), which in turn increases hemoglobin oxygen affinity.

### Modulation of Nitric Oxide

NO is an active biogas and a free radical species that mediates arterial relaxation, cellular adhesion to endothelium, hemostasis, and blood viscosity. In SCD, NO bioactivity is reduced as a result of decreased production due to endothelial perturbation and NO scavenging by cell-free hemoglobin generated during intravascular hemolysis. Dietary supplementation with L-arginine, a precursor of NO, and delivery of exogenous NO or NO bioactivity to the microvasculature in SCD, should promote dilatation of the terminal arterioles where obstruction to flow and tissue damage occurs, improvement of lung ventilation and perfusion is matching, decrease in pulmonary artery pressures, and inhibition of platelet aggregation and cellular adhesion. Although two recent clinical trials on L-arginine supplementation and inhaled NO (DeNOVO trial) for vasoocclusive episodes failed to show a clinical benefit, optimization of timing and dosing and novel strategies to target the NO pathway might lead to valuable NO therapeutics in the future.

### Gene Therapy

The ultimate cure for SCD, gene therapy, is finally on the horizon. A French group first reported that a patient had been successfully treated with lentiviral-mediated insertion of an anti-sickling  $\beta$ -globin gene into autologous stem cells. The transduced cells were then transplanted into the patient who has since experienced long-term remission from SCD. Subsequently, in a clinical trial at the National Institutes of Health (NIH), several patients were treated with autologous hematopoietic stem cells transduced with a lentiviral vector that encodes for a nonsickling hemoglobin with very promising results. Other gene therapy approaches have targeted fetal hemoglobin induction and have harnessed the CRISPR-Cas9 gene editing technology.

Several hurdles need to be overcome before gene therapy will become a viable, large scale therapeutic option for SCD, including technical limitations (e.g., the need for *ex vivo* gene transduction or editing, with the potential loss of stem cell viability), toxicity concerns (e.g., the need for myeloablative chemotherapy to accommodate the auto transplant), cost considerations, and ethical concerns. It is also important to note that gene therapy approaches may not necessarily lead to a cure if they do not result in permanent and high-level suppression of HbS polymerization. Further compounding these concerns, in early 2021 a company performing clinical trials of a lentiviral gene therapy approach for SCD has halted its studies after one gene therapy recipient developed acute myeloid leukemia and

another a myelodysplastic syndrome. The causes of this serious setback are currently being investigated.

### Surgical Issues

Preoperative patient optimization includes prophylactic transfusion, close monitoring of pulse oximetry, adequate analgesia based on the patient's opiate tolerance, and monitoring for sickle cell-related complications.

AVN of the femoral heads, and more rarely of the humeral heads, is the most common orthopedic problem in SCD. Surgery is usually deferred until the pain and disability from AVN become intolerable and usually involves total hip or shoulder arthroplasty. This is usually a more involved procedure than in the general population on account of the altered bone anatomy in SCD. Patients with bone marrow expansion may experience thinning of the cortical bone and prosthetic instability, whereas some may suffer from the opposite problem of obliteration of the medullary shaft by sclerotic bone in response to multiple necrotic events.

Patients with SCD tend to develop pigmented gallstones and cholelithiasis. Cholecystectomy is performed in patients with SCD with cholelithiasis, right upper quadrant pain, and a positive hepatobiliary iminodiacetic acid (HIDA) scan. In SCD, the rate of intraoperative complications is higher and so is the rate of reversion from laparoscopic to open cholecystectomy.

Splenectomy has been reserved for patients with massive splenic infarction (>50% of the spleen volume); intractable, recurrent splenic pain; and splenic abscess in the setting of splenic infarction. It is important to limit splenectomy to these few specific circumstances, because overwhelming sepsis and acute PH have been reported in the postsplenectomy period in SCD.

Kidney transplantation has been successfully performed in patients with SCD on chronic renal replacement therapy, although survival at 7 years is lower than in African Americans without SCD (67% vs. 83%). This difference is mostly due to vasoocclusive complications in the transplanted kidney, possibly exacerbated by the higher hematocrit in the postoperative period from resumption of endogenous erythropoietin production and increased blood viscosity. It is therefore critical to closely monitor ESA therapy in the posttransplantation period to prevent overdosing and relative erythrocytosis. A chronic transfusion program to prevent intrarenal sickling and maximization of hydroxyurea therapy should also be entertained, although its benefits need to be balanced against the risk of HLA alloimmunization and rejection. Combined solid organ and HCT protocols are being developed to overcome these complications. Recently, lung transplantation has been successfully performed in a SCD patient with severe pulmonary arterial hypertension and pulmonary venoocclusive disease.

## THALASSEMIA

Method of

Sarah A. Holstein, MD, PhD; and Raymond J. Hohl, MD, PhD

### CURRENT DIAGNOSIS

- Complete blood count: anemia (very severe in  $\beta$ -thalassemia major, mild in  $\beta$ -thalassemia minor and  $\alpha$ -thalassemia trait), low mean corpuscular volume, variable leukocytosis, thrombocytopenia (secondary to splenomegaly) or thrombocytopenia (after splenectomy)
- Peripheral blood smear: hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells, Heinz bodies, nucleated red blood cells
- Evidence of hemolytic anemia: indirect hyperbilirubinemia, elevated lactate dehydrogenase, decreased haptoglobin
- Hemoglobin electrophoresis pattern:
  - $\beta$ -Thalassemia minor: elevated HbA<sub>2</sub> ( $\alpha_2\delta_2$ )
  - $\beta$ -Thalassemia intermedia: elevated HbA<sub>2</sub>, elevated HbF ( $\alpha_2\gamma_2$ ), and decreased HbA ( $\alpha_2\beta_2$ )
  - $\beta$ -Thalassemia major: absence of HbA, markedly elevated HbF, and elevated HbA<sub>2</sub>
  - $\alpha$ -Thalassemia trait: normal
  - Hemoglobin H disease: decreased HbA, presence of HbH ( $\beta_4$ ) and HbBart ( $\gamma_4$ )
  - Hemoglobin Barts hydrops fetalis: HbBart, absence of HbA, HbA<sub>2</sub>, and HbF
- Timing of symptomatic disease:
  - $\beta$ -Thalassemia minor: asymptomatic
  - $\beta$ -Thalassemia intermedia: variable
  - $\beta$ -Thalassemia major: within first year of life
  - $\alpha$ -Thalassemia trait: asymptomatic
  - Hemoglobin H disease: symptomatic at time of birth
  - Hemoglobin Barts hydrops fetalis: death during gestation

### CURRENT THERAPY

- Chronic packed red blood cell transfusions for  $\beta$ -thalassemia major (1 to 3 units of packed leukoreduced erythrocytes every 3 to 5 weeks) with a target hemoglobin concentration of 9 to 10.5 g/dL; variable transfusion needs for  $\beta$ -thalassemia intermedia and hemoglobin H disease
- Splenectomy with antibiotic prophylaxis and vaccination
- Iron chelation: deferoxamine (Desferal), or deferasirox (Exjade); deferiprone (Ferriprox)
- Osteoporosis management: calcium with vitamin D supplementation; bisphosphonates
- Allogeneic hematopoietic cell transplantation for  $\beta$ -thalassemia major
- Luspatercept (Reblozy) for transfusion-dependent adults with beta-thalassemia

### Globin Gene Arrangements

Thalassemia syndromes encompass a spectrum of hemoglobin disorders that arise from impaired production of globin chains. The genes that encode globins are located in two clusters: the  $\beta$  gene cluster on chromosome 11 and the  $\alpha$  gene cluster on chromosome 16 (Figure 1). The  $\beta$  gene cluster includes the adult globin genes ( $\beta$  and  $\delta$ ) as well as the fetal  $\gamma$  and  $G\gamma$  genes and the embryonic  $\epsilon$  gene. The arrangement of the 5' to 3' sequence of these genes parallels the order of their developmental expression. Functional hemoglobin is a tetramer that includes two  $\alpha$  and two  $\beta$  globin units. The  $\alpha$  gene cluster includes two fetal/adult  $\alpha$  genes ( $\alpha_1$  and  $\alpha_2$ ) and the embryonic  $\zeta$  genes. In

the embryo, three hemoglobins are found ( $\zeta_2\varepsilon_2$ ,  $\alpha_2\varepsilon_2$ , and  $\zeta_2\gamma_2$ ). Fetal hemoglobin (HbF) is composed of two  $\alpha$  chains and two  $\gamma$  chains ( $\alpha_2\gamma_2$ ). In adults, the predominant hemoglobin is hemoglobin A (HbA), consisting of two  $\alpha$  chains and two  $\beta$  chains ( $\alpha_2\beta_2$ ) (see Figure 1). Hemoglobin A2, consisting of two  $\alpha$  chains and two  $\delta$  chains ( $\alpha_2\delta_2$ ), is a normal variant in adults and typically represents less than 3% of the total hemoglobin (see Figure 1).

In  $\beta$ -thalassemia, there is diminished production of  $\beta$  globin genes, resulting in an excess of  $\alpha$  globin chains. Conversely, in  $\alpha$ -thalassemia there is impaired production of  $\alpha$  globin genes, resulting in an excess of  $\beta$  globin chains. This imbalance of globin production is variable, and the degree of accumulation of unpaired globin chains is directly related to the severity of the disease phenotype. The genetic basis of thalassemia is heterogeneous, and several hundred mutations have been identified. These mutations may affect any level of globin gene expression, including arrangement of the globin gene complex, gene deletion, splicing, transcription, translation, and protein stability. In general,  $\beta$ -thalassemia occurs as a result of mutations, whereas  $\alpha$ -thalassemia occurs as a result of gene deletion.

It has been estimated that there are 270 million carriers of thalassemia in the world, including 80 million  $\beta$ -thalassemia carriers. The frequency of  $\beta$ -thalassemia carriers is highest in the malarial tropical and subtropical regions of Asia, the Mediterranean,

and the Middle East. The term *thalassemia*, derived from Greek, refers to the Mediterranean Sea. This distribution is secondary to the selective advantage of heterozygotes against malaria.  $\beta$ -Thalassemia is subdivided into major, intermedia, and minor types (Table 1).  $\alpha$ -Thalassemia is classified into four syndromes:  $\alpha$ -thalassemia trait 2 (loss of one  $\alpha$  globin gene [ $\alpha\alpha/\alpha-$ ]);  $\alpha$ -thalassemia trait 1, also referred to as  *$\alpha$ -thalassemia minor* (loss of two  $\alpha$  globin genes [ $\alpha\alpha/-$  or  $\alpha-/\alpha-$ ]); hemoglobin H (HbH) disease (loss of three alleles [ $\alpha-/-$  -]); and hemoglobin Barts hydrops fetalis (loss of all four  $\alpha$  globin loci [ $-/-$  -]).

### Pathophysiology

The clinical manifestations of thalassemia and their severity are a consequence of the relative excess of unpaired globin chains. In particular, excess  $\alpha$  globin chains are unstable and insoluble and therefore precipitate inside the red blood cell (RBC). These inclusions (precipitated hemoglobin) may be visualized as Heinz bodies. The accumulation of  $\alpha$  globin chains leads to a variety of insults to the erythrocyte, including changes in membrane deformability and increased fragility. Free  $\beta$  chains are more soluble than free  $\alpha$  chains and are able to form a homotetramer (HbH). The hallmark of thalassemia is an anemia that is a consequence of both increased destruction (i.e., hemolysis) and decreased production (i.e., ineffective erythropoiesis). The bone marrow typically displays erythroid hyperplasia.

Oxidant injury is closely linked with the pathology of thalassemia. Under normal conditions, a small amount of methemoglobin ( $\text{Fe}_{3+}$ ) is formed via oxidation and can then be reduced back to hemoglobin ( $\text{Fe}_{2+}$ ). However, isolated globin chains can be oxidized to hemichromes, some forms of which are irreversibly oxidized. The hemichromes can then generate reactive oxygen species, which can oxidize membrane components, leading to cell injury. There is an increase in membrane rigidity in  $\beta$ -thalassemia, and this appears to be secondary to the binding of partially oxidized  $\alpha$  globin chains to components of the membrane skeleton. Increased membrane rigidity in turn leads to decreased membrane deformability and increased destruction. In  $\alpha$ -thalassemia, HbH has a left-shifted oxygen disassociation curve and therefore does not readily transport oxygen. HbH erythrocytes have increased rigidity, which is thought to be secondary to interactions between excess  $\beta$  globin chains and the membrane. Unlike with  $\beta$ -thalassemia, HbH erythrocytes have increased membrane stability. Inclusion bodies have been identified in HbH cells, and there appears to be a correlation between RBC age and solubility

**Figure 1** Representation of the  $\beta$  and  $\alpha$  globin gene clusters. Also shown are the globin tetramers produced during embryonic development.

**TABLE 1** Summary of Hematologic and Clinical Features of the Thalassemias

TYPE	HEMATOLOGIC FINDINGS	HEMOGLOBIN ELECTROPHORESIS PATTERN	CLINICAL FEATURES
$\beta$ -Thalassemia major	Severe anemia, microcytosis, hypochromia, target cells, nucleated RBCs	Absence of HbA, markedly elevated HbF, elevated HbA2	Splenomegaly, jaundice, skeletal abnormalities, abnormal facies; transfusion dependent
$\beta$ -Thalassemia intermedia	Mild to moderate anemia, microcytosis, hypochromia	Elevated HbA2, elevated HbF, decreased HbA	Splenomegaly; variable transfusion dependence
$\beta$ -Thalassemia minor	Mild anemia, microcytosis, target cells	Elevated HbA2	None
Hemoglobin Barts hydrops fetalis	Severe anemia, anisopoikilocytosis, hypochromia, nucleated RBCs	HbBart; absence of HbA, HbA2, and HbF	Death during gestation; fetus with massive hepatosplenomegaly, generalized edema
Hemoglobin H disease	Moderately severe anemia, anisopoikilocytosis, microcytosis, Heinz bodies	Decreased HbA; HbH and HbBart present	Splenomegaly, jaundice; generally transfusion dependent
$\alpha$ -Thalassemia trait 1	Mild anemia, hypochromia, microcytosis, target cells	Normal	None
$\alpha$ -Thalassemia trait 2	Normal	Normal	None

Hb, Hemoglobin; HbA, hemoglobin A; HbF, fetal hemoglobin; HbH, hemoglobin H; RBCs, red blood cells.

of HbH. As cells age, the amount of soluble HbH decreases, and the level of inclusions increases.

It has also been recognized that there is increased phagocytosis of thalassemia RBCs compared with normal controls. The etiology is not completely understood, but it may be a consequence of reduction in surface levels of sialic acid, increase in surface immunoglobulin G binding, and changes in phosphatidylserine localization.

Despite the pronounced hemolysis and marrow erythroid hyperplasia, patients with thalassemia generally do not display the compensatory reticulocytosis that is indicative of the other basis for anemia, ineffective erythropoiesis. Accumulation of  $\alpha$ -chain aggregates is thought to lead to death of erythrocyte precursors. Furthermore, abnormal assembly of membrane proteins in erythroid precursors has been demonstrated.

Iron overload is one of the primary causes of morbidity. Even without transfusion, the long-standing anemia, however mild, leads to increased iron absorption in the gut and eventual chronic iron overload. Excessive iron deposition causes devastating damage to multiple organs, particularly affecting the heart, liver, and endocrine organs.

### $\beta$ -Thalassemia Major

Symptoms of  $\beta$ -thalassemia major are not present at birth, because HbF ( $\alpha_2\gamma_2$ ) is present. However, as HbF levels decline over the first year, the signs and symptoms of severe hemolytic anemia begin to manifest. Affected individuals display hepatosplenomegaly from expansion of the reticuloendothelial system as well as extramedullary hematopoiesis, pallor, growth retardation, and abnormal skeletal development. If left untreated, 80% of children with  $\beta$ -thalassemia major will die before 5 years of age.

### Laboratory Features

Thalassemia major is characterized by a severe microcytic anemia. Hemoglobin levels may be as low as 3 to 4 g/dL. The peripheral blood smear is markedly abnormal and is notable for hypochromia, microcytosis, anisocytosis, poikilocytosis, target cells, and teardrop cells. Routine stains show the presence of precipitated  $\alpha$  globin chains as Heinz bodies. The reticulocyte count is often low. The white blood cell count is often high but may be artifactually elevated as a consequence of automated inclusion of high numbers of circulating nucleated RBCs. The platelet count is typically normal, but progressive hypersplenism can result in decreased platelet counts. Patients who have undergone splenectomy often have increased white blood cell and platelet counts. Iron studies reveal elevated serum iron, transferrin saturation, and ferritin. Consistent with hemolysis and ineffective erythropoiesis, indirect bilirubin and lactate dehydrogenase levels are increased, and haptoglobin levels are low.

### Clinical Features

Unique to  $\beta$ -thalassemia major is the development of extramedullary erythropoiesis. This may be so severe that the masses of bone marrow lead to broken bones and spinal cord compression. Sites of involvement include the sinuses and the thoracic and pelvic cavities. The expansion of the erythroid bone marrow can lead to a number of skeletal changes. In particular, characteristic changes in the facial bones and skull result in frontal bossing, overgrowth of the maxillae, and malocclusion. This has sometimes been referred to as *chipmunk facies*. Other bones are also affected, and premature fusion of the epiphyses results in shortened limbs. Compression fractures of the spine may occur. Even if the disease is managed appropriately with transfusions and iron chelation, patients will still suffer from osteopenia and osteoporosis. Possible mechanisms include changes secondary to hypogonadism or increased bone resorption secondary to vitamin D deficiency.

Hepatomegaly and splenomegaly, secondary to extramedullary erythropoiesis and RBC destruction, are prominent. Injury to Kupffer cells and hepatocytes from chronic overload leads to fibrosis and end-stage liver disease. Hepatic iron overload is

probably caused in part by comparatively high levels of transferrin receptors. Iron overload and perhaps other factors increase susceptibility to viral hepatitis. Laboratory studies show indirect hyperbilirubinemia, hypergammaglobulinemia, and elevated liver markers. The chronic hemolysis leads to formation of bilirubin gallstones, although cholecystitis or cholangitis is not common. Splenic dysfunction results in immune dysfunction. The shortened erythrocyte survival time leaves patients susceptible to aplastic crisis induced by parvovirus B19 infection. Extramedullary hematopoiesis may also affect the kidneys, and patients often have large kidneys. Rapid cell turnover leads to hyperuricemia, and children may develop gouty nephropathy.

A number of endocrine abnormalities are commonly seen in  $\beta$ -thalassemia major, including hypogonadism, growth failure, diabetes, and hypothyroidism. These abnormalities occur even in chronically transfused patients and may be in part related to iron overload. Endocrine glands, such as the liver and heart, have high levels of transferrin receptor and therefore are more susceptible to iron overload. The typical growth pattern for a child with  $\beta$ -thalassemia major is relatively normal until 9 to 10 years of age. After that time, the growth velocity slows, and the pubertal growth spurt is either absent or reduced. Although secretion of growth hormone does not appear to be altered in thalassemic patients, a reduction in peak amplitude and nocturnal levels of growth hormone has been observed. Amenorrhea is quite common, with 50% of girls presenting with primary amenorrhea. Secondary amenorrhea also develops, particularly in patients who do not receive regular chelation therapy. In males, impotence and azoospermia are common. Primary hypothyroidism typically appears during the second decade of life. The prevalence of diabetes mellitus and impaired glucose intolerance has been estimated at 4% to 20%. Unlike type 1 diabetes mellitus, diabetes associated with thalassemia is rarely complicated by diabetic ketoacidosis. The risk of diabetic retinopathy is lower, but the risk of diabetic nephropathy is higher. Patients with a high ferritin level ( $>1800 \mu\text{g/L}$ ) experience faster progression to hypothyroidism, hypogonadism, and other endocrinopathies.

Thalassemic patients suffer from extensive cardiac abnormalities. Chronic anemia causes cardiac dilation. Although long-term transfusion can help prevent cardiac dilation, the resulting iron overload leads to cardiac hemosiderosis. Pericarditis, ventricular and supraventricular arrhythmias, and end-stage cardiomyopathy can develop. Ventricular arrhythmia is a common cause of death. Patients may also develop pulmonary hypertension. The degree of iron overload in the heart has traditionally been assessed by cardiac biopsy, but cardiac magnetic resonance imaging (MRI) is increasingly being used.

Vitamin and mineral deficiencies may occur. Folic acid deficiency may develop in patients, presumably as a consequence of increased cell turnover. Although the cause is unknown, patients with  $\beta$ -thalassemia major often have very low serum zinc levels. Serum levels of vitamin E and vitamin C may also be low.

### Management of $\beta$ -Thalassemia Major

#### Transfusion

The key intervention for the management of  $\beta$ -thalassemia major is chronic transfusion therapy. In particular, during the first decade of life, regular transfusion results in improvements in hepatosplenomegaly, skeletal abnormalities, and cardiac dilation. Patients typically require 1 to 3 units of packed RBCs every 3 to 5 weeks. The optimal target total hemoglobin level has yet to be determined. Alloimmunization does occur, and some blood centers try to leukodeplete their products, match donors by ethnicity, and limit the donor pool for any particular patient. Although the risk of bloodborne infections is currently quite small, regular transfusion of blood products still carries a risk for infections such as human immunodeficiency virus (HIV) and hepatitis C.

#### Splenectomy

The general indication for splenectomy is an increase of more than 50% in the RBC transfusion requirement over a period of

1 year. Splenectomy may initially yield a decrease in the RBC transfusion requirement. It has been noted that thalassemia patients are at higher risk for infection after splenectomy than patients who are splenectomized for other reasons. The bacteria that most frequently cause infections in these patients include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Klebsiella*, *Escherichia coli*, and *Staphylococcus aureus*. The increased susceptibility to infection compared with other splenectomized patients is thought to be a result of greater immune dysfunction secondary to iron overload. In particular, it has been reported that iron-overloaded macrophages lose the ability to kill intracellular pathogens. Antibiotic prophylaxis with penicillin, amoxicillin, or erythromycin is recommended for children up to 16 years of age. In addition, patients should receive immunizations, including the pneumococcal, influenza, and *H. influenzae* vaccines.

### Iron Chelation Therapy

Because of increased iron absorption and long-term transfusion therapy, iron overload develops. As noted earlier, iron overload causes damage to multiple organs. Because iron is poorly excreted, removal must be accomplished by phlebotomy (not an option in thalassemic patients) or by chelation therapy. Historically, deferoxamine (Desferal) has been the most widely used chelator. This agent may be administered subcutaneously (SQ), intramuscularly (IM), or intravenously (IV). The dosing for chronic iron overload is 1000 to 2000 mg/day (or 20 to 40 mg/kg/day) SQ or 500 to 1000 mg/day IM or 40 to 50 mg/kg/day IV. The IV-only route is indicated for patients with cardiovascular collapse. Multiple studies have shown that deferoxamine therapy improves long-term survival. In addition, intensive therapy with deferoxamine has been shown to improve cardiac function in patients with severe iron overload. However, compliance with daily injections has been a particular problem, and unless regular therapy is given, iron will reaccumulate.

Deferiprone (Ferriprox) was the first orally active chelator to be introduced. It is given three times daily (total of 75 mg/kg/day). Studies have indicated that deferiprone may be as effective as deferoxamine in lowering iron levels. A recent Cochrane Review concluded that deferiprone is indicated in the treatment of iron overload in thalassemia major if deferoxamine therapy is contraindicated or inadequate. Agranulocytosis associated with deferiprone has been reported, and because of this risk, the drug has a black box warning on its label. The U.S. Food and Drug Administration (FDA) also requires that Medication Guides be issued to patient when the drug is dispensed. Deferiprone is currently available at selected specialty pharmacies. Deferiprone is available in Europe and Asia. There has also been interest in combined therapy with deferiprone and deferoxamine, and one study showed that the combination was more effective in removing cardiac and hepatic iron but did not further improve cardiac function.

Deferasirox (Exjade) is the first orally active agent approved for use in the United States. Its longer half-life in comparison with deferiprone allows this drug to be given once daily (total of 20 to 40 mg/kg/day). A phase III trial comparing deferiasirox to deferoxamine in patients with thalassemia revealed similar decreases in liver iron concentrations. Side effects include gastrointestinal complaints (abdominal pain, nausea, vomiting, diarrhea) and skin rash. There have been postmarketing reports of acute renal failure, hepatic failure, and cytopenias. It is recommended that serum creatinine, ferritin, and alanine aminotransferase be monitored monthly during therapy. A prospective, randomized study comparing deferiprone and deferoxamine versus deferiprone and deferiasirox in 96 patients with  $\beta$ -thalassemia major demonstrated that both regimens reduced iron overload. However, the latter regimen was found to be superior with respect to improving cardiac iron, patient compliance, and patient satisfaction.

The "gold standard" for measurement of liver iron concentration has been liver biopsy with iron measurement by atomic absorption spectrometry. More recently, there has been

increasing use of MRI technology to measure liver iron levels. In general, iron content determined by MRI methodology correlates with liver iron concentration determined by biopsy. However, the precision of liver MRI measurement appears to be dependent on iron levels, liver fibrosis, and calibration. Hepatic iron concentration has also been measured using a superconducting quantum interference device (SQUID), although reported consistency has varied and widespread use of this technique has been limited by expense and complexity.

### Novel Agents Targeting Iron Homeostasis

A variety of agents that modulate hepcidin activity are being explored as potential therapies for  $\beta$ -thalassemia. Preclinical data demonstrated that minihepcidins restrict iron absorption. A synthetic hepcidin, LJPC-401, was studied in a phase II trial involving patients with transfusion-dependent thalassemia. However, the study was stopped early as a result of lack of efficacy at an interim analysis. Another phase II study of MTG-300, a hepcidin mimetic, was also stopped. Studies are underway evaluating VIT-2763, an oral ferroportin inhibitor. Finally, approaches that increase hepatic synthesis of hepcidin by suppressing the gene transmembrane protease serine 6 (either via siRNA or antisense oligonucleotides) are currently being evaluated in early-phase trials.

### Management of Osteoporosis

Even with calcium and vitamin D supplementation, iron chelation, transfusion therapy, and hormonal therapy, bone loss continues to be a significant problem for thalassemia patients. Recently, there has been interest in the use of bisphosphonates. This class of drugs, which includes clodronate (Bonefos)<sup>2</sup>, alendronate (Fosamax), pamidronate (Aredia), zoledronate (Zometa), and neridronate (Nerixia)<sup>2</sup>, inhibit osteoclastic bone resorption and have found extensive use in the management of Paget disease, osteoporosis, and skeletal metastases. Small studies performed in thalassemia patients have failed to show benefit with clodronate 100 mg IM every 10 days or 300 mg IV every 3 weeks. A very small study using alendronate (Fosamax)<sup>1</sup> 10 mg PO daily revealed an increase in bone mineral density only at the femoral level. Conversely, in a study involving pamidronate (Aredia)<sup>1</sup> 30 or 60 mg IV every month, there was an increase in bone density only at the lumbar level. The most promising results have been achieved with the most potent member of the class, zoledronate. Several trials demonstrated that zoledronate (Zometa)<sup>1</sup> 4 mg IV every 3 or 4 months results in significant improvement in femoral and lumbar bone mineral density and reduces bony pain. The largest randomized trial involved 118  $\beta$ -thalassemia patients who received calcium plus vitamin D with or without neridronate<sup>2</sup> (given every 90 days). At 6 and 12 months, there was increased bone mineral density as well as decreased back pain and analgesic use in the neridronate arm. Larger long-term trials are necessary before this agent finds widespread use in the management of thalassemia-induced osteoporosis.

### Hematopoietic Cell Transplantation

Hematopoietic cell transplantation is the only curative strategy for patients with hemoglobinopathies. Patients are assigned to a risk class (Pesaro class) based on adherence to regular iron chelation therapy, presence or absence of hepatomegaly, and presence or absence of portal fibrosis. Those children with no or little hepatomegaly, no portal fibrosis, and regular iron chelation therapy (class I) have a better than 90% chance of cure, whereas those with both hepatomegaly and portal fibrosis (class III) have long-term survival rates of approximately 60% in older studies. More recent reports indicate that class III survival has improved to 90%.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

The use of human leukocyte antigen (HLA)-identical sibling donors has been preferred, because the use of HLA-mismatched donors has produced inferior results and is associated with increased graft rejection, graft-versus-host disease, and infection. However, it is estimated that only one-third of patients will have a matched donor. The use of unrelated donors has been explored, and initial studies showed poorer outcomes. However, more recent data suggest that matched unrelated donors might be a viable option if a suitable sibling donor is lacking, thanks to improved donor selection and transplantation techniques. The use of partially HLA-matched unrelated cord blood has been reported, although four of nine children did not engraft.

Another emerging technique is the use of reduced-intensity conditioning regimens, although long-term success has yet to be achieved. However, no randomized controlled studies have been performed evaluating the role of transplant in thalassemia patients.

### Gene Therapy

Globin gene therapy, achieved through manipulation of autologous stem cells, is an attractive alternative to allogeneic transplantation. There are three major scientific hurdles that must be overcome: design of vectors that yield therapeutic levels of globin gene expression, ability to isolate and transduce autologous stem cells, and development of transplantation conditions that will permit host repopulation. In addition, the safety of viral and nonviral transfections is an issue. Initial studies involved *ex vivo* transduction of autologous hematopoietic stem cells with a lentiviral vector carrying the transgene. This gene therapy has been administered intravenously or via intrabone injection following a myeloablative conditioning regimen. Many of the patients treated to date have achieved transfusion independence, and thus far no unusual toxicities have been observed. The first gene therapy to obtain regulatory approval is Zynteglo<sup>2</sup>, which was granted conditional approval by the European Commission for patients with transfusion-dependent non- $\beta_0/\beta_0$ -thalassemia who are 12 years of age and older. Zynteglo therapy involves the *ex vivo* transduction of autologous CD34+ cells with the gene-encoding  $\beta$ A-T87Q-globin via a BB305 lentiviral vector. Following a myeloablative conditioning regimen with busulfan (Busulfex)<sup>1</sup>, the transduced CD34+ cells are administered (single dose of  $5.0 \times 10^6$  cells/kg). An ongoing single-group, open-label, single-dose, phase III study of this product reported that 20 of 22 patients (12–50 years of age) and 6 of 7 patients (<12 years of age) achieved transfusion dependence. Another approach that is currently under investigation involves the use of genome editing techniques such as CRISPR/Cas9.

### Pharmacologic Induction of Fetal Hemoglobin

Induction of HbF expression has been proposed as a therapeutic strategy. For  $\beta$ -thalassemia, induced  $\gamma$  globin gene expression would be predicted to decrease globin chain imbalance by complexing with free  $\alpha$  chains. Hydroxyurea (Hydrea)<sup>1</sup> is an anti-metabolite thought to interfere with DNA synthesis. It is well established in the management of sickle cell disease, where it has been shown to increase levels of HbF. The use of hydroxyurea in  $\beta$ -thalassemia is much less well established. In the United States, hydroxyurea has been approved for use in sickle cell disease but not for thalassemia. Studies published elsewhere in the world have generally shown improvements in hemoglobin levels in thalassemia intermedia patients, with some patients becoming transfusion independent. A recent meta-analysis on the use of hydroxyurea in patients with transfusion-dependent  $\beta$ -thalassemia concluded that this agent might offer some benefit but that double-blinded placebo-controlled studies are lacking.

5-Azacytidine (azacitidine [Vidaza])<sup>1</sup>, an inhibitor of DNA methyltransferase, has been shown to induce HbF. However,

concerns regarding long-term use have prevented further evaluation in thalassemia. Decitabine (Dacogen),<sup>1</sup> an analogue of 5-azacytidine, has been shown to increase HbF levels in patients with sickle cell disease refractory to hydroxyurea. A small pilot study of low-dose decitabine in  $\beta$ -thalassemia intermedia patients demonstrated an increase in total hemoglobin and hemoglobin F levels. Butyrate,<sup>5</sup> an inhibitor of histone deacetylases, is another agent capable of inducing HbF. However, butyrate and its derivatives (arginine butyrate<sup>5</sup>, sodium isobutyramide,<sup>5</sup> and sodium phenylbutyrate [Buphenyl]<sup>1</sup>) have failed to show significant clinical benefit in thalassemia patients. Therefore no agent has been approved for use in thalassemia patients at this time.

IMR-687 (tovinontrine),<sup>5</sup> a small molecule inhibitor of phosphodiesterase (PDE) 9, increases intracellular cGMP levels and leads to reactivation of HbF. A randomized, double blind, placebo-controlled phase IIb study of this agent in adults with  $\beta$ -thalassemia is underway.

### Novel Agents Targeting Ineffective Erythropoiesis

An alternative strategy that is being investigated involves the targeting of ineffective erythropoiesis. Luspatercept-aamt (Reblozyl) and sotatercept (ACE-011)<sup>5</sup> are activin receptor trap ligands that were developed to treat postmenopausal osteoporosis but were noted to increase Hb levels. Initial phase II studies with these agents in thalassemia patients revealed reductions in transfusion burden, increase in Hb, and reduction in liver iron levels. A phase III study comparing luspatercept plus best supportive care to placebo plus best supportive care revealed that 21.4% of patients receiving luspatercept achieved a reduction in transfusion burden compared with 4.5% in the placebo group. Luspatercept (1 mg/kg SQ every 3 weeks) is approved by the FDA for the treatment of anemia in adult patients with  $\beta$ -thalassemia who require regular RBC transfusions.

Janus kinase 2 (JAK2) plays a key role in erythropoiesis, and there is interest in the potential use of JAK2 inhibitors in thalassemia. A phase II study with ruxolitinib (Jakafi)<sup>1</sup> showed a reduction in spleen size. However, there was no clinically relevant improvement in pretransfusion hemoglobin, and subsequent phase III studies are not planned.

The pyruvate kinase activator AG-348 (mitapivat) increased ATP levels, reduced markers of ineffective erythropoiesis, and improved anemia in mouse models of  $\beta$ -thalassemia. Initial results from a phase II study of mitapivat (Pyrukynd)<sup>1</sup> reported an increase in hemoglobin in patients with non-transfusion-dependent thalassemia. Two randomized, placebo-controlled phase III studies evaluating mitapivat in patients with thalassemia are underway.

### Antioxidants

Oxidative damage is believed to be an important cause of tissue damage, and there has been interest in the use of antioxidants in thalassemia patients. A variety of substances have been investigated, including ascorbate<sup>1</sup>, vitamin E<sup>1</sup>, N-acetylcysteine (Mucosyst)<sup>1</sup>, flavonoids, and indicaxanthin.<sup>5</sup> A variety of antioxidant effects have been observed *in vitro* with these agents, but none have been shown to improve anemia in patients with thalassemia.

### $\beta$ -Thalassemia Intermedia

Given the underlying genetic heterogeneity, it is not surprising that the clinical manifestations of  $\beta$ -thalassemia intermedia are also quite varied. Some patients with more mild forms of  $\beta$ -thalassemia intermedia do not require long-term transfusion therapy. There is no clear consensus about when long-term transfusion should be initiated. Factors that are considered for children include growth patterns, spleen size, and bone development. Transfusion may be necessary during infection-induced aplastic

<sup>1</sup>Not FDA approved for this indication.

<sup>1</sup>Not FDA approved for this indication.

<sup>5</sup>Investigational drug in the United States.

crises. In some instances, transfusions are begun in childhood to help with growth and then discontinued after puberty. Some adults gradually become more anemic and eventually require transfusion. Some authors have argued that starting transfusions early in life is advantageous because the prevalence of alloimmunization appears to increase if transfusion is started after the first few years of life.

Splenomegaly usually develops in all patients, including those who do not require transfusion. With progression of splenomegaly and the accompanying sequestration and hemolysis, there is usually worsening of anemia to the point at which transfusions may be required. Most patients achieve transfusion independence after splenectomy. Gallstones may develop, and a prophylactic cholecystectomy is sometimes performed at the same time as the splenectomy. As with  $\beta$ -thalassemia major patients, thalassemia intermedia patients are at increased risk for infection and should be appropriately vaccinated.

For reasons that are not entirely clear, there is an increased risk of thromboembolic complications in thalassemia intermedia patients compared with thalassemia major patients. An Italian study reported that 10% of thalassemia intermedia and 4% of thalassemia major patients experienced a thromboembolic event. Another study reported that thromboembolism occurred four times more frequently in patients with intermedia versus major disease. This report noted that venous events were more common in the thalassemia intermedia population, whereas arterial events were more common in the thalassemia major population. An even higher rate of venous thrombotic events (29%) was reported in a population of splenectomized patients with thalassemia intermedia. It has been suggested that exposed anionic phospholipids on the surface of damaged RBCs may induce a procoagulant effect. There is no consensus regarding the prophylactic use of antiplatelet agents or anticoagulants in this population.

Patients with thalassemia intermedia may develop iron overload, although it is less severe than in patients with thalassemia major. Even those who are not regularly transfused may develop a degree of iron overload as a result of increased iron absorption. Iron overload may be managed with the iron chelating agents described earlier. Cardiac toxicity, including congestive heart failure, valvular problems, and pulmonary hypertension (leading to secondary right-sided heart failure) resulting from iron overload is not infrequent in the thalassemia intermedia population.

Bone abnormalities and osteoporosis may develop in thalassemia intermedia patients. In a North American study, the prevalence of fractures in these patients was 12%. Leg ulcers involving the medial malleolus are common and are often difficult to treat. Hypogonadism, hypothyroidism, and diabetes may occur, with frequency related to the severity of anemia and iron overload. Pseudoxanthoma elasticum, a syndrome consisting of skin lesions, angioid streaks in the retina, calcified retinal walls, and aortic valve disease, is more common in thalassemia intermedia than in thalassemia major. Currently, no effective therapy exists, although it has been reported that aluminum hydroxide (Alternagel)<sup>1</sup> reduces skin calcification.

### $\beta$ -Thalassemia Minor

Most patients with  $\beta$ -thalassemia minor are asymptomatic. However, they have an abnormal complete blood cell count that may sometimes lead to the misdiagnosis of iron deficiency. Although these patients have a microcytic anemia, it is much less severe than in patients with  $\beta$ -thalassemia major. In general, the hematocrit is greater than 30%. The mean corpuscular volume is typically less than 75 fL, and the RBC distribution width index is normal, in contrast with iron deficiency in which the degree of microcytosis is less and the distribution width index is usually

increased. The peripheral blood smear shows the presence of target cells. Hemoglobin electrophoresis typically reveals an increase in HbA<sub>2</sub>. The normal anemia experienced during pregnancy may sometimes be exacerbated in patients with  $\beta$ -thalassemia minor, necessitating transfusion. Otherwise, no long-term effects of  $\beta$ -thalassemia minor have been described, and no interventions are required.

## $\alpha$ -Thalassemia

### Laboratory and Clinical Features

Patients with  $\alpha$ -thalassemia trait 2 are symptom free and have normal laboratory values, including complete blood count, peripheral smear, and hemoglobin electrophoresis. Individuals with  $\alpha$ -thalassemia trait 1 are symptom free, and the disease resembles  $\beta$ -thalassemia minor. The peripheral smear shows a hypochromic microcytic anemia with the presence of target cells. Hemoglobin electrophoresis is normal.

HbH disease does produce symptoms. Unlike  $\beta$ -thalassemia major, in which HbF production protects the fetus, individuals with HbH disease develop hemolytic anemia during gestation and are symptomatic at birth. This is because  $\alpha$  globin production is required for HbF ( $\alpha_2\gamma_2$ ). As with  $\beta$ -thalassemia major, patients with HbH disease suffer from the consequences of chronic hemolytic anemia, although the severity is somewhat less. The transfusion requirements for HbH patients resemble those for patients with  $\beta$ -thalassemia intermedia, with transfusion support initiated in the second and third decades of life. These patients also develop iron overload, necessitating treatment with chelation therapy.

Hydrops fetalis with hemoglobin Barts is usually fatal in utero. The utter lack of  $\alpha$  globin chain production results in absence of HbF. Hemoglobin Barts, a homotetramer consisting of four  $\gamma$  globin genes, is unable to deliver oxygen to tissues. Severe tissue hypoxia develops, leading to widespread tissue ischemia. High cardiac output failure leads to massive edema (hydrops). In most cases, death occurs in the third trimester or late second trimester. There have been reports of live births after intrauterine transfusion, but survival beyond the perinatal period is exceedingly rare. Prenatal diagnosis of hemoglobin Barts hydrops fetalis may be achieved through DNA-based testing using amniocytes from amniocentesis or chorionic villi sampling. Noninvasive testing is under development, including methods that isolate circulating fetal DNA in maternal peripheral blood.

### Management

Patients with  $\alpha$ -thalassemia 1 and 2 traits do not require treatment. The management of HbH disease is similar to that described for  $\beta$ -thalassemia.

## THROMBOTIC THROMBOCYTOPENIC PURPURA

Method of  
Ravi Sarode, MD

### CURRENT DIAGNOSIS

- A provisional diagnosis based on unexplained microangiopathic hemolytic anemia (MAHA) and thrombocytopenia in the absence of oliguric renal failure is sufficient to initiate emergent plasma exchange (PLEX) for a suspected diagnosis of autoimmune acquired thrombotic thrombocytopenic purpura (TTP).
- The final diagnosis is usually established by the documentation of a severe deficiency (<10% activity) of ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin 1 motif, 13th member of the family).
- These laboratory tests are recommended for patient evaluation:
  - Complete blood count ([CBC] shows anemia and decreased platelet count, usually <30,000/uL)
  - Peripheral blood smear (shows “schistocytes/fragmented red blood cells,” a hallmark of thrombotic microangiopathy [TMA])
  - Reticulocyte count (elevated)
  - Haptoglobin (usually undetectable in TTP)
  - Lactate dehydrogenase ([LDH] usually more than twice the upper limit of normal in TTP)
  - Blood urea nitrogen, serum creatinine (determine nonoliguric renal insufficiency, serum creatinine <2.5 mg/dL)
  - Liver function tests, including direct and indirect bilirubin
  - Troponin (some patients have an ischemic cardiac injury)
  - Plasma ADAMTS13 activity: (<10% is diagnostic of TTP) and inhibitor level (usually detected in 90% of cases of acquired TTP) or ADAMTS 13 antibodies by enzyme-linked immunosorbent assays (ELISA) (almost all acquired TTP)
  - Prothrombin time, partial thromboplastin time, fibrinogen, and D-dimers (to rule out disseminated intravascular coagulation [DIC])
  - Direct antiglobulin test (to rule out autoimmune hemolytic anemia)
  - Urinalysis

### CURRENT THERAPY

- The goal is to normalize ADAMTS 13 levels (>50%)
- Daily PLEX using plasma as a replacement fluid (1–1.5 total body plasma volume) until the platelet count is greater than 150,000/uL for 2 days. Thereafter, the frequency of PLEX may be guided more judiciously if ADAMTS13 levels are obtained once or twice a week during hospitalization.
- Caplacizumab (Cabliivi, 11 mg IV loading dose followed by daily 11 mg SQ), a nanobody that interferes with the binding of von Willebrand factor (vWF) to the GPIb domain on platelets and disrupts the pathophysiology of the disease in severe presentations or refractory cases, may prevent deaths and reduce the number of PLEXs needed. Given daily until ADAMTS13 levels >20% to 30%.
- Prednisone 1 mg/kg/day tapered gradually as platelet count remains >150,000/uL
- Rituximab (Rituxan)<sup>1</sup> (either 100 mg fixed dose or 375 mg/m<sup>2</sup> weekly for 4 weeks) upfront as soon as the diagnosis of autoimmune TTP is confirmed (reduces length of stay, number of PLEXs, and exacerbations and relapses, and thus overall cost).

- Plasma (10–15 mL/kg) or cryoprecipitate (one dose = 10 units of pooled cryoprecipitate) infusion, if PLEX will be delayed more than 6 hours on day 1.
- ADAMTS13 testing during follow-up to detect early biologic relapse and preemptive Rituxan to avoid clinical relapse and hospitalization.
- Exacerbation or relapsing TTP
  - Rituximab (Rituxan)<sup>1</sup> (100 mg fixed dose or 375 mg/m<sup>2</sup> weekly for 2 to 4 weeks)
  - Cyclosporine (Neoral)<sup>1</sup> (2–3 mg/kg/day up to 6 months)
  - Vincristine (Oncovin)<sup>1</sup> (1.4 mg/m<sup>2</sup> once a week for 4 weeks)
  - Bortezomib (Velcade)<sup>1</sup> (1.3 mg/m<sup>2</sup> one to two cycles or 1 mg fixed dose weekly for 4 weeks)
  - Splenectomy as a last resort

<sup>1</sup>Not FDA approved for this indication.

Thrombotic thrombocytopenic purpura (TTP) is a rare (one to two cases per million) but life-threatening thrombotic microangiopathy (TMA) disorder characterized by the presence of microthrombi in the microcirculation of various organs, including the brain, kidneys, heart, and abdominal viscera. Microthrombi consist of platelets and von Willebrand factor (VWF), resulting in microangiopathic hemolytic anemia (MAHA) and thrombocytopenia. MAHA refers to the fragmentation of red blood cells (schistocytes) during their passage through partially occluded arterioles and capillaries by microthrombi. TTP diagnosis requires a high degree of suspicion because a delay in initiating plasma exchange (PLEX), the current standard of care, could result in a poor response or fatal outcome. In the past, diagnosis of TTP was made based on a pentad that included MAHA, thrombocytopenia, neurologic involvement, renal affection, and fever. This pentad was found in patients who had died of TTP, indicating advanced disease; therefore, one should not wait for the development of a pentad, which could delay TTP diagnosis and lead to a potentially fatal outcome. Currently, unexplained MAHA and thrombocytopenia in the absence of oliguric renal failure are sufficient to make a working diagnosis of TTP and initiate emergent PLEX. Patients may present with only severe thrombocytopenia and/or with warm autoimmune hemolytic anemia and be managed as nonresponding immune thrombocytopenia/Evan syndrome. However, after a few days, such patients may develop MAHA, establishing a TTP diagnosis. Therefore, such patients not responding to standard therapy should have high suspicion of TTP. Similarly, but rarely, a young patient may present with unexplained ischemic stroke without hematologic features and later develop hematologic features.

### Pathophysiology

In congenital TTP (Upshaw-Shulman syndrome), ultralarge (UL) multimers of vWF were detected during remission but were absent during relapse. Later, a ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin 1 motif, 13th member of the family), vWF-cleaving protease, was identified that was responsible for cleaving UL multimers secreted from endothelium into normal-sized vWF multimers seen in normal plasma. This cleavage occurs under high-shear-rate flow conditions in smaller blood vessels where the UL-vWF undergoes unfolding, exposing the cleavage site for ADAMTS13. ADAMTS13 is severely deficient (<10%) in patients with both congenital and acquired (autoimmune) TTP. Persistence of UL-vWF multimers in the microcirculation results in unfolding of the molecule, enabling it to bind to platelets at GPIb, thus producing platelet-vWF microthrombi in capillaries and arterioles that cause end organ ischemic damage (Figure 1). Elevated lactate dehydrogenase (LDH) reflects not only MAHA but also tissue damage; hence very high LDH reflects more severe disease.

**Figure 1** During normal hemostasis, *ADAMTS13* enzyme cleaves ultralarge multimers of von Willebrand factor (vWF) in normal sizes and prevents the formation of platelet-vWF aggregates under high shear rates. However, in the absence of *ADAMTS13* (a disintegrin and metalloproteinase with thrombospondin 1 motif, 13th member of the family) due congenital deficiency or autoantibodies, vWF persist as ultralarge multimers that unfold under high shear rates in small blood vessels and induce vWF-platelet microthrombi in various organs, causing ischemic damage.

### Classification

TTP can be divided into (1) a congenital form resulting from a genetic defect in the *ADAMTS13* gene and (2) an acquired form due to an autoantibody against the *ADAMTS13* enzyme (Figure 2). Congenital TTP can present in the neonatal period, early childhood, or later in life, when it is usually associated with an inciting trigger in the form of pregnancy, severe infection, surgery, or other stress. Acquired TTP is usually idiopathic without an underlying disorder, or secondary when associated with an underlying autoimmune disorder such as systemic lupus erythematosus (SLE), human immunodeficiency virus (HIV), use of ticlopidine (Ticlid),<sup>2</sup> and so on. Other clinical conditions that present with MAHA and thrombocytopenia with nonsevere *ADAMTS13* deficiency are grouped under the broader term TMA.

### Clinical Presentation

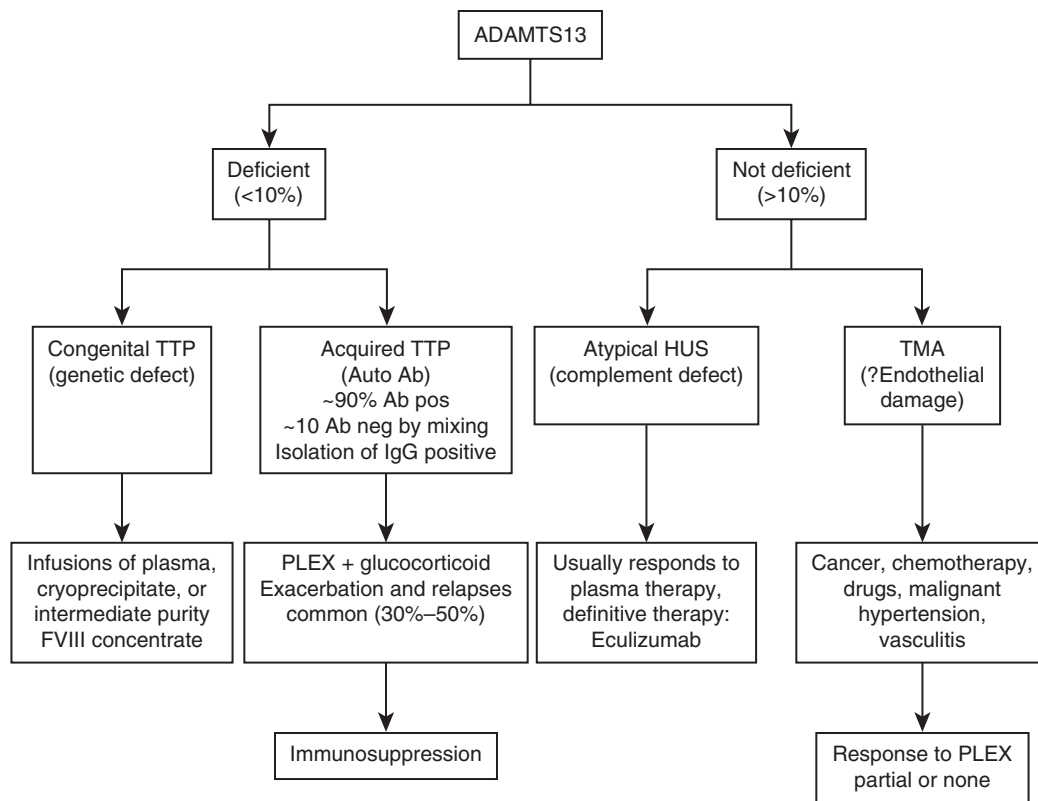

Autoimmune TTP is a disease of young adults (20–50 years of age, female-to-male ratio 2:1), with the majority being African

American. Most patients present in the emergency department with an acute onset of vague, anemia-like symptoms (malaise, fatigue, weakness) and thrombocytopenia (petechiae, bleeding gums). Detailed evaluation reveals that these symptoms had their onset several days before presentation. Up to 70% to 80% of patients have some neurologic features, including severe headaches, visual disturbances, focal neurologic deficits, transient ischemic attacks, memory deficits, unusual behavior, confusion, seizures, paraparesis, stupor, and coma. Mild renal insufficiency is seen in less than 50% and fever in less than 15%. Because of the generalized nature of the disease, any organ system can be affected, and ischemic insult to the heart is not uncommon.

### Diagnosis

Unexplained MAHA and thrombocytopenia constitute the diagnostic features and are associated with elevated LDH, reticulocytosis, undetectable haptoglobin, elevated bilirubin, and nonoliguric renal insufficiency in some patients. A severe deficiency of *ADAMTS13* (<10% activity with a detectable inhibitor in up to 90% of patients and antibodies by enzyme-linked immunosorbent assays [ELISA] in almost all) confirms the diagnosis. Because this test is usually

<sup>2</sup>Not available in the United States.

**Figure 2** Classification of TTP. *Ab*, Antibody; *ADAMTS13*, a disintegrin and metalloproteinase with thrombospondin motif 1, 13th member of the family; *HUS*, hemolytic uremic syndrome; *MAHA*, microangiopathic hemolytic anemia; *PLEX*, plasma exchange; *TMA*, thrombotic microangiopathy; *TTP*, thrombotic thrombocytopenic purpura.

sent to a reference laboratory, this level is unavailable in most hospitals at the time of clinical diagnosis. Therefore, based on the initial clinical and laboratory features, PLEX should be initiated emergently because a delay can increase not only morbidity but also mortality. A sample for ADAMTS13 must be drawn before initiating PLEX or plasma/cryoprecipitate infusion to avoid measuring enzyme from transfused products. ADAMTS13 is a stable enzyme; if a sample for ADAMTS13 could not be drawn before plasma therapy, a routine coagulation test sample may be used. In congenital TTP, a persistent severe deficiency of ADAMTS13 (without an inhibitor) is associated with *ADAMTS13* gene defect. However, this diagnosis is sometimes made difficult because many patients, especially children and young adults, are often misdiagnosed as having immune thrombocytopenia or anemia of unknown origin or the hemolysis elevated liver enzymes and low platelets (HELLP) syndrome in pregnancy.

### Differential Diagnosis

The differential diagnosis of TTP includes clinical conditions that present with MAHA and thrombocytopenia but without severe ADAMTS13 deficiency—that is, TMA. These conditions include hematopoietic stem cell transplantation, drug toxicities (mitomycin, clopidogrel [Plavix], cyclosporine A [Neoral], etc.), malignant hypertension (usually mild to moderate thrombocytopenia), HELLP syndrome with severe preeclampsia, mechanical cardiac devices (for example, left ventricular assist devices, intraaortic balloon pumps, and mechanical heart valves), disseminated intravascular coagulation (DIC), vasculitis, and both diarrhea-associated and atypical hemolytic uremic syndrome (HUS).

### Treatment

PLEX is the standard of care therapy. Its use has reduced mortality from more than 90% to less than 20%. Ideally it should be initiated within 4 to 6 hours of suspected diagnosis. The patient's plasma (which contains autoantibody) is selectively removed during PLEX (1.0–1.5 plasma volume processed) and replaced with donor

plasma containing ADAMTS13. Neurologic symptoms usually disappear within 24 to 48 hours. The platelet count is the most useful laboratory parameter in the assessment of initial response. Complete clinical response, defined as normalization of platelet count for at least 2 days with near normal LDH, is generally achieved in most patients with seven to nine daily PLEXs. Thereafter, a gradual taper—that is, PLEX every other day in the first week, twice in the next week, and once in the third week—may be performed. However, the number of PLEXs can be guided by frequent ADAMTS13 measurements to avoid unnecessary PLEXs and reduce exposure to hundreds of plasma donors, thus reducing the risk of transmitting known and unknown pathogens. Another option is to use pathogen-inactivated plasma such as Octaplas (Octapharma Plasma Centers), which is approved by the FDA for the treatment of TTP. Given the autoimmune nature of the disease, glucocorticoid therapy is often given from the beginning. Approximately 30% to 50% of patients will have an exacerbation of the disease (worsening of clinical or laboratory features after initial response) or relapses (recurrence of the disease 30 days after discontinuation of PLEX). Such patients require additional PLEXs and other immunomodulatory therapies (e.g., rituximab [Rituxan],<sup>1</sup> cyclosporine [Neoral],<sup>1</sup> vincristine [Oncovin],<sup>1</sup> bortezomib [Velcade],<sup>1</sup> or splenectomy as a last resort). Early rituximab use, within the first week, has recently been shown to reduce number of PLEXs, length of stay, and exacerbation/relapse. Preliminary data also suggest that a lower dosage of rituximab (100 mg weekly for 4 weeks) elicits a similar clinical response as a higher dosage (375 mg/m<sup>2</sup> weekly for 4 weeks). However, the former offers the benefits of reduced cost, lower infusion time, and fewer side effects. A dialysis-type catheter is required for PLEX and can be placed with ultrasound guidance in patients with platelet counts as low as 5000/ $\mu$ L. With the exception of a life-threatening bleed, platelet transfusion is contraindicated in TTP because it is a thrombotic disorder of

<sup>1</sup>Not FDA approved for this indication.

platelet consumption and transfused platelets may worsen the condition (with the appearance of new neurologic symptoms, myocardial infarction, etc.). Most fatalities occur during the first few days of diagnosis, probably because of the severity of the disease or delay in the initiation of PLEX. If initiation of PLEX is likely to be delayed, either plasma or cryoprecipitate can be infused temporarily to supplement ADAMTS13.

Caplacizumab (Cabliivi), a nanobody that binds to the A1 domain of vWF and blocks its interaction with GPIIb/IX/V receptors on platelets, has recently been approved by the FDA for the treatment of TTP. A randomized clinical trial showed that caplacizumab given once as an intravenous (IV) bolus (of 11 mg) followed by daily subcutaneous injections (of 11 mg) up to 30 days post-PLEX led to normalization of the platelet count slightly faster and reduced the numbers of PLEXs, disease exacerbations, and possibly deaths but also led to more relapses compared with placebo. It seems that the use of caplacizumab can definitely benefit severe and refractory TTP and may be tailored based on frequent ADAMTS13 testing during the treatment course. Once ADAMTS13 levels are greater than 20% to 30%, caplacizumab should be discontinued to prevent a bleeding tendency due to development of acquired von Willebrand syndrome. Congenital TTP is treated with plasma infusions (10–15 mL/kg); however, cryoprecipitate and intermediate purity Factor VIII concentrate that contain adequate ADAMTS13 have been used successfully to avoid volume overload in susceptible patients. In congenital TTP, a recombinant ADAMTS13 has recently been shown to produce very promising results in a phase I clinical trial.

### Monitoring

Considering the relatively high frequency of cardiac involvement, cardiac monitoring should be performed initially. Although PLEX is an otherwise safe procedure, complications related to catheter infection and line thrombosis are not uncommon and should be identified as soon as possible to avoid exacerbation of

the disease. Exacerbation of TTP is often related to an infection. There is increasing awareness of delayed long-term psychological and psychosocial effects in up to 50% patients; a careful follow-up is recommended to identify and manage these issues.

### Prognosis

Although PLEX has reduced TTP mortality in the last two decades, most deaths occur within 24 to 48 hours of presentation and are due to delay in the administration of PLEX for a variety of reasons, including a delay in diagnosis or line placement or nonavailability of PLEX at the institution. After one PLEX, survival rates can increase to greater than 90%. Importantly, no clinical or laboratory parameter exists to predict outcome or relapse. Frequent ADAMTS13 monitoring is now used during follow-up to detect early biologic relapse (drop in activity <30%–50%); preemptive rituximab<sup>1</sup> has been used to prevent overt hematologic and clinical relapse and avoid hospitalization.

<sup>1</sup>Not FDA approved for this indication.

## DRY EYE SYNDROME

Method of

Lauren A. Jeang, MD

### CURRENT DIAGNOSIS

- Dry eye disease can manifest as a multitude of symptoms, including dryness, burning, irritation, foreign body sensation, and fluctuating vision.
- Patients of older age are more commonly affected.
- Patients can have a combination of contributing factors that culminate in reduced aqueous tear production and increased tear evaporation.
- Environmental causes include fans, air conditioning, low humidity, and electronic screen use.
- Ocular risk factors include contact lens use, blepharitis, and eyelid malposition.
- Systemic diseases such as Sjögren syndrome, thyroid eye disease, graft-versus-host disease, and mucous membrane pemphigoid should be considered in the differential diagnosis, especially if there are other suggestive signs or symptoms.
- Slit-lamp examination and ocular surface staining provide the most helpful clinical findings. Corneal esthesiometry, Schirmer tests, and tear composition assays are useful as adjunct testing.

### CURRENT THERAPY

- Patients should be educated on the chronic nature of dry eye disease.
- Treatment depends on the contributing factors and severity of disease. Multiple simultaneous therapies may be required.
- For mild and moderate disease, initial treatment includes environmental modification and artificial tear lubrication.
- If artificial tears are required more than four times a day, preservative-free artificial tears are recommended to avoid ocular surface irritation from preservatives.
- Other treatment options include prescription anti-inflammatory topical medication, punctal plugs, oral medications, autologous serum tears, and scleral contact lenses. Management of blepharitis should also be considered.
- Cases of eyelid malposition or dysfunction may require surgical intervention.
- Extreme disease can lead to sight- or eye-threatening complications and require more aggressive treatment.

### Epidemiology

Dry eye syndrome is a multifactorial disease with a wide range of findings including eye discomfort, burning, irritation, blurry vision, altered tear film, and ocular surface damage. The prevalence of dry eye is unclear because of the broad disease definition

and lack of universal diagnostic criteria. It is estimated that 20 million people in the United States suffer from dry eye. Signs and symptoms of dry eye increase by every decade of age. Among older age groups, higher rates of dry eye have been reported in women than in men. Additional terms associated with dry eye include dry eye disease, dry eye syndrome, dysfunctional tear syndrome, and keratoconjunctivitis sicca.

### Risk Factors

Multiple risk factors have been associated with dry eye disease. Demographic risk factors include older age (>65 years), female sex, and Asian race. Ocular risk factors include blepharitis, meibomian gland dysfunction, ocular rosacea, contact lens wear, and eyelid malposition such as entropion and ectropion. Systemic diseases strongly associated with dry eye include mixed connective tissue disorders, Sjögren disease, androgen deficiency, and hematopoietic stem cell transplantation. Thyroid orbitopathy increases ocular exposure and tear evaporation, while Parkinson disease decreases blink rate. A wide range of medications including antihistamines, antidepressants, anxiolytics, and isotretinoin can induce eye dryness. Environmental risk factors such as prolonged electronic screen time, low humidity, and fan use can increase tear evaporation from the ocular surface.

Blepharitis and meibomian gland dysfunction are often diagnosed in conjunction with dry eye disease. Blepharitis is a chronic inflammation of the eyelid margins, including the eyelashes and meibomian glands. Meibomian gland dysfunction, which is considered a subcategory of blepharitis, is defined by duct obstruction/atrophy or altered glandular secretions. Both blepharitis and meibomian gland disease can cause eye irritation, inflammatory tear film state, and ocular surface changes.

### Pathophysiology

Healthy tears are important in maintaining a lubricated ocular surface. The precorneal tear film is classically described as having an inner mucin layer, middle aqueous layer, and outer lipid layer. More recent studies suggest that the tear film may be a complex gel substance containing soluble mucus, water, electrolytes, proteins, and lipids. Mucus from goblet cells protects and hydrates the eye through formation of a glycocalyx on the surface epithelium. Aqueous fluid, protein, and electrolytes are produced by the lacrimal gland. The outer lipid layer is secreted by meibomian glands and prevents rapid tear evaporation of the aqueous layer to the air.

Adequate tear production, maintenance, and clearance is the responsibility of the lacrimal functional unit, which includes the lacrimal glands, cornea, conjunctiva, meibomian glands, eyelids, and their associated sensory and motor nerves. Cranial nerve V1 sensory input from the ocular surface stimulates eyelid blinking, which allows for even distribution of tears across the eye surface and directs excess tears down through the eyelid punctum. Blinking also allows for expression of lipid material into the tear film from the meibomian glands.

Dry eye disease is the result of any condition that affects a component of the tear film or the lacrimal functional unit. Lacrimal gland secretion inhibition may be caused by lacrimal duct obstruction in sclerosing diseases such as mucous membrane pemphigoid, graft-versus-host disease, ocular burns, or by inflammation of the ductal and acinar epithelial cells in Sjögren syndrome. Systemic medications can reduce tear secretion. Corneal hypoesthesia caused by previous herpes simplex or herpes zoster keratitis,

prior laser-assisted in-situ keratomileusis (LASIK) surgery, or trigeminal nerve damage can lead to decreased tear production and decreased blinking. Poor eyelid movement from Parkinson disease, Bell's palsy, or increased ocular surface exposure from thyroid eye disease and electronic screen use prevent formation of an even and adequate tear film. Blepharitis and meibomian gland dysfunction prevent adequate meibum secretion and increase inflammatory factors on the ocular surface.

The combination of poor aqueous secretion by the lacrimal gland and increased tear evaporation leads to tear film hyperosmolality, which in turn triggers an inflammatory cascade in the junction between ocular surface epithelial cells. This in turn leads to a loss of epithelial and goblet cells and T-cell recruitment. The resulting loss of corneal epithelium and unstable tear film then propagates this cycle.

### Clinical Manifestations

Dry eye can be classified as mild, moderate, or severe. Patients with mild dry eye may have a multitude of complaints including dryness, discomfort, irritation, burning, foreign body sensation, and fluctuating or blurry vision. Vision may improve with blinking or with use of lubricating drops. Worsening vision may be reported with prolonged screen use, upon awakening, or toward the evening. Moderate disease manifests as increasing symptoms and more persistent visual changes. Severe dry eye, especially when caused by an underlying inflammatory condition, may cause sight- or eye-threatening problems such as corneal scarring, thinning, sterile or infectious ulcers, and perforation.

### Diagnosis

The diagnosis of dry eye is made clinically. A gross external examination may reveal proptosis, excessive eyelid laxity, trichiasis, entropion, or ectropion. Patients may demonstrate incomplete blinking or lagophthalmos. The skin may demonstrate changes consistent with blepharitis and rosacea, including rhinophyma, erythema, and telangiectasias. Eyelid changes consistent with blepharitis include debris at the eyelash bases, lid margin telangiectasias, and poor meibum flow from the meibomian glands. Slit lamp examination with the aid of fluorescein staining may show evidence of poor tear production and distribution. A drop of saline applied to a fluorescein strip, or a drop of premade 1% or 2% solution is placed on the lower tarsal conjunctiva. Using the cobalt blue filter on the slit lamp, fluorescein may highlight a low tear lake over the lower eyelid (normal is 1 mm), irregular or rapid breakup of the tear film (normal is 10 seconds), and punctate changes representing epithelial cell loss over the cornea. Lissamine Green is another type of stain used to reflect areas of mucin or glyocalyx loss on the conjunctiva. The pattern of staining may suggest the underlying cause. Corneal hypoesthesia is evaluated before the use of any eyedrops. Sensation is evaluated by using a cotton-tip applicator with the fibers twisted to a point or using a Cochet-Bonnet aesthesiometer device.

Schirmer's testing is useful in assessing decreased aqueous tear production. The test can be performed with or without topical anesthesia. A thin strip of filter paper is placed along the lateral one-third of the lower eyelid. The amount of aqueous absorbed after 5 minutes is measured. If topical anesthesia is not used, a value less than 10 mm is considered abnormal. However, there is no established cutoff, and results are poorly reproducible. Therefore the use of Schirmer's testing as a sole diagnostic test is not recommended.

Multiple tear composition assays are available that examine different markers of dry eye including elevated tear osmolality, decreased lactoferrin and lysozyme, and increased matrix metalloproteinase-9 (MMP-9). However, there are conflicting studies on whether or not these markers strongly correlate with symptoms and other examination findings. There is some suggestion that multiple measurements over time may be more useful.

Additionally, the workup should include a careful review of medications and systemic symptoms. Patients with severe or intractable dry eye should raise questions of concurrent dry mouth, arthritis, or history of inflammatory or autoimmune disease. These patients may benefit from evaluation for Sjögren syndrome or another

autoimmune condition. Similarly, patients with significant proptosis and lagophthalmos should be examined for possible thyroid disease.

### Differential Diagnosis

The differential diagnosis for dry eye disease can be broad because of overlapping signs and symptoms with other ocular diseases. Burning and irritation may be caused by blepharitis or meibomian gland dysfunction without dry eye. Patients presenting with severe dry eye may have another underlying ocular condition such as a thermal or chemical ocular burn, Stevens-Johnson syndrome, graft-versus-host disease, or mucous membrane pemphigoid.

Additional history may elucidate other conditions in the differential diagnoses. Patients with ocular irritation after initiating eye drops may be suffering from topical drug toxicity. Redness, itching, and mucoid discharge can be suggestive of allergic or viral conjunctivitis. Foreign body sensation or eye pain in the setting of recent ocular trauma may be due to a corneal abrasion. Infectious corneal ulceration should also be considered if there is redness, tearing, or decreased vision in a patient with prior ocular trauma or poor contact lens hygiene.

### Therapy

Treatment of dry eye disease begins with addressing the underlying cause and educating patients on the nature of this disease. Potential environmental factors should be eliminated first. Air conditioners, heaters, and fans should be avoided or diverted away from the eyes. Patients should be reminded to take short breaks every 20 minutes or consciously blink during prolonged digital screen use. Moisture chamber goggles and humidifiers may help improve periocular humidity. Discontinuation of an offending systemic drug should be considered if medically appropriate.

Basic treatment includes the use of eye lubricants to enhance aqueous volume. Over-the-counter artificial tears dosed two to six times a day is often the first treatment modality. If patients need lubricants more than four times a day, preservative-free artificial tears are recommended over non-preservative-free products. Artificial tear ointments are also available over the counter and are best used at nighttime to avoid blurred vision. Introductory blepharitis management includes warm compresses over the eyelids to soften meibomian gland secretions and eyelid scrubs twice a day to loosen adherent eyelash debris.

Medications can be added in cases of moderate or severe disease. Topical anti-inflammatory medications include cyclosporine 0.05% and 0.09% and lifitegrast 5% which are dosed BID. Patients should be educated on the side effects of these medications, which include burning and, in the case of lifitegrast, a bitter taste. Topical steroids such as prednisolone, fluorometholone, and loteprednol (0.25% suspension) dosed QD to QID are useful in inflammatory dry eye, but should be limited to a few weeks as they can elevate intraocular pressure and promote cataract formation. Topical erythromycin or bacitracin ointment applied to the eyelids multiple times a day or at bedtime for a few weeks has been used for treatment of blepharitis. Oral medications such as doxycycline<sup>1</sup> (20 to 100 mg QOD to BID), minocycline<sup>1</sup> (50 mg QD to BID) and azithromycin<sup>1</sup> (500 mg per day for 3 days in three cycles with 7-day intervals) can be used for their anti-inflammatory properties. Clinicians should keep in mind that tetracyclines are contraindicated in children younger than 8 years of age and in pregnant and nursing patients. Side effects include photosensitivity, gastrointestinal upset, and vaginitis. Azithromycin may cause arrhythmias. Initiation of omega-3 and omega-6 supplementation<sup>7</sup> has been suggested to enhance tear film quality, although more studies are required to confirm their efficacy. Patients with Sjögren syndrome or other autoimmune disorders may need more aggressive management of their underlying disorder through oral steroids or disease-modifying antirheumatic drugs (DMARDs).

Punctal occlusion is another option to improve tear volume on the ocular surface once ocular surface inflammation has been controlled. Occlusion can be achieved with dissolvable polymer plugs or more

<sup>1</sup>Not FDA approved for this indication.

<sup>7</sup>Available as dietary supplement.

durable silicone plugs. Polymer plugs are positioned deep into the canaliculus to allow for patient comfort, but they require replacement every few months. Silicone plugs are placed over the punctum opening. These are advantageous in that they can last years and be removed at any time. However, if incorrectly sized, they can self-extrude or cause ocular irritation. The largest-diameter plug should be used to avoid dislocation. Permanent punctum occlusion by thermal cautery is reserved for patients who show consistent improvement with plugs or those with severe disease. The biggest side effect of punctal occlusion is epiphora. Therefore it is highly recommended to perform a trial with silicone plugs before performing cautery because of the irreversibility of the procedure.

Various in-office procedures that warm and express the meibomian glands are available. Many involve devices that apply localized heat and massage to the eyelids. Other options include intense pulsed light (IPL) followed by manual gland expression, direct intraductal probing, and microblepharoxfoliation. These procedures can be costly, and data on long-term success are limited. Additional studies are required to confirm their efficacy.

Severe disease states may need “third-tier” treatments. Patients with Sjögren syndrome–associated dry eye disease may benefit from oral secretagogues. Although neither are approved by the U.S. Food and Drug Administration (FDA) for the treatment of dry eye, studies suggest that pilocarpine (Salagen)<sup>1</sup> dosed at 10 to 30 mg a day or cevimeline (Evoxac)<sup>1</sup> may improve symptoms, although perhaps not tear production. Side effects include excessive salivation and sweating.

Another option is autologous serum drops, which are thought to contain anti-inflammatory mediators. They have shown the most benefit in patients with Sjögren syndrome, graft-versus-host-disease, and other dry eye–related ocular surface conditions. Serum drawn from the patient is diluted to various concentrations and is dosed anywhere from four to eight times a day. The need for repeated blood draws, medication refrigeration, and out-of-pocket cost to patients are the biggest drawbacks. This treatment is not formally FDA approved, and more studies are necessary to confirm their general utility.

Scleral contact lenses have been shown to help in refractory or severe cases of dry eye. Scleral lenses are rigid and vaulted over the globe to create a chamber of fluid. This technology protects the corneal surface from eyelid trauma and exposure while constantly hydrating the eye. These lenses require consultation with a specialty-trained optometrist.

Patients with poor eyelid positioning caused by entropion and ectropion may require surgical repair. Patients with severe corneal exposure from poor eyelid closure may need eyelid reconstruction, upper-lid weight placement, tarsorrhaphy (placement of a suture through the eyelids to promote eye closure), or placement of retained amniotic membranes.

Dry eye treatment continues to evolve. There are many promising medications and devices in the pipeline that may expand options for patients in the future.

### Monitoring

Patient follow-up depends on the severity of disease and the treatments initiated. Severe disease may require weeks or months of follow-up visits. Patients should be monitored for medication side effects.

### Complications

Complications are usually limited to cases of severe dry eye. Persistent corneal epithelial defects may form and cause significant decreased vision. Such compromised corneal epithelium places the eyes at risk for microbial keratitis. Additionally, corneal stromal thinning can occur as a result of prolonged dehydration and uncontrolled inflammation. In some cases, thinning progresses and may result in corneal perforation. Both sterile and infectious keratitis may lead to loss of vision or loss of the eye itself. Therefore urgent ophthalmology referral is warranted in these cases to initiate aggressive dry eye treatment, frequent topical antibiotics, placement of corneal glue, and/or surgical rehabilitation.

## GLAUCOMA

Method of

Albert P. Lin, MD; and Kristin Schmid Biggerstaff, MD

### CURRENT DIAGNOSIS

#### Primary Open Angle Glaucoma

- Primary open angle glaucoma is an irreversible optic neuropathy typically associated with elevated intraocular pressure.
- Primary open angle glaucoma is the most common form of glaucoma, affecting over three million Americans. It is more common in African Americans (6% to 7%), Asians (2% to 3%), and Hispanics (2%) and less common in whites (1%). It is more common in older adults: 1 to 2% in 50-year-olds compared with 6% to 12% in 80-year-olds.
- Primary open angle glaucoma is diagnosed by a complete ophthalmic examination, including dilated stereoscopic optic nerve examination and formal visual field.
- Untreated primary open angle glaucoma can lead to slow irreversible loss of vision and blindness. Other common causes of slow and progressive vision loss in older adults include cataracts, macular degeneration, and diabetic retinopathy.

#### Acute Angle Closure Glaucoma

- Pupillary block in susceptible patients leads to block of aqueous drainage and sudden and extreme rise of intraocular pressure. Acute angle closure can damage the optic nerve, resulting in acute angle closure glaucoma.
- About 0.5% to 1.0% of US adults are at risk for acute angle closure. It is more common in Inuits and Asians and rare in African Americans. The risk of acute angle closure increases with age. It is also more common in hyperopes.
- Patients can present with blurry vision, red eye, pain, headache, nausea, or vomiting. Acute angle closure is sometimes misdiagnosed as migraines or gastrointestinal illnesses. Patients with conjunctivitis, keratitis, uveitis, and corneal abrasion can also present with the same symptoms.
- Peripheral iridotomy prevents acute angle closure in susceptible patients. High intraocular pressure can result in irreversible damage of the optic nerve within hours, making acute angle closure one of the true ophthalmic emergencies.

### CURRENT THERAPY

#### Primary Open Angle Glaucoma

- Topical eye drops, including  $\beta$ -blockers, selective  $\alpha_2$  agonists, carbonic anhydrase inhibitors, prostaglandin analogues, and rho kinase inhibitors, can be used to reduce intraocular pressure.

<sup>1</sup>Not FDA approved for this indication.

- Oral carbonic anhydrase inhibitors are typically used in recalcitrant cases until surgery can be performed.
- Laser trabeculoplasty may be used as first-line or adjunct therapy.
- Glaucoma surgery, including trabeculectomy, tube shunt, and cyclodestruction, may be performed if goal intraocular pressure cannot be reached with medical therapy or in nonadherent patients.

#### Acute Angle Glaucoma

- All glaucoma eye drops are used to reduce intraocular pressure.
- Oral and intravenous medications are added sequentially to reduce intraocular pressure as needed.
- Laser iridotomy can be performed as prophylactic treatment or acutely to break the pupillary block if the patient is unresponsive to medical intervention.
- Emergency glaucoma incisional surgery is performed if the patient is unresponsive to all other treatments.

Glaucoma is an optic neuropathy with characteristic optic nerve head appearance: narrowing of the neuroretinal rim. The optic nerve is a collection of more than 1 million axons from the retinal ganglion cells. The anterior 1-mm portion of the optic nerve within the globe is referred to as the *optic disk* or simply the disk. When the disk is examined with direct or indirect ophthalmoscopy, a cup, or a physiologic empty space, is observed centrally. The remainder of the disk, which has a yellow-orange appearance, contains the axons and is referred to as the *neuroretinal rim*. The area of the cup compared to the entire disk is the cup-to-disk ratio, which is normally less than 0.4 (Figure 1A). When patients develop glaucoma, axons are lost from the neuroretinal rim and the size of the cup increases in relation to the disk. Narrowing of the neuroretinal rim and increased cup-to-disk ratio are the hallmarks of glaucomatous optic neuropathy (see Figure 1B).

Glaucoma can result in significant and irreversible loss of vision and is one of the leading causes of blindness in the United States. Early in the disease state, glaucoma is asymptomatic; it is sometimes called “the sneak thief of sight.” As the disease progresses, the patient develops decreased peripheral vision and eventually loss of the central vision.

Glaucoma is typically associated with increased intraocular pressure (IOP), but it is possible to have normal-tension or low-tension glaucoma. Glaucoma treatment is focused on the reduction of IOP to prevent or slow optic nerve damage and preserve visual function.

Glaucoma is classified in many ways, and it is most useful to approach it clinically based on the status of the angle, the area between the cornea and iris where aqueous humor exits the globe through the trabecular network. We further discuss primary open angle glaucoma, the most common form of glaucoma in the United States, and the management of acute angle closure, one of the true ophthalmic emergencies.

### Primary Open Angle Glaucoma

Glaucoma is one of the leading causes of blindness in older adults, especially in patients of African American descent. Vision loss from glaucoma is irreversible, and the treatment goal is to reduce IOP, slow disease progression, and preserve visual function during the patient’s lifetime. Glaucoma is a slowly progressive disease, and progression to blindness often takes more than 10 years, even in untreated patients. Given its slow progression and the fact that central vision loss occurs in late disease, most patients do well with early diagnosis and treatment. Treatment is more difficult in late disease because the rate of disease progression and visual deterioration is accelerated, sometimes despite good control of IOP.

Due to the early asymptomatic nature of the disease, the patient’s adherence to and persistence with treatment is often less than optimal. Studies have shown patients who obtain glaucoma information from physicians other than their ophthalmologists have a higher rate of medication adherence. Ophthalmologists have the options to use treatment modalities such as laser and surgery to obtain pressure control and decrease or eliminate the need for medication use.

The American Academy of Ophthalmology recommends asymptomatic patients older than 40 years be referred for ophthalmic evaluation once every several years for early detection of glaucoma and other chronic eye diseases. However, the US Preventive Services Task Force found insufficient evidence to recommend for or against screening for glaucoma in adults. Risks, benefits, and cost effectiveness of screening are beyond the scope of this chapter, but symptomatic patients or patients at high risk for glaucoma (African American ethnicity and family history) might benefit from ophthalmology consultation. It is possible to diagnose glaucoma by direct ophthalmoscopy, but this is not a substitute for binocular assessment of the disk through dilated pupils and formal visual field testing. If glaucoma is suspected or diagnosed, primary care visits should include inquiries regarding glaucoma medication use, medication side effects, and the time of last eye examination. Primary care physicians can improve glaucoma outcome by promoting adherence to medication and follow-up. Glaucoma patients need to follow up with their ophthalmologists at least annually, and in severe cases every 3 months, for intraocular pressure checks.

### Treatment

#### Topical Glaucoma Medications

Topical glaucoma medications are administered once or twice daily. Patients should look up, pull down their lower eye lid, drop the medication on the inferior conjunctival cul-de-sac, and keep their eyes closed for 5 minutes. Applying gentle pressure next to the bridge of the nose to occlude the puncta can improve absorption of the medication. Medication bottle caps are color-coded by their class, and patients can usually identify their eye drops by color. Glaucoma medications are not subject to first-pass effect through the liver and

**Figure 1** Disk appearance. (A) Normal disk. Cup-to-disk ratio is less than 0.4. (B) Glaucoma. Increased cup-to-disk ratio and narrow neuroretinal rim superiorly and inferiorly (arrows).

**TABLE 1** Topical Glaucoma Medications: Carbonic Anhydrase Inhibitors

CLASS	$\beta$ -BLOCKER	SELECTIVE $\alpha_2$ AGONIST	CARBONIC ANHYDRASE INHIBITOR	PROSTAGLANDIN ANALOGUE	RHO KINASE INHIBITOR	COMBINATION
Medication	Timolol (Timoptic) Betaxolol (Betoptic) Levobunolol (Betagan)	Brimonidine (Alphagan)	Dorzolamide (Trusopt) Brinzolamide (Azopt)	Latanoprost (Xalatan) Travoprost (Travatan) Bimatoprost (Lumigan) Latanoprostene bunod (Vyzulta)	Netarsudil (Rhopressa)	Timolol/Dorzolamide (Cosopt) Timolol/Brimonidine (Combigan) Brimonidine/Brinzolamide (Simbrinza) Netarsudil/Latanoprost (Rocklatan)
Dosing	qd or bid	bid	bid	qhs	qd	bid or qd (Rocklatan)
Cap color	Yellow	Purple	Orange	Teal	White	Blue (Cosopt, Combigan), light green (Simbrinza), white (Rocklatan)
Side effects	Bradycardia, COPD, and asthma exacerbation	Allergic conjunctivitis, dry mouth, and fatigue in elderly	Stinging and bitter taste	Hyperemia, lash growth, and increased pigmentation	Hyperemia	See individual components

COPD, Chronic obstructive pulmonary disease.

can sometimes have significant systemic side effects, especially the  $\beta$ -blockers. Topical glaucoma medications are described later and summarized in [Table 1](#).

**Prostaglandin Analogues.** Latanoprost (Xalatan), travoprost (Travatan), and bimatoprost (Lumigan) are prostaglandin analogues and are color-coded by teal caps. They are administered once at bedtime but may be administered once at any time during the day to promote adherence. They decrease IOP by increasing uveoscleral outflow. Latanoprostene bunod (Vyzulta) is converted into latanoprost and nitric oxide inside the eye and decreases IOP by promoting aqueous outflow through both the uveoscleral and trabecular meshwork pathways. It is considered a prostaglandin analogue with an additional mechanism of action. Side effects are primarily local and include increased conjunctival hyperemia, increased lash growth, and possible irreversible increase in periocular and iris pigmentation.

**$\beta$ -Blockers.** Timolol (Betimol, Istalol, Timoptic), levobunolol (Betagan), and betaxolol (Betoptic) are color-coded by yellow caps. They are administered once or twice daily and decrease IOP by decreasing aqueous production. Side effects include bradycardia, exacerbation of chronic obstructive pulmonary disease (COPD) and asthma, impotence, and decreased serum high-density lipoprotein (HDL) cholesterol. Physicians need to be aware that a topical  $\beta$ -blocker is a potential cause of acute changes in cardiovascular or pulmonary status. There are several reported incidents of death following the use of topical  $\beta$ -blockers mostly due to exacerbation of asthma.

**Selective  $\alpha_2$  Agonists.** Brimonidine (Alphagan) and apraclonidine (Iopidine) belong to the class of selective  $\alpha_2$  receptor agonists, and brimonidine is more commonly prescribed; it is color-coded by purple caps. It is administered twice daily and decreases IOP by decreasing aqueous production. Allergic conjunctivitis has been reported in up to 25% of patients. Rarely, it causes dry mouth and chronic fatigue and drowsiness in the elderly.

**Carbonic Anhydrase Inhibitors.** Dorzolamide (Trusopt) and brinzolamide (Azopt) are color-coded by orange caps and are sulfa-based medications. They are administered twice daily and decrease IOP by decreasing aqueous production. This class of medication has minimal systemic side effects. However, some patients complain about transient stinging and a bitter taste in the mouth after administration. These side effects, if tolerable, are not indications for discontinuing therapy.

**Rho Kinase Inhibitors.** Netarsudil (Rhopressa) affects actin and myosin contraction and decreases IOP by increasing aqueous outflow through the trabecular meshwork. It is color coded white and administered once daily. Conjunctival hyperemia is reported in up to 50% of the patients. Ophthalmologists have also observed pinpoint

conjunctival hemorrhages and corneal verticillata (lipid deposits on the corneal epithelium) because these observations are asymptomatic and generally not reported by the patients. Compared to other medications, rho kinase inhibitor has a unique mechanism of action and is considered to be an excellent adjunct medication to lower IOP when other medications are already in use.

**Combined Topical Medications.** Timolol and dorzolamide (Cosopt) and timolol and brimonidine (Combigan) are color-coded by blue caps. Brimonidine and brinzolamide (Simbrinza) are color-coded by a light green cap. Netarsudil and latanoprost (Rocklatan) are color-coded by white caps. Combined medications decrease exposure to preservatives and can decrease irritation and problems with dry eyes. Adherence might also be improved.

#### Oral Carbonic Anhydrase Inhibitors

Oral carbonic anhydrase inhibitors include acetazolamide (Diamox), 250 mg or 500 mg given twice daily, and methazolamide (Nep tazane), 25 mg or 50 mg given twice daily. They are sulfa-based medications and decrease IOP by decreasing aqueous production. Oral carbonic anhydrase inhibitors are not commonly used today because effective topical medications are available. They are typically used on a short-term basis to achieve IOP control in acute or refractory cases. Side effects can include aplastic anemia, kidney stones, bitter taste, indigestion, paresthesia of the extremities, tinnitus, and polyuria. Clinicians need to consider the possibility of hypokalemia when patients take other diuretics to control blood pressure ([Table 2](#)). Acetazolamide may also be given intravenously.

#### Laser Trabeculoplasty

Argon or selective laser trabeculoplasty can be used to increase aqueous outflow. Laser trabeculoplasty is noninvasive and safe, and it can be performed in the office in less than 10 minutes. Compared to surgery, IOP reduction is limited, up to 25% as primary treatment, but less as an adjunct modality. It is ineffective or less effective in some patients with light trabecular meshwork pigmentation. The effect of laser decreases over time but may be repeated in the case of selective laser trabeculoplasty.

#### Surgery

The most commonly performed conventional glaucoma surgeries are trabeculectomy, tube shunt, and cyclodestruction. Trabeculectomy (with or without Xen gel stent) and tube shunt are procedures that create an opening in the sclera to increase aqueous outflow. Cyclodestruction destroys the ciliary body and decreases aqueous production. The procedure can be transscleral or endoscopic; the endoscopic method is typically done at the time of cataract surgery.

**TABLE 2** Oral and Intravenous Glaucoma Medications

	ACETAZOLAMIDE (DIAMOX)	METHAZOLAMIDE (NEPTAZANE)	MANNITOL (OSMITROL)	GLYCERIN 50% <sup>1</sup>
Class	CAI	CAI	Hyperosmotic	Hyperosmotic
Dosage	250 or 500 mg bid	25 mg or 50 mg bid	1 g/kg in 30 min	1 g/kg once
Route	PO or IV	PO	IV	PO
Side effects	Bitter taste, indigestion, paresthesia, tinnitus, polyuria, kidney stones, hypokalemia, aplastic anemia, and sulfa allergy		Polyuria, dehydration Exacerbate CHF and diabetes (glycerin)	

CAI, Carbonic anhydrase inhibitor; CHF, congestive heart failure  
<sup>1</sup>Not FDA approved for this indication.

Alternative surgical methods such as deep sclerectomy, Trabectome, canaloplasty, iStent, Kahook dual blade, Hydrus, and trabeculotomy (GATT, Trab 360, OMNI) are performed at the time of cataract surgery to minimize the invasiveness and potential complications associated with traditional glaucoma surgery. However, these minimally invasive glaucoma surgeries (MIGS) are not as effective at lowering the IOP.

### Visual Impairment and Blindness

Patients who are visually impaired (Snellen vision of <20/40) or legally blind (Snellen vision of <20/200 or visual field of <20 degrees) may have significantly decreased mobility and ability to function. Continued glaucoma treatment is still important in these patients because even maintenance of count-finger vision can allow the patients some degree of independence. Low-vision devices and services, including high-contrast video magnifiers, audiobooks, eccentric viewers, and mobility training, can allow patients maximal use of their residual vision and improve their confidence and quality of life.

### Acute Angle Closure Glaucoma

Pupillary block in susceptible patients blocks aqueous drainage and leads to sudden and extreme rise of intraocular pressure. Acute angle closure can damage the optic nerve, resulting in acute angle closure glaucoma.

About 0.5% to 1.0% of US adults are at risk for acute angle closure. It is more common in Inuits and Asians and rare in African Americans. The risk of acute angle closure increases with age. It is also more common in hyperopes (farsightedness).

### Mechanism of Acute Angle Closure: Pupillary Block

After aqueous is produced in the ciliary body in the posterior chamber, it travels through the pupil and exits the anterior chamber through the trabecular meshwork located between the iris and the cornea. Pupillary block occurs when the iris contacts the lens and obstructs the flow of aqueous through the pupil. Increased posterior chamber pressure displaces the iris anteriorly against the trabecular meshwork and stops aqueous outflow.

Patients at risk for acute angle closure have narrow occludable angles. These patients have smaller eyes, allowing the lens to contact the iris to initiate pupillary block. The distance between the iris and the lens is the shortest when the pupil is mid-dilated. Therefore, patients who present with acute angle closure might have a history of dim light exposure (movies) or use of medications with anticholinergic properties (antihistamines, decongestants, antispasmodics). High IOP causes iris and corneal endothelial cell dysfunction, resulting in nonreactive pupil and hazy cornea, respectively. High IOP also results in inflammation and red eye, as well as severe pain, nausea, and vomiting (Figure 2). Elevated IOP can damage the optic nerve within hours, and acute angle closure needs to be treated on an emergency basis to prevent permanent loss of vision.

### Diagnosis

Patients with acute angle closure can present with blurry vision, red eye, pain, headache, nausea, or vomiting. History can

**Figure 2** Acute angle closure patient with red eye and mid-dilated and nonreactive pupil.

include hyperopia, onset after exposure to a dim environment, or taking anticholinergic medications. Examination findings include decreased vision, conjunctival hyperemia, mid-dilated, nonreactive pupil with or without an afferent pupillary defect, and increased IOP (by palpation or tonometry). Acute angle closure is sometimes misdiagnosed as migraines or gastrointestinal illness. Patients with conjunctivitis, keratitis, uveitis, and corneal abrasion can also present with the same symptoms.

### Treatment

If acute angle closure is suspected, an emergent referral to ophthalmology is indicated. If an ophthalmologist is not immediately available, the goal will be to medically control the IOP as soon as possible. One drop of topical aqueous suppressant— $\beta$ -blocker, selective  $\alpha_2$  agonist, or carbonic anhydrase inhibitor—should be administered (timolol, brimonidine, and dorzolamide) (see Table 1). The maximum dose of oral or intravenous carbonic anhydrase inhibitor is given: acetazolamide 500 mg or methazolamide 50 mg (see Table 2). The patient is placed in the supine position to allow the lens and iris to fall posteriorly. The patient is reassessed in 30 minutes, and if the condition is not improved, topical drops are repeated. If there is no improvement after another 30 minutes, a hyperosmotic, oral glycerin<sup>1</sup> 1 g/kg or intravenous mannitol (Osmitrol) 1 g/kg over 30 minutes, is administered. Hyperosmotics may be contraindicated in patients with congestive heart failure, and glycerin can cause severe hyperglycemia in diabetic patients.

An ophthalmologist can break the pupillary block by medically lowering the IOP or by performing anterior chamber paracentesis, compression gonioscopy, laser peripheral iridotomy, and, in recalcitrant cases, emergent trabeculectomy. Once the pressure is controlled, it is important to perform an iridotomy in both eyes to prevent future episodes. Patients with patent iridotomies may safely take anticholinergic medications.

<sup>1</sup>Not FDA approved for this indication.

## MÉNIÈRE'S DISEASE

Method of

Terry D. Fife, MD

### CURRENT DIAGNOSIS

- Ménière's disease is characterized by recurrent attacks of severe vertigo, nausea, and vomiting typically lasting 1 to 6 hours.
- Ménière's disease causes tinnitus on the side of the affected ear; the tinnitus can change in pitch and loudness during attacks of vertigo.
- Attacks of vertigo are associated with reduced or muffled hearing on the side of the affected ear.
- Fluctuating unilateral hearing loss and low-frequency hearing loss on the side of the affected ear is characteristic.

### CURRENT THERAPY

- Initial therapy includes a sodium-restricted diet (preferably <1500mg of sodium daily) and a diuretic agent (e.g., thiazide diuretics).
- Betahistine,<sup>1</sup> a medication widely used in Europe that may be obtained at compounding pharmacies in the United States, may be helpful in selected patients at a dosage 16 to 48 mg three times daily though some authors have recommended even higher dosages.
- Transtympanic infusion of gentamicin<sup>1</sup> or corticosteroids and endolymphatic sac surgery may be considered as minimally invasive options in patients with serviceable hearing. Gentamicin poses a moderate risk of inducing hearing loss.
- Vestibular nerve sectioning is highly effective in stopping vertigo attacks with a reasonably low risk of causing further hearing loss, but it is a more invasive procedure.
- Labyrinthectomy is highly effective in stopping vertigo attacks but causes complete hearing loss, so it is only an option for patients who have already lost all useful hearing.

Patients who have undergone procedures that cause acute loss of vestibular function often have vertigo for a while after the surgery; the vertigo improves more quickly with vestibular rehabilitative therapy.

<sup>1</sup>Not FDA approved for this indication.

Ménière's disease is a disorder of the inner ear that results in recurrent, spontaneous episodes of vertigo, hearing loss, ear fullness, and tinnitus affecting the same ear. The hearing loss often fluctuates early in Ménière's disease, but fluctuating hearing is not always present. Eventually permanent hearing loss occurs, affecting the low frequencies initially but ultimately affecting all frequencies.

### Epidemiology

The reported prevalence of Ménière's disease varies from about 50 to 200 per 100,000. Females are somewhat more prone to Ménière's disease than males, with a female/male ratio of about 1.9:1.

### Risk Factors

Possible risk factors for later development of Ménière's syndrome include autoimmune disorders, migraine, syphilitic otitis and viral infection of the inner ear, head trauma, and a family history of Ménière's disease. Despite the emergence of COVID-19, no correlation with Ménière's is evident with infection or following vaccination (Wachova, 2021).

### Pathophysiology

The underlying mechanism is generally thought to be due to endolymphatic hydrops, a type of swelling of the endolymphatic compartment that ultimately leads to permanent damage of the inner ear structures. Possible reasons for this periodic swelling of the endolymph compartment include mechanical obstruction of endolymph flow or at least dysregulation of the electrochemical membrane potential between endolymph and perilymph compartments.

Endolymphatic hydrops appears to be the mechanism for a number of conditions that can lead to Ménière's syndrome. When no primary cause is identified, the idiopathic form of the syndrome is called Ménière's disease. When an underlying cause is found, it is referred to as Ménière's syndrome or secondary Ménière's or secondary endolymphatic hydrops. Secondary Ménière's syndrome can result from delayed endolymphatic hydrops in which symptoms come on years after a prior disorder or viral injury of the labyrinth, syphilitic otitis, autoimmune inner ear disease, and trauma.

### Prevention

There is no known way of preventing the development of Ménière's disease because it occurs in many people with no risk factors.

### Clinical Manifestations

Ménière's disease can manifest with periodic unilateral (or, less commonly, bilateral) hearing loss or isolated attacks of vertigo. Not uncommonly, Ménière's disease has both elements present at its onset, but the vertigo is usually the symptom that gets the most attention. Vertigo usually lasts 1 to 6 hours but can last as little as 30 minutes or as long as all day. Patients prone to motion sickness often report that their dizziness lasts longer because the aftereffect of vertigo lingers longer in those who are motion sensitive. Vertigo attacks in Ménière's disease are often quite severe and generally render patients unable to move around owing to the vertigo, nausea, and recurrent vomiting.

The hearing loss is usually unilateral, and patients might notice fluctuation in hearing accompanied by ear fullness and a low-pitched roaring tinnitus either before or coincident with the vertigo. If audiometry can be performed during this time, low-frequency (250–1000 Hz) hearing loss may be documented and might improve after the attack ceases. This signature fluctuating low-frequency sensorineural hearing loss is very helpful (Figure 1) when found, but getting patients with vertigo attacks in for testing while they are in the acute stage of vertigo is usually not feasible.

Occasionally, patients with Ménière's have sudden random drop attacks in which they abruptly fall without loss of consciousness. These spells, referred to as otolithic crises of Tumarkin, can lead to serious injury and should prompt aggressive treatment. The mechanism is presumed to be related to sudden mechanical deformation or sudden neural discharges related to the otolith structures of the inner ear. Because there is no specific treatment for Tumarkin crises, treatment entails the standard treatments for Ménière's disease in general.

## RIGHT-SIDED MÉNIÈRE'S DISEASE

**Figure 1** Audiogram showing typical low-frequency hearing trough of Ménière's disease affecting the right ear.

As Ménière's disease progresses, usually over months to years, permanent low-frequency hearing loss develops that gives way to hearing loss at all frequencies. Eventually, the patient can lose all or most hearing on the affected side. Meanwhile, with each vertigo attack, some vestibular function is lost, and so as vertigo attacks continue, vestibular loss ensues, often paralleling the hearing loss. Ménière's occasionally burns out, meaning that enough vestibular function has been lost that acute hydrops no longer produces vertigo. Patients might report less severe dizziness or just a vague feeling of unsteadiness. This usually indicates advanced Ménière's, and unilateral hearing and vestibular loss should be expected.

Bilateral Ménière's disease is present at the time of initial diagnosis in about 10% of cases and by 10 years of symptoms, about 35% have bilateral involvement. Bilateral Ménière's disease has treatment implications because treating one side alone will be unlikely to stop the vertigo attacks, which could be emanating from the untreated side. Surgical treatment of both sides is also problematic because it could leave the patient with bilateral hearing loss, vestibular loss, or both.

### Diagnosis

The diagnosis of Ménière's disease is made clinically based on unilateral hearing loss, tinnitus, ear fullness, and episodic vertigo typically lasting 1 to 6 hours. The criteria for definite, probable, and possible Ménière's disease are listed in [Box 1](#). Recent studies using three-dimensional fluid-attenuated inversion recovery (3D-FLAIR) 24 hours after administration of bilateral intratympanic gadolinium (Gd) injection and similar techniques have demonstrated abnormalities consistent with endolymphatic hydrops. MRI at this point, however, is not yet established as useful in affirming the diagnosis of Ménière's disease.

### Differential Diagnosis

Vestibular neuritis causes a single attack of vertigo, sometimes with acute hearing loss (labyrinthitis), but it can usually be distinguished from Ménière's disease because vestibular neuritis has a lifetime recurrence rate of only 2%, whereas Ménière's vertigo attacks recur multiple times and cause fluctuating and gradual decline in hearing.

When a patient reports episodic vertigo attacks in the absence of unilateral tinnitus, ear fullness, and hearing loss, one must be cautious in diagnosing Ménière's disease because vestibular migraine

### BOX 1 Diagnostic Criteria for Ménière's Disease

#### Definite Ménière's Disease

1. Two or more spontaneous attacks of vertigo, each lasting 20 minutes to 12 hours
2. Audiometrically documented low- to mid-frequency SNHL in the affected ear on at least 1 occasion before, during, or after 1 of the episodes of vertigo
3. Fluctuating aural symptoms (hearing loss, tinnitus, or ear fullness) in the affected ear
4. Other causes excluded by other tests

#### Probable Ménière's Disease

1. At least 2 episodes of vertigo or dizziness lasting 20 minutes to 24 hours
2. Fluctuating aural symptoms (hearing loss, tinnitus, or fullness) in the affected ear
3. Other causes excluded by other tests

Basura GJ, Adams ME, Monfared A, et al: Clinical practice guideline: Ménière's disease, *Otolaryngol Head Neck Surg* 162:415–434, 2020.

(basilar-type migraine) can produce a similar pattern. Diagnostic criteria have been published for vestibular migraine (Lempert, 2013).

Benign paroxysmal positional vertigo causes brief recurrent spells of spinning without hearing loss, so it is rarely confused with Ménière's disease.

Vertebrobasilar insufficiency can cause isolated vertigo, but the duration is usually only several minutes and without hearing loss, whereas Ménière's attacks last hours and are associated with unilateral auditory symptoms.

Acoustic neuroma (vestibular schwannoma) typically leads to slowly progressive unilateral sensorineural hearing loss, but vertigo is infrequently a prominent feature because patients compensate gradually as their vestibular function wanes due to compressive effects of the tumor.

Fluctuating unilateral hearing loss, ear fullness, and tinnitus can occur without vertigo and is referred to as cochlear hydrops. Such symptoms can precede the development of vertigo but may be treated as Ménière's nonetheless. Lermoyez's syndrome refers to transiently improved hearing and tinnitus during attacks of

vertigo. More commonly, however, hearing declines around and during vertigo spells.

## Treatment

### Medical Management

Treatment of Ménière's disease is mainly aimed at preventing the vertigo attacks, but no treatments are known that reliably restore or arrest hearing loss or tinnitus. It is presumed that if attacks of vertigo, ear fullness, fluctuating hearing, and tinnitus are all stopped, hearing should stabilize, but this is still a supposition. The management of Ménière's is hierarchical, starting with a low-sodium diet and a diuretic and proceeding to more-invasive or destructive surgical procedures only when initial medical treatment fails. When a patient has very frequent vertigo attacks and is disabled, more-aggressive treatment may be considered sooner.

Dietary sodium should be restricted to 1000 to 1500 mg daily. The average person consumes about 4000 mg daily, and the maximum recommended daily intake of sodium is 2300 mg. Because more than 70% of the daily sodium comes from processed foods, this dietary restriction generally requires more than simply stopping the use of table salt, which generally accounts for only about 10% of daily sodium intake for most people.

A diuretic is usually added to the sodium restriction. The most commonly prescribed diuretic is hydrochlorothiazide 25 mg combined with triamterene 37.5 mg (Dyazide)<sup>1</sup> because this combination usually obviates the need for potassium supplementation. Acetazolamide (Diamox)<sup>1</sup> 125 to 250 mg bid or furosemide (Lasix)<sup>1</sup> 10 to 20 mg daily are also options. Patients with severe sulfa allergy can use low-dose ethacrynic acid (Edecrin)<sup>1</sup> 12.5 to 25 mg daily.

An acute attack of vertigo from Ménière's disease can be managed with vestibular suppressants such as dimenhydrinate (Dramamine)<sup>1</sup> 50 mg, meclizine (Antivert) 25 to 50 mg, diazepam (Valium)<sup>1</sup> 2 to 5 mg, or promethazine (Phenergen)<sup>1</sup> 12.5 to 50 mg. Scopolamine in patch form (Transderm-Scōp)<sup>1</sup> is too slow to be useful because it takes hours to be absorbed transdermally. Scopace (oral scopolamine) has been discontinued and is no longer being manufactured in the United States. Scopolamine tablets<sup>1</sup> may be available in certain compounding pharmacies. Nausea can additionally be managed with prochlorperazine (Compazine) 10 mg orally or 25 mg by suppository, with oral or sublingual ondansetron (Zofran)<sup>1</sup> 4 to 8 mg, or with other antiemetics. Generally, the vertigo attacks subside in several hours even without treatment.

Betahistine hydrochloride or dihydrochloride<sup>2</sup> may also be helpful in Ménière's, although it is not commonly used in the United States. The role of betahistine is not firmly established, although it is widely prescribed for vertigo throughout the world. Betahistine may be helpful when successful medical management with diet and diuretics has helped but is inadequate to stop attacks. Betahistine is a vasodilator, a modest H<sub>1</sub> histamine agonist, and a powerful H<sub>3</sub> histamine receptor antagonist. Its method of action in Ménière's is unknown, though it may influence perfusion of the stria vascularis to reduce pressure in the endolymphatic space. Doses of betahistine may start at 8 mg PO three times daily and may be increased to 48 mg three times daily. It is available outside the United States in the form of Serc®, Vertin®, Vertipress®, Betavert® and many other trademarks throughout the world. Betahistine may be made within the United States at compounding pharmacies with a physician prescription<sup>1</sup> and may also be imported from outside the United States for personal use. This is often done using an encapsulated powder form of betahistine dihydrochloride USP (from manufacturers such as Fagron, Inc., St. Paul, MN USA) by weight in capsules with or without filler. Side effects are few, although occasionally

patients report some gastrointestinal upset or mild headache. Betahistine is not histamine, and has not been found to cause or aggravate urticaria.

Oral corticosteroids are often used but rarely seem effective except in cases of bilateral Ménière's resulting from autoimmune inner ear disease (AIED). Oral corticosteroids rarely seem to be effective in typical Ménière's disease.

Ménière's attacks have been said to be triggered by caffeine, chocolate, stress, visual stimuli, and dropping barometric pressure. Such triggers should be avoided when possible, but strong associations with these triggers can also occur in migrainous vertigo. Vestibular rehabilitative therapy is not generally helpful in Ménière's because most vertigo attacks remit and the patients have few vestibular symptoms between attacks. However, when vestibular loss has occurred and the patient appears to have not compensated well for it, vestibular rehabilitation can be helpful.

### Bilateral Ménière's Disease

The estimated incidence of bilateral Ménière's disease varies in the literature but is estimated to occur in about 15% of cases and bilateral involvement increases over time. The possibility of bilateral involvement weighs on the decision-making for any procedures that sacrifice hearing or vestibular function because it leaves the patient with only one functioning labyrinth.

### Serviceability of Hearing

Serviceable hearing is residual hearing that can be useful to the patient by wearing hearing aids. In general, because hearing loss is permanent, one should avoid sacrificing any serviceable hearing.

### Injections and Surgical Treatments

Patients who continue to have disabling vertigo despite a low-salt diet, diuretics, and possibly betahistine are considered to have failed conservative medical therapy. The next step in treatment depends on the age, health status, and residual hearing and vestibular function of the patient and also on the surgeon's opinion and experience with the various options. If spells are infrequent, symptomatic management of vertigo attacks may be the best option. Table 1 outlines some of the additional interventional options.

### Intratympanic Gentamicin

Transtympanic gentamicin (Garamycin)<sup>1</sup> administration has become increasingly used as an effective treatment of Ménière's disease. This is partly due to the ease of administration of gentamicin and its relative safety. Gentamicin is a commonly used aminoglycoside antimicrobial agent with activity against gram-negative bacteria that also happens to be ototoxic. It damages hair cells of the labyrinth and preferentially affects hair cells of the vestibular neuroepithelium over that of the cochlea. Even so, transtympanic administration still has some risk of causing hearing loss. Gentamicin is administered by injecting a small amount (usually about 0.5 mL) of gentamicin sulfate (80 mg/2 mL) solution through the tympanic membrane into the middle ear space. To avoid rapid drainage through the eustachian tube, the injection is done with the patient supine and kept in that position for an hour or so to allow the gentamicin to absorb through the round window into the inner ear. There are many protocols, but commonly an injection is given once, and additional injections can be considered every 3 to 4 weeks until improvement in vertigo attacks is realized. Studies suggest that intratympanic gentamicin is an effective treatment for vertigo complaints in Ménière's disease but there is some risk of hearing loss.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Procedures Used in the Management of Ménière's Disease

METHOD	TECHNIQUE	ADVANTAGES	DISADVANTAGES
<b>Procedures Intended to Spare Serviceable Hearing</b>			
Intratympanic corticosteroids	Injection of steroid through the tympanic membrane to the middle ear to be absorbed in the inner ear	Minimally invasive, few side effects	Effectiveness unclear when compared to placebo
Intratympanic gentamicin (Garamycin) <sup>1</sup>	Injection of gentamicin through the tympanic membrane to the middle ear to be absorbed in the inner ear	Simple office-based procedure, low risk profile	Number of injections is unpredictable; some risk of hearing loss
Endolymphatic mastoid shunt	Placing a shunt from the endolymphatic sac to the mastoid air cells	Effective in 50%–75% of cases; low risk of hearing loss; day procedure	Vertigo can recur; effectiveness depends on surgical experience and technique
Vestibular neurectomy	Surgical sectioning of the vestibular part of cranial nerve VIII, sparing the auditory part of the nerve	Highly effective in eliminating vertigo attacks	Requires general anesthesia; risk of facial weakness, hearing loss
<b>Procedures Expected to Eliminate Residual Hearing</b>			
Labyrinthectomy or cochleosacculotomy	Several methods of removing all or part of the labyrinth	Highly effective in stopping vertigo attacks	Inevitable complete hearing loss

<sup>1</sup>Not FDA approved for this indication.

### Endolymphatic Sac Surgery

Another option for patients with residual functional hearing is endolymphatic sac shunt or decompression. This procedure eliminates vertigo in 50% to 75% of those treated. Nevertheless, its effectiveness compared with placebo has remained a point of contention based on a number of studies. It has been suggested that the procedure's effectiveness depends on the operative technique and experience of the surgeon.

### Intratympanic Steroids

Sometimes, a trial of intratympanic corticosteroids may be offered (Basura, 2020), although its effectiveness in controlled trials is still not compelling. Even so, a trial of corticosteroids administered in this manner poses little risk.

### Vestibular Neurectomy

The most definitive procedure for stopping vertigo attacks in Ménière's when the goal is to preserve hearing is vestibular neurectomy. This procedure involves craniotomy and severing the vestibular nerve while preserving the cochlear nerve. This procedure requires overnight hospitalization and general anesthesia, and it does pose some risk to facial nerve function and hearing on the affected side.

### Labyrinthectomy

For patients who have unilateral Ménière's disease and no serviceable hearing, labyrinthectomy is a commonly used procedure. This procedure entails the removal of the membranous labyrinth and is highly effective in stopping recurrent vertigo attacks from that ear. In elderly patients or those who are poor surgical candidates, a more limited transtympanic cochleosacculotomy may be performed.

### Meniett Treatment

The Meniett device is a portable, low-frequency, pressure-wave delivery system that administers a wave of pressure of about 12 cm H<sub>2</sub>O to the middle ear via a tympanostomy tube for about 0.6 seconds pulsed at 6 Hz for 5 minutes about three to five times daily. Quality randomized trials demonstrating effectiveness of this treatment are lacking, and it is recommended by a recent evidence-based guideline that this treatment should NOT be prescribed (Basura, 2020).

### Monitoring

Following patients with Ménière's disease should include monitoring of the frequency and severity of vertigo spells and the fluctuation in hearing, ear fullness, and tinnitus. Periodic audiometry is probably the most sensitive measure of stabilization of the condition. Vestibular testing may be considered when changes might alter the treatment strategy. Brain imaging is only helpful in excluding other disorders, but does not yet have an established role in the management of Ménière's disease.

### Complications

Known complications include the progression of unilateral and occasionally bilateral hearing and vestibular function. There may also be complications associated with some of the treatments as described earlier. Owing to the unpredictability of the vertigo attacks, many patients avoid certain activities and might even develop agoraphobic features because the attacks are so severe and disruptive. In most cases, these avoidance behaviors improve if Ménière's disease can be controlled.

### Conclusion

The management of Ménière's disease is still part art and part science. Treatment options are many, but patients should be reassured that, in most cases, something can be offered to help improve their vertigo and quality of life.

## OTITIS EXTERNA

Method of

Kimberly Williams, MD

### CURRENT DIAGNOSIS

- Pain, itching, or fullness of the ear
- Tenderness of tragus, pinna, or both
- Onset <48 h
- Physical examination findings of erythema, edema, ± drainage and debris

### CURRENT THERAPY

- Aural toilet
- Topical antimicrobials
- Analgesic treatment

Otitis externa is an inflammation of the ear canal and can be either acute or chronic. It is often called swimmer's ear.

### Epidemiology

Acute otitis externa is a common problem seen in the primary care office. The annual incidence falls between 1:100 and 1:250 with a lifetime incidence approaching 10%. Peak incidence is in children 7 to 12 years old. It does appear to have a genetic link, because it occurs more often in people with blood group type A. Chronic otitis externa affects 3% to 5% of the population.

### Risk Factors

Otitis externa is more common in warmer climates with high humidity. Increased water exposure, especially from swimming, places a person at higher risk. Other risk factors include debris from dermatologic conditions such as psoriasis, trauma due to use of hearing aids and ear plugs and abrasions from cleaning of the ear canal. Cerumen helps prevent microbial growth by providing an acidic pH; when cerumen is removed in cleaning, an environment ready for microbial growth is set up.

### Pathophysiology

Approximately 95% of acute otitis externa is due to bacterial infection (Figure 1). The other 5% can be attributed to fungal infections or, less commonly, herpes zoster. Fungal infection is more common in chronic otitis externa. Of the bacterial infections, 20% to 60% are due to *Pseudomonas aeruginosa*. *Staphylococcus aureus* is the next major causative organism. Gram-negative organisms account for 2% to 3% of bacterial infections.

### Prevention

Prevention is aimed at avoiding water accumulation and retention in the ear canal. Using ear plugs while swimming and using a hair dryer to dry the ear canal after water exposure can be beneficial. The use of acidifying eardrops, such as acetic acid 2% (Vosol), before and after swimming can also help prevent otitis externa. Other preventive measures include stopping the removal of cerumen and avoiding trauma to the ear canal. Finally, proper treatment of dermatologic conditions such as eczema and psoriasis can help reduce debris that can be a risk factor for infection.

### Clinical Manifestations

Otitis externa usually develops rapidly over 1 to 2 days. Most patients complain of a feeling of ear pain, fullness, or itching. Hearing loss may be another symptom. Key physical examination findings include tenderness on palpation of the tragus, discomfort with traction on the pinna, edema of the ear canal, and erythema of the canal. Pain may be out of proportion to examination findings.

**Figure 1** Acute otitis externa with the canal somewhat narrowed from edema and obstructed by desquamating epithelium, soft cerumen, and purulent discharge; this must be removed to visualize the tympanic membrane and to allow ototopical therapy to penetrate to all the superficially infected areas of the canal skin. Reprinted with permission from Osguthorpe JD, Nielsen DR. Otitis externa: review and clinical update. *Am Family Physician*. 2006;76:9.

Regional lymphadenitis and cellulitis of the pinna and adjacent skin can also be present.

### Diagnosis

The diagnosis of otitis externa is made clinically by history and physical examination. The history should be positive for otalgia, itching, or sense of fullness. The exam should be positive for tenderness if the tragus is palpated or if the pinna is pulled up and out. If the cause is bacterial, purulent drainage is usually present. Otoscopy will show diffuse canal edema, usually present with erythema. Often there will be copious amounts of debris. Debris should be cleared to visualize the tympanic membrane. There should be good mobility of the tympanic membrane and the tympanometry curve will be normal unless there is concomitant acute otitis media.

### Differential Diagnosis

Middle ear disease should be distinguished from external disease by ensuring that the tympanic membrane is normal. Acute otitis media with perforation of the tympanic membrane may result in purulent middle ear secretions into the external ear canal. Contact dermatitis of the ear canal can mimic otitis externa, and a thorough history of exposure to metals such as nickel and copper, chemicals such as new soaps, topical antibiotics, detergents, cosmetics, and other irritants should be obtained. Fungal infection of the ear canal can mimic bacterial otitis externa. Fungus tends to infect the medial portion of the ear canal and has spores and filaments that can be seen both macroscopically and microscopically. Also in the differential are carcinoma of the external auditory canal, which mimics chronic infection; herpes, which is rare and forms vesicles on the outer ear canal; and radiation therapy.

### Therapy

Topical therapy is the treatment of choice in mild to moderate disease in healthy patients. The choice of topical agent is based on cost, ease of administration, and risk of side effects (Table 1). Topical aminoglycoside and fluoroquinolone antibiotics have a response rate of more than 70%. If there is a perforation of the tympanic membrane, ciprofloxacin topical solutions are preferred because of the risk of ototoxicity from aminoglycosides and neomycin. Using a topical steroid in conjunction with topical antibiotic therapy has been shown to shorten duration of ear pain. Duration of topical therapy should be 7 to 10 days. Clotrimazole 1%<sup>1</sup> may be used for superficial fungal infections of the ear canal.

<sup>1</sup>Not US Food and Drug Administration approved for this indication.

**TABLE 1** Topical Otic Preparations for Treatment of Otitis Externa.

ACTIVE DRUG	BRAND NAME	DOSING	COMMENTS
Acetic acid 2% solution with steroid	Vosol HC, Acetasol HC	q4–6h	Can sting/local irritation
Ciprofloxacin/hydrocortisone	Cipro HC	q12h	Approved if tympanic membrane is perforated
Ciprofloxacin/dexamethasone	Ciprodex	q12h	Approved if tympanic membrane is perforated
Neomycin, polymyxin B, hydrocortisone	Cortisporin Otic	q6h	Neomycin can cause local irritation, ototoxic potential
Ofloxacin	Floxin Otic	q24h	Can cause local irritation
Tobramycin <sup>1</sup>	Tobrex	q6h	Minimally irritating, ophthalmic preparation, ototoxic potential
Gentamycin <sup>1</sup>	Garamycin	q6h	Ophthalmic preparation, ototoxic potential

<sup>1</sup>Not FDA approved for this indication.

For the topical therapy to be effective, it must be delivered to the tissue of the ear canal. First, the canal must be cleared of debris. This can be done in the physician's office under direct visualization or with lavage of the ear canal using saline or hydrogen peroxide warmed to body temperature. The patient should then be instructed on the proper delivery of the ear-drops. Eardrops are administered more effectively if another person delivers the drops. The patient should lie on his or her side with the affected ear up, and drops should be placed in the ear canal until it is filled. The patient should remain on his or her side for 3 to 5 minutes. If greater than 50% of the canal is edematous, a wick made of cellulose material should be placed to facilitate delivery of the drops. The wick may fall out or can be removed by either patient or clinician once the edema has resolved.

Systemic therapy should be used in patients who are immune compromised, including those with diabetes, and in patients with surrounding cellulitis. The systemic therapy chosen should be effective against pseudomonas.

Adequate pain control is another important factor in the treatment of otitis externa. Often this can be achieved with nonsteroidal antiinflammatory medications, but opioid analgesics may be necessary, especially to remove debris. Analgesics should be used early in treatment of the disease.

### Monitoring

Patients should respond to therapy in 48 to 72 hours. If therapy fails, the clinician should evaluate adherence to therapy and ability of the drug to be delivered properly. Alternative diagnoses should be considered, including fungal infections, dermatitis, foreign bodies, and middle ear disease with perforation of the tympanic membrane. If the infection has spread outside of the ear canal, systemic therapy should be started.

### Complications

One complication of simple otitis externa is malignant otitis externa, an invasive infection of the external auditory canal causing osteomyelitis of the temporal bone. It most commonly occurs in elderly diabetic patients or the immunocompromised. Complications include meningitis, dural sinus thrombosis, cranial abscess, and cranial nerve neuropathy including facial nerve paralysis. Diagnosis may require computed tomography and cultures. Treatment includes systemic antipseudomonal antibiotics and surgical débridement. Contact dermatitis from the topical antimicrobials prescribed for otitis externa may also complicate treatment. This is due to a delayed-type hypersensitivity reaction to one or more of the components of the topical therapy. Neomycin is the most common cause, but hypersensitivity reactions can also occur from other agents including preservatives and fragrances. The reaction is characterized by pruritus, edema, and inflammation of the skin in the auditory canal. It can spread beyond the canal to the pinna and even the skin of the neck. This is treated with topical steroids and by stopping the offending agent.

## OTITIS MEDIA

Method of

Gretchen Irwin, MD, MBA

### CURRENT DIAGNOSIS

- History of acute onset of symptoms
- Middle ear effusion
  - Bulging tympanic membrane
  - Limited mobility of tympanic membrane or air fluid level visible behind tympanic membrane
- Middle ear inflammation
  - Erythema of tympanic membrane or distinct otalgia

### CURRENT THERAPY

- Watchful waiting—appropriate for children:
  - Older than 2 years of age with nonsevere illness
  - Older than 6 months of age with uncertain diagnosis and nonsevere illness
  - Older than 2 years of age with severe illness, but uncertain diagnosis
    - Need close follow-up in 48 hours
    - Consider delayed prescription
- Antibiotics
  - First-line therapy should be amoxicillin (Amoxil) 80 to 90 mg/kg/day<sup>3</sup>
  - Treat 10 days if child younger than 6 years of age, 5 to 7 days if older than 6 years of age
  - Follow up if not improving in 48 hours
- Analgesia
  - Acetaminophen (Tylenol), ibuprofen (Motrin, Advil)
  - Benzocaine in combination with antipyrine (Allergen, Auroguard), benzocaine with antipyrine and acetic acid (Auralgan)

- Antihistamines and decongestants are of no benefit
- Surgery—consider tympanostomy tubes when:
  - First acute otitis media (AOM) episode at younger than 6 months of age and child with two or more episodes in 6 months or three episodes in 24 months
  - First AOM episode at older than 12 months of age and child with three episodes in 6 months, five episodes in 12 months, or seven episodes in 24 months

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

## Epidemiology

Acute otitis media (AOM) is a common condition of childhood, with 1 in 4 children having at least one episode of AOM by 10 years of age. In fact, 86% of children will have at least one episode of AOM within the first year of life. Younger children are more likely to be affected, with a peak incidence noted between 6 and 20 months of age, likely because of the relative immaturity of the immune system and eustachian tube function. On average, \$5 billion are spent per year on office visits, lost productivity, and diminished parental quality of life as a result of AOM infections. As a result, research has focused on effective strategies both to prevent episodes of AOM and also to efficiently treat episodes that do occur.

## Risk Factors

Identifying children at risk for AOM has been an important strategy to attempt to limit instances of AOM. Unfortunately, many of the risk factors associated with AOM are not modifiable, including male sex, Native American ethnicity, presence of siblings within the home, and a family history of recurrent AOM. Additional risk factors include low socioeconomic status, premature birth, attendance at out-of-home daycare, lack of breastfeeding, and history of poor maternal health during pregnancy. Limited studies have suggested that interventions such as avoiding supine feeding or bottle propping, reducing pacifier use after the first 6 months of life, and eliminating passive tobacco exposure can help reduce the incidence; however, the evidence in which these interventions demonstrate clear impact is limited. Public health programs that encourage breastfeeding and optimal maternal health during pregnancy as well as those focused on reducing tobacco use have perhaps the best opportunity to affect AOM incidence rates. Not only are these identified risk factors for any episode of AOM, but children with these characteristics are also more likely to have recurrent AOM. Although many children will be affected in their lifetimes, those with recurrent disease are most at risk of complications leading to morbidity or mortality.

Other risk factors specifically for recurrent AOM include an early onset of the first episode and low parental education. Pathophysiology AOM has classically been associated with three bacteria, namely, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*. The introduction of pneumococcal vaccines has led to a shifting in the frequency with which each pathogen causes disease. In 1999, *S. pneumoniae* was responsible for 40% to 45% of acute otitis media, while *H. influenzae* was responsible for 25% to 30%. In 2017, the bacteria were responsible for 15% to 25% and 50% to 60% of infections, respectively. The frequency of *M. catarrhalis* infections has remained consistent at 12% to 15%. The bacteria responsible for AOM become pathogenic in the setting of eustachian tube dysfunction. A relative obstruction of the eustachian tube develops most commonly secondary to secretions from an antecedent viral upper respiratory infection or allergies, but it may result from neuromuscular conditions or abnormal anatomy. Such relative obstruction creates a negative pressure within the middle ear leading to serous effusion and secondary infection of this collection of interstitial fluid. Thus prevention of AOM is aimed at both reducing the presence of pathogenic bacteria and preventing upper respiratory infections that may create eustachian tube dysfunction. Interestingly,

during the COVID-19 pandemic, cases of otitis media in children decreased. This may be a result of infection control measures such as widespread use of masks or avoidance of healthcare as a strategy to avoid contracting COVID-19.

## Prevention

The successes of immunization programs in virtually eliminating childhood illnesses such as measles, polio, and varicella have led to great interest in the development of vaccines capable of eradicating the causative agents of AOM. Immunizations targeting the specific bacteria most commonly associated with AOM have had mixed success, however. For example, although the serotypes contained in the 7-valent pneumococcal conjugate vaccine (PCV, Prevnar) are responsible for approximately 66% of pneumococcal-related AOM, only moderate effectiveness has been noted in reducing AOM incidence among vaccinated children. After the introduction of the 7-valent PCV into practice in February 2000, the incidence of AOM decreased only 6% to 7% among vaccinated children. The 9-valent and 11-valent PCVs<sup>2</sup> have been shown to result in a risk reduction of *S. pneumoniae* isolates in children with AOM of 17% and 34%, respectively. An increase in serotype 19A has been noted that is not covered in the 7-, 9-, or 11-valent PCVs<sup>2</sup> but is included in the new 13-valent PCV (Prevnar 13). The 13-valent PCV was incorporated into the recommended childhood immunization schedule in February 2010. Since 2010, there has been a steady decline in otitis media attributable to *S. pneumoniae*. Similar vaccines are in development for *H. influenzae* and *M. catarrhalis* as causative agents of AOM. The current *H. influenzae* b vaccine (Hib) has had little impact on AOM because less than 5% of episodes are caused by the type b strain of *Haemophilus*. Instead, nontypeable *H. influenzae* is a much more common cause of AOM. Although the vaccines targeting specific bacteria that have been shown to cause AOM have been successful, so too has the influenza vaccine been shown to affect the course of AOM. In several studies, children who received seasonal influenza vaccine (Fluzone) were found to have fewer episodes of AOM than unvaccinated children. Furthermore, those who did have an AOM episode were found to use fewer antibiotics and have shorter duration of middle-ear effusion compared with unvaccinated counterparts.

With evidence that reducing the incidence of viral influenza may reduce the occurrence of secondary AOM, several other interventions aimed at reducing viral upper respiratory infection incidence have been studied for their impact on AOM rates. The use of zinc<sup>7</sup> and propolis<sup>7</sup> as agents to prevent viral upper respiratory infections, for instance, has been shown to have mixed benefit in reducing AOM in children. In multiple studies, zinc has been well tolerated with no contraindications to use identified. Zinc as a single agent has been shown to prevent AOM only when used in children younger than 5 years of age who are also malnourished. However, when combined with propolis, zinc was shown to be effective at reducing AOM episodes for children with a history of recurrent AOM. Of note, in several trials zinc did not reduce upper respiratory infection rates; rather, rates of secondary AOM alone were decreased. Although not necessarily effective as a preventive measure for all children, zinc and propolis may be an option for children with recurrent infections.

Similarly, probiotics<sup>7</sup> added to infant formula have been shown to be beneficial for some children. Although breastfeeding has been shown to be most beneficial in preventing AOM compared with formula supplementation, infant formulas supplemented with *Lactobacillus rhamnosus* GG and *Bifidobacterium lactis* Bb-12 (Enfamil Premium, Nestlé Good Start) were shown to reduce the incidence of AOM over the first 7 months and the first year. Children who received placebo formula had an incidence of AOM of 50% in the first 7 months, whereas children who received the probiotic-supplemented formula had an incidence of only 22%.

<sup>7</sup>Available as a dietary supplement.

Dietary supplementation to limit AOM is not limited to infant formulas, however. Xylitol,<sup>7</sup> a polyol sugar alcohol found in birch plants, plums, strawberries, and raspberries, has been demonstrated in several studies to be effective at preventing both dental caries and AOM, although its dosage forms make administration difficult. Xylitol is available as a chewing gum, which raises concern as a choking hazard in young children. Similarly, in its oral syrup form, xylitol must be administered five times daily to be effective. Studies of thrice-daily dosing have not been able to demonstrate the same preventive effect as dosing five times daily despite a consistent total daily dose of 10 grams per day. Furthermore, emerging evidence suggests that xylitol must be given daily to remain effective at reducing AOM episodes because prophylaxis only during winter months or use only during upper respiratory tract infections is ineffective. Of note, children who have already received tympanostomy tubes receive no prevention benefit from xylitol administration. Research is ongoing to increase physician awareness of xylitol as a possible prophylactic measure because current studies suggest less than one-half of U.S. physicians are aware of xylitol, and less than one-fourth discuss or recommend its use to patients.

Echinacea<sup>7</sup> and osteopathic manipulation have also been cited as potential prophylactic treatments, particularly for children at high risk of recurrence. However, little evidence exists that either are effective. In fact, one large study demonstrated an increased risk of AOM with echinacea use during an upper respiratory tract infection episode and no benefit to manipulation treatment. Ongoing studies are examining the use of these modalities.

### Clinical Manifestations

AOM presents with a rapid onset of symptoms that may include fever, chills, ear pain, or ear pulling. In fact, ear pulling and ear rubbing have been demonstrated to be quite sensitive for the diagnosis of AOM in the setting of a history consistent with AOM and middle ear effusion. Often, symptoms may be preceded by upper respiratory symptoms such as rhinorrhea, cough, or congestion. Children who have had tympanostomy tubes placed will likely have a far different presentation, with fever and pain being quite unlikely; rather, a thin, yellow or milky discharge may be the only sign that AOM is present.

### Diagnosis

The 2013 update of the guidelines of the American Academy of Pediatrics (AAP) for the diagnosis and treatment of AOM acknowledged that no gold standard exists for the clinical diagnosis of AOM. History and physical examination should be consistent with rapid onset of inflammation in the middle ear. Both pneumatic otoscopy and tympanometry may be useful in the diagnosis of AOM. Tympanic membranes should be evaluated for position, mobility, color, and degree of translucency using pneumatic otoscopy to assess for presence of middle ear effusion or inflammation. Moderate to severe bulging of the tympanic membrane, new onset of otorrhea without other cause, or mild bulging of the tympanic membrane with intense erythema or ear pain should prompt diagnosis of AOM. Furthermore, tympanometry may be useful in determining whether an effusion is present if the diagnosis is otherwise unclear.

One concern of physicians has been accurately diagnosing middle ear inflammation after a child has been vigorously crying. A study of 125 healthy children, age younger than 30 months, assessed the impact of crying on tympanic membrane color by performing otoscopy both before and after administering at least two immunizations. Although crying can cause a pinkening of the tympanic membrane, it should disappear when the child quiets and should be less intense than what is observed with inflammation. True middle ear inflammation results in an angry, red eardrum, not the milder, pink flush seen with vigorous crying. The presence of effusion should also help support a diagnosis of inflammation.

### Differential Diagnosis

Otitis media with effusion (OME) is often misdiagnosed as an episode of AOM. Like AOM, OME is common, with 2.2 million episodes annually, representing an estimated cost of \$4 billion. OME can also occur with a viral upper respiratory infection and may follow or precede an episode of AOM. OME differs from AOM, however, because fluid may be present in the middle ear with OME, but there are no signs of acute infection. Although OME is not associated with acute infection, it is nonetheless critical to diagnose because research has demonstrated that chronic OME is associated with hearing loss and subsequent developmental delay. In fact, OME in infancy has been shown to be associated with, on average, a 7-point reduction in IQ at 7 years of age. The cornerstone of treatment for OME is observation for 2 to 3 months to allow the effusion to clear. Avoidance of allergens and tobacco exposure that may worsen eustachian tube dysfunction is also important. Decongestants and antihistamines are not effective. If an effusion does not clear within 2 months, a single course of amoxicillin (Amoxil) or penicillin may be given.

Audiometry should be performed in all children with OME for longer than 3 months or, in the setting of language delay, learning problems or suspected hearing loss in a child with OME. If the effusion persists or if a child has multiple episodes of OME or has hearing or learning difficulties as a result of OME, surgical intervention should be considered. Initial surgical intervention for children with persistent OME should be myringotomy with placement of tympanostomy tubes. Tonsillectomy and myringotomy alone are not indicated for treatment of OME. However, adenoidectomy may have a role, particularly in children 4 to 8 years of age. Current recommendations include adenoidectomy only if repeat surgery for OME is needed. However, emerging evidence suggests that adenoidectomy may decrease the need for surgical retreatment, reduce ongoing hearing loss, and be of benefit during initial surgery for older children.

### Treatment

The treatment of AOM has been controversial in recent years. Because it is the most common childhood bacterial infection for which antibiotics are prescribed worldwide, debate continues about both the most effective regimen and appropriate time to treat AOM. On average, \$2.8 billion are spent per year on antibiotics for episodes of AOM, yet emerging evidence suggests that watchful waiting is appropriate for some children. However, schema that involve watchful waiting have not been fully embraced by U.S. physicians. Judicious use of antibiotic therapy remains key in the prevention of morbidity and mortality associated with otitis media but is not an appropriate therapy for every child. All children require analgesia of some type as well as close, scheduled follow-up, but use of observation or an antibiotic varies with severity of illness and age of the child. Treatment options are summarized in [Table 1](#).

### Treatment Options

#### Observation

For some children with AOM, observation has been shown to be an appropriate therapy that avoids the possible side effects of antibiotics, with low risk of complications developing from an untreated otitis media. Evidence suggests that 78% of AOM episodes will spontaneously resolve within the first few days of infection. In fact, for every 100 otherwise healthy at-risk children with AOM, 80 will improve within 3 days without antibiotic therapy. If the same 100 children were all treated with amoxicillin or ampicillin, 92 would improve, although 3 to 10 would develop a rash and 5 to 10 would develop diarrhea. Thus, in a typical family medicine practice, 16 children with AOM would need to be treated with antibiotics to prevent 1 child from experiencing ongoing otalgia, whereas 1 of every 24 children treated will experience harm related to therapy. Hence, the use of antibiotics is not without risk. Multiple studies have demonstrated that even in children as young as 2 months of age, many will improve without antibiotic therapy, and delaying antibiotics may prevent

**TABLE 1** Treatment Options for Acute Otitis Media

AGE OF CHILD	AOM WITH OTORRHEA		AOM WITHOUT OTORRHEA		AOM WITH SEVERE SYMPTOMS*	
	UNILATERAL	BILATERAL	UNILATERAL	BILATERAL	UNILATERAL	BILATERAL
6 months to 2 years	Antibiotics	Antibiotics	Antibiotics or observation	Antibiotics	Antibiotics	Antibiotics
>2 years	Antibiotics	Antibiotics	Antibiotics or observation	Antibiotics or observation	Antibiotics	Antibiotics

\*Severe symptoms include toxic-appearing child, persistent otalgia for >48 hours, temperature >39°C in the past 48 hours, or uncertain access to follow-up. AOM, Acute otitis media.

undesirable side effects without exposing the child to undue risk. No studies have demonstrated a resurgence of either mastoiditis or meningitis with implementation of watchful waiting for AOM. If observation is chosen as a management strategy for AOM, it is important to reevaluate the child in 48 to 72 hours to ensure that they are improving and that a rescue antibiotic is prescribed if symptoms are not resolving.

Delayed prescriptions are one strategy that has been effective at reducing antibiotic use, maintaining parental satisfaction, and improving healthcare efficiency. Physicians are often concerned that parental satisfaction will decrease if watchful waiting for an episode of AOM is recommended. Interestingly, satisfaction has been tied to the receipt of an antibiotic prescription, though not necessarily the administration of antibiotics to the child. Declines in satisfaction are noted when parents are advised to return to care in 2 to 3 days if the child is not improving while undergoing watchful waiting. By offering a delayed prescription, the parent can avoid the difficulties associated with needing to be seen again if the child fails to improve, and parental satisfaction is maintained even if the child never receives any medication. Parents should be educated that up to one-third of children who initially are treated with observation will eventually need antibiotic therapy. Although this suggests that up to two-thirds of children can avoid unnecessary antibiotics, parents should be aware that many children will go on to need antibiotic therapy. Clearly, however, not every child is a candidate for observation therapy.

### Antibiotic Therapy

Antibiotic therapy may be associated with less duration of pain, less analgesic use, and less absence for both children and parents from school and work, respectively. The AAP and the American Academy of Family Physicians in a joint position statement have recommended that, when a decision is made to use antibiotics, amoxicillin (Amoxil) be given as a first-line agent at a dose of 80 to 90 mg/kg/day.<sup>3</sup> For penicillin-allergic children, cefdinir (Omnicef), cefpodoxime (Vantin), or cefuroxime (Ceftin) may be used. Although the cross-reactivity of cephalosporins and penicillins is likely lower than previously believed, if concern exists about treating a child with a cephalosporin, clindamycin<sup>1</sup> (30 to 40mg/kg/day)<sup>3</sup> may be used. Macrolide antibiotics may have limited efficacy. Ceftriaxone (Rocephin) may be used as a single dose for a child who is unable to tolerate oral medications. Although amoxicillin continues to be the preferred first-line agent, 30% to 70% of *S. pneumoniae* strains have become penicillin and macrolide resistant, whereas 20% to 40% of *H. influenzae* has beta-lactamase-producing capabilities. Given the various resistance patterns of organisms, a child who fails to improve on amoxicillin should receive amoxicillin with clavulanate (Augmentin) or ceftriaxone as second-line therapy. Clindamycin (Cleocin) or tympanocentesis to identify a causative organism may also be considered. Current evidence continues to suggest that a 10-day course is optimal for children younger than 2 years of age. Less benefit to longer-duration therapy is noted in older children, and therefore a shorter 5- to 7-day course is recommended for those older than 2 years of age. If a child has a perforation of the tympanic

membrane, treatment considerations may be slightly different. Oral antibiotics continue to be recommended if perforation is a result of the AOM episode; however, if a child has an episode of AOM with tympanostomy tubes in place, topical 0.3% ciprofloxacin/0.1% dexamethasone (Ciprodex Otic) should be added to oral amoxicillin. Table 2 provides antibiotic dosing recommendations. Regardless of the decision to implement watchful waiting or antibiotic therapy, any child with AOM should be expected to improve within 48 to 72 hours. If improvement is not occurring, the child should be reevaluated.

### Surgery

For some children, AOM will not be an isolated event. Instead, the child will have recurrent infections and require multiple antibiotic courses throughout a year, prompting consideration of tympanostomy tube placement. Currently, referral for evaluation for tympanostomy tubes is recommended when a child has had three or more episodes of AOM within a 6-month period or more than four episodes within a 12-month period. Some have argued, however, that this recommendation should be considered within the context of the child's age at first presentation. A child who has the first episode of AOM before 6 months of age is likely to go on to have many more episodes. Ultimately, they will likely meet the criteria for myringotomy and thus may warrant a more aggressive approach from the outset. Conversely, a child who presents with a first episode of AOM as an older child is less likely to have recurrent episodes and can therefore be treated in a more conservative manner. Using an age-stratified approach, children who experience a first episode of AOM before 6 months of age should receive tympanostomy tubes if they have two episodes in a 6- or 12-month time period or three episodes in 24 months. Similarly, children who have a first episode of AOM after 1 year of age should receive tympanostomy tubes only if they have three episodes within 6 months, five within 12 months, or seven within 24 months. Referral may also occur if a child has a history of AOM associated with meningitis, facial nerve paralysis, coalescent mastoiditis, or brain abscess. Tympanostomy tubes are also often placed because of prolonged OME resulting in hearing loss and language delay. Myringotomy without tube placement may be considered for either diagnosis of an infection that has not responded to numerous antibiotics or for relief of severe otalgia. AOM episodes will continue to occur despite tympanostomy tube placement. However, episodes will likely be less severe, of shorter duration, and less frequent. In addition to ongoing AOM episodes, tympanostomy tubes can be problematic if they become clogged. New studies in animal models suggest that applying colchicine<sup>1</sup> in the external ear may prevent this complication.

### Analgesia

Regardless of a decision to pursue watchful waiting or antibiotics, analgesics are an important component in the treatment of AOM. Multiple homeopathic interventions and home remedies including application of heat, ice, or mineral oil (Min-O-Ear)<sup>1</sup> have been used for pain control, although no studies exist to verify their effectiveness. Acetaminophen (Tylenol), ibuprofen (Motrin), narcotics, and tympanostomy have all been demonstrated to be effective at reducing pain. However, the side effects of altered

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

mental status, gastrointestinal upset, and respiratory depression with narcotics as well as the skill needed to perform tympanostomy limit the usefulness of these interventions in primary care practice. Antihistamines and decongestants have often been prescribed in an attempt to reduce the fluid volume in the middle ear and hence provide relief. Unfortunately, use of antihistamines and decongestants has been shown to result in a fivefold to eightfold increase in the risk of side effects with no benefits, including no decreased time to cure, no prevention of surgery or complications, and no increased symptom resolution. Therefore antihistamines and decongestants have not been routinely recommended.

### Conclusion

AOM continues to be one of the most costly and common childhood illnesses in developed nations throughout the world. Successful management of this condition requires much more than choosing amoxicillin at an appropriate dose and duration or appropriately timing a surgical referral. Vigilant attention to modifying risk factors when possible, promoting immunization, and limiting the spread of viral illnesses has been shown to prevent AOM instances. Furthermore, adhering to diagnostic criteria to attempt to accurately distinguish between AOM and OME as well as implementing observation when appropriate can significantly reduce antibiotic usage, thereby minimizing side effects for patients and the opportunity to develop resistance in pathogens.

## RED EYE

Lynn Fisher, MD; and John N. Dorsch, MD

### CURRENT DIAGNOSIS

- Bacterial, viral, and allergic conjunctivitis can often be distinguished by the course of spread in the eye, the type of ocular discharge present, and associated symptoms.
- Subconjunctival hemorrhage can occur from trauma, increased intrathoracic pressure, anticoagulants, or idiopathically.
- Physicians should consider referring to an ophthalmologist patients with traumatic injury to the eye, loss of vision, extreme pain not explained by pathology, keratitis, suspected uveitis or glaucoma, chemical injury, or nonhealing corneal abrasion.

### CURRENT THERAPY

- Do not use eye patches in patients with corneal abrasions.
- Do not use topical anesthetics for the eye outside a clinic or hospital setting because corneal toxicity can occur.
- Patients with corneal abrasions should be reexamined the following day.
- Patients with corneal abrasions from extended-wear contact lenses often become colonized with *Pseudomonas aeruginosa* and should be treated with appropriate antibiotics (quinolones).

In the primary care office, the most common causes of red eye are conjunctivitis, subconjunctival hemorrhage, and corneal abrasions due to a foreign body. Other common causes of red eye include blepharitis and hordeolum. Less common but serious causes of red eye include viral keratitis, uveitis, scleritis, and angle-closure glaucoma. Other usually less serious causes of red eye include episcleritis, pingueculum, and pterygium. All primary care physicians should have expertise in recognizing and treating the common causes of red eye and should recognize and refer patients with higher-stakes diagnoses (Boxes 1 and 2).

### BOX 1 Approach to the Patient with Red Eye

The following questions are often helpful in making the diagnosis in patients with red eyes.

- *Is one eye or are both eyes involved?* Infections, allergy, and systemic illness are more likely to cause bilateral eye involvement.
- *Does the patient have intense eye pain?* If yes, likely diagnoses include acute angle closure glaucoma, uveitis, scleritis, keratitis, foreign body, or corneal abrasion.
- *Does the patient have a foreign body sensation?* If so, consider corneal abrasion, trauma, dry eye, keratitis, and other corneal disorders.
- *Is there a discharge?* If it is very copious and purulent, consider gonococcal conjunctivitis. If it is discolored and purulent, consider bacterial conjunctivitis. Copious watery discharge is typical of viral conjunctivitis. Stringy, mucoid discharge is typical of allergic or chlamydial conjunctivitis.
- *Do the eyes itch?* If so, consider blepharitis or allergy in the differential.
- *Are the eyelids swollen?* Consider allergy or infection.
- *Do the eyelids have lumps?* Hordeolum and chalazion should be considered.
- *Do the eyes burn?* Consider blepharitis or dry eye.
- *Is the eye redness recurrent?* Consider herpes keratitis, uveitis, and allergic conjunctivitis.
- *Does the patient have photophobia?* Corneal problems (abrasions, keratitis) and uveitis should be considered.
- *Is there loss of vision?* Consider corneal ulcer, uveitis, and angle closure glaucoma.
- *Is the patient using ocular medications?* Prolonged use of neomycin and sulfa ophthalmic medications can cause sensitization and redness of the eyes.

### BOX 2 Red Eye

#### Common Causes

- Conjunctivitis: bacterial, viral, allergic
- Subconjunctival hemorrhage
- Corneal abrasion
- Blepharitis

#### Less Common Causes

##### Less Serious

- Episcleritis
- Pingueculum
- Pterygium

##### More Serious

- Viral keratitis
- Uveitis
- Scleritis
- Angle closure glaucoma

## Physical Examination

Always check visual acuity in any patient with an eye complaint. Fluorescein strips (Flu-Glo, Fluorets), topical anesthetic drops, and cobalt blue light are used to examine the cornea for abrasions, keratitis, and ulceration. Cotton-tipped applicators are used to evert the upper eyelid and look for a foreign body.

Pupillary reaction is often affected by angle closure glaucoma and uveitis, but it is rarely affected by conjunctivitis, blepharitis, and corneal disorders. The pupil may be irregular in the patient with uveitis.

Patients with uveitis often have pain in the closed affected eye when a bright light is shined in the normal eye or with convergence of the eyes. This is due to consensual reflex of the pupils to light and accommodation.

Examine the conjunctiva by pulling the lower eyelid down with the examiner's finger. If the bulbar or palpebral conjunctivae are inflamed (i.e., hyperemic, edematous, discharge), conjunctivitis is present. Palpable preauricular nodes may be present with viral conjunctivitis and chlamydial conjunctivitis.

## Conjunctivitis

Conjunctivitis is the most common cause of red eye encountered by primary care clinicians. Among the etiologies of conjunctivitis, viral conjunctivitis is the most common. Although patients with conjunctivitis might have some minor irritation of the eyes, they usually do not complain of pain in the eye or loss of vision. Ocular discharge is generally considered to be an important diagnostic feature of conjunctivitis (Table 1). Although much has been written about characterizing conjunctivitis by the nature of the discharge, one meta-analysis failed to find evidence of the diagnostic usefulness of clinical signs or symptoms in distinguishing bacterial conjunctivitis from viral conjunctivitis.

## Viral Conjunctivitis

Viral conjunctivitis is often seen in epidemics and is most commonly caused by members of the Adenovirus family. Typically, viral conjunctivitis starts in one eye and spreads to the other eye a few days later. The conjunctivae appear red and swollen, with copious watery discharge (Figure 1). The natural course of viral conjunctivitis is self-limiting, lasting 10 to 14 days. Tender preauricular lymph nodes, when present, indicate the presence of viral or chlamydial conjunctivitis. Management should be directed at scrupulous hygiene. Patients must be informed that their infection is highly contagious. They should avoid close contact with other persons (e.g., towels, direct contact, swimming pools) for 2 weeks and wash hands or use hand sanitizer frequently to prevent the spread of their infection. Topical antibiotics have been prescribed to try to prevent bacterial superinfection, but there is no good evidence that they have any significant impact. Symptomatic treatment with cold compresses and topical vasoconstrictors may be helpful. Conjunctivitis has been reported in patients with coronavirus. If a patient has a red eye with burning and watery discharge that is also associated with fever, cough, shortness of breath, fatigue, or loss of taste/smell, coronavirus should be considered as a potential cause. Clinically significant conjunctivitis was observed in less than 4% of inpatients and 2% of outpatients with confirmed mild to moderate coronavirus from one 2020 study in a training and research hospital in Istanbul, Turkey. There is no specific treatment for conjunctivitis caused by coronavirus.

## Bacterial Conjunctivitis

Bacterial conjunctivitis typically starts abruptly in one eye and spreads to the other eye in 1 to 2 days. Usually a purulent discharge is present that persists throughout the day. A variety of gram-positive and gram-negative organisms cause bacterial conjunctivitis, but the most common causes are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus pneumoniae*. Treatment of bacterial conjunctivitis is usually empiric, but conjunctival scraping for smears and cultures should be done in infants, immunocompromised patients, and patients

**TABLE 1** Conjunctivitis

TYPE	COURSE	CHARACTERISTICS	DISCHARGE
Bacterial	Starts in one eye, often spreads to other eye		Purulent
Allergic	Accompanies allergic rhinitis	Itchy eyes	Mucus
Viral	Usually bilateral	Very red eyes	Watery

**Figure 1** Viral conjunctivitis. Reproduced with permission from the University of Michigan Kellogg Eye Center, <https://www.kellogg.umich.edu>.

with hyperacute conjunctivitis in which *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection is suspected. Treatment of bacterial conjunctivitis (excluding gonococcal or chlamydial conjunctivitis) usually consists of a topical antibiotic used four times a day (Table 2). Topical antibiotics are usually prescribed for 5 to 7 days, and resolution of conjunctivitis is expected within that time.

Hyperacute bacterial conjunctivitis has an abrupt onset, copious purulent discharge, and rapid progression, and it is usually associated with gonococcal infection in a sexually active patient. Chemosis (edema of the conjunctivae) may be present.

Chlamydial conjunctivitis is acquired through exposure to infected secretions from the genital tract, either direct or indirect. The infection is usually unilateral (at least initially), and often there is involvement of the preauricular node on the ipsilateral side. Gonococcal and chlamydial infections are treated systemically (Box 3).

### Conjunctivitis of the Newborn

Chlamydial conjunctivitis is the most common cause of infectious conjunctivitis of the newborn in the United States. Onset of conjunctivitis is 3 to 10 days after birth, but it has been reported as late as 2 months after birth. Erythromycin ointment (Ilotycin 0.5%) or tetracycline ointment<sup>2</sup> given shortly after delivery is effective in preventing chlamydial conjunctivitis but not systemic chlamydial infections. *Chlamydia trachomatis* infections, causing pneumonia and otitis media, can be treated either with ethylsuccinate (EryPed Drops) orally 50 mg/kg/day in four divided doses for 14 days or azithromycin (Zithromycin)<sup>1</sup> 20 mg/kg/day orally up to 1 g daily for 3 days. Chlamydial infections of rectal and urogenital sites can only be treated with erythromycin ethylsuccinate orally 50 mg/kg/day in four divided doses for 14 days.

Gonococcal conjunctivitis of the newborn is a hyperacute infection that occurs 2 to 4 days after birth. It can cause corneal ulceration and loss of vision. Gonococcal conjunctivitis can be prevented with silver nitrate drops<sup>2</sup> or erythromycin (Ilotycin) or tetracycline ointment<sup>2</sup> administered shortly after delivery. Silver nitrate commonly causes a self-limited chemical conjunctivitis, which can delay visual bonding of the infant to the parents in the

<sup>2</sup>Not available in the United States.

**TABLE 2** Topical Antibiotics Used to Treat Bacterial Conjunctivitis

DRUG	DOSAGE
Bacitracin (Ak-Tracin, Bacticin) ointment	Apply 0.5 inch in eye q3–4 h
Ciprofloxacin (Ciloxan) 0.3% ophthalmic solution	1–2 gtt in eye q15 min × 6 h, then q30 min × 18 h, then q1 h × 1 d, then q4 h × 12 d <sup>3</sup>
Gatifloxacin (Zymar) 0.5% ophthalmic solution	1 gtt in eye q2 h up to 8 ×/d on day 1, then 1 gtt 2–4 ×/day on day 2–7
Gentamicin (Gentak, Gentasol) 0.3% ophthalmic solution or ointment	Ointment: 0.5 inch applied to eye 2–3 times per day Solution: 1–2 gtt in eye q4 h
Levofloxacin (Quixin) 0.5% ophthalmic solution	1–2 gtt in eye q2 h × 2 d while awake, then q4 h while awake × 5 d
Moxifloxacin (Vigamox) 0.5% ophthalmic solution	1 gtt in eye tid × 7 d
Neomycin/polymyxin B/gramicidin (Neosporin) ophthalmic solution	1–2 gtt in eye q4 h × 7–10 d
Ofloxacin (Ocuflox) 0.3% ophthalmic solution	1–2 gtt in eye q2–4 h × 2 d, then 1–2 gtt in eye qid × 5 d
Polymyxin B and trimethoprim (Polytrim) ophthalmic solution	1 gtt in eye q3 h × 7–10 d
Sulfacetamide (Isopto Cetamide, Ocusulf-10, Sodium Sulamyd, Sulf-10, AK-Sulf) 10% ophthalmic solution, ointment	Ointment: 0.5-inch ribbon in eye q3–4 h and q h × 7 d Solution: 1–2 gtt in eye q2–3 h × 7–10 d
Tobramycin (AK-Tob, Tobrex) 0.3% ophthalmic solution	1–2 gtt in eye q4 h

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

### BOX 3 Treatment of Chlamydial and Gonococcal Conjunctivitis

#### Chlamydial Conjunctivitis

- Doxycycline (Vibramycin) 100 mg PO bid × 7 days
- Or
- Azithromycin (Zithromax) 1 g PO X 1
- Treat partners

#### Gonococcal Conjunctivitis

- Ceftriaxone (Rocephin) 1 g IM x 1 in patients ≥150 kg, or 500 mg IM x 1 in patients <150 kg)
- Azithromycin (Zithromax) 1 g PO x 1

first few hours of life. Gonococcal conjunctivitis of the newborn is treated with Ceftriaxone (Rocephin) 25 to 50 mg/kg up to 125 mg IM/IV.

#### Conjunctivitis–Otitis Media Syndrome

Conjunctivitis–otitis media syndrome is a common condition in which children with otitis media also have purulent bilateral ocular discharge. It responds to treatment of otitis media; no topical treatment of conjunctivitis is required.

#### Methicillin-Resistant *Staphylococcus Aureus* Conjunctivitis

Increasing numbers of cases of bacterial conjunctivitis are caused by methicillin-resistant *S. aureus* (MRSA). MRSA conjunctivitis manifests as bacterial conjunctivitis resistant to conventional therapy and is treated with the same drugs

used to treat MRSA in other parts of the body (Doxycycline [Vibramycin],<sup>1</sup> vancomycin [Vancocin], sulfamethoxazole-trimethoprim [Bactrim]<sup>1</sup>). Cultures should be obtained when MRSA is suspected.

### Allergic Conjunctivitis

Allergic conjunctivitis is an immunoglobulin E (IgE)-mediated condition characterized by bilateral eye involvement, itchy eyes, and mucoid discharge. *Seasonal* conjunctivitis is caused by exposure to common allergens (e.g., pollens, dander) and usually accompanies allergic rhinitis. *Perennial* allergic conjunctivitis is similar to seasonal allergic conjunctivitis, but the symptoms are usually less severe. Patients are usually treated with a systemic antihistamine. Ophthalmic (topical) medications include antihistamine or decongestants, mast cell inhibitors, nonsteroidal antiinflammatory drugs (NSAIDs), H<sub>1</sub>-antagonists, and various combinations of these (Table 3). Milder cases can be treated with a decongestant-antihistamine combination for about 2 weeks. Moderate to more severe cases can require longer use of these medications or the addition of systemic antihistamines or mast cell inhibitors. Some patients

require topical corticosteroids or cyclosporine (Restasis)<sup>1</sup> for severe allergic conjunctivitis, but these should be evaluated by an ophthalmologist because of potential complications of therapy.

### Subconjunctival Hemorrhage

In subconjunctival hemorrhage, the redness of the eye is localized and sharply circumscribed, and the underlying sclera is not visible (Figure 2). Conjunctivitis is not present, and there is no discharge. There is typically no pain or visual change. Subconjunctival hemorrhage may be spontaneous, but it can also result from trauma, hypertension, bleeding disorders, or increased intrathoracic pressure (e.g., straining, coughing, retching). No treatment is necessary, but investigation may be warranted if the etiology is in question or the hemorrhage is recurrent. Referral to an ophthalmologist should be considered if the subconjunctival hemorrhage is from trauma or has not resolved within 2 to 3 weeks.

### Corneal Abrasion

Corneal abrasions typically result from scratching of the corneal epithelium due to trauma, but they can also occur from extended-wear contact lenses. Patients with corneal abrasions present with pain, excessive tearing from the involved eye, photophobia, a foreign-body sensation (like having sand in the eye), and blurry vision.

Corneal abrasions are identified by staining the cornea with fluorescein and examining under cobalt blue light (Figure 3). The eye should also be examined carefully to check for foreign bodies. Topical anesthetic is administered to make the patient comfortable during the examination, but continued use can cause corneal damage.

Management of corneal abrasions consists of pain relief and prevention of infection. Pain can be relieved with topical NSAIDs such as ketorolac (Acular)<sup>1</sup> and diclofenac (Voltaren),<sup>1</sup> oral over-the-counter analgesics, and occasionally oral narcotics. Topical antibiotics are usually prescribed to prevent infection. Antibiotic ointments are lubricating and soothing to the eye, making them

#### BOX 4 Patient Hygiene Measures for Conjunctivitis

- Do not wear contact lens until the conjunctivitis has cleared and resume wear with a new set. Wear and clean your contact lens as recommended by your eye doctor.
- Avoid touching the eyes and if you do, immediately wash your hands. Use a clean towel or tissue each time you wipe your face and eyes.
- Wash your hands or use hand sanitizer frequently. Always wash them before and after eating, after using bathroom, and after sneezing/coughing.
- Do not use eye makeup while an eye is infected with conjunctivitis. Replace eye makeup if the eye becomes infected and never share makeup.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Topical Medications for Allergic Conjunctivitis

GENERIC NAME	BRAND NAME(S)	DOSING	MODE OF ACTION
Azelastine 0.05% solution	Optivar	1 gtt in eye(s) bid	H <sub>1</sub> -antagonist, mast cell inhibitor
Cromolyn 4% solution	Crolom, generic	1–2 gtt in eye(s) 4–6 times per day	Mast cell inhibitor
Emedastine 0.05% solution	Emadine	1 gtt in eye(s) qid	H <sub>1</sub> -antagonist
Epinastine 0.05% solution	Elestat	1 gtt in eye(s) bid	H <sub>1</sub> - and H <sub>2</sub> -antagonist, mast cell inhibitor
Ketorolac 0.5% solution	Acular	1 gtt in eye(s) qid up to 1 week	NSAID
Diclofenac 0.1% solution <sup>1</sup>	Voltaren ophthalmic	1 gtt in eye(s) qid × 2 weeks	NSAID
Lodoxamide 0.1% solution	Alomide	1–2 gtt in eye(s) qid up to 3 months	Mast cell inhibitor
Loteprednol 0.2% susp.	Alrex	1 gtt in eye(s) qd	Corticosteroid
Naphazoline/pheniramine (solution)	<ul style="list-style-type: none"> <li>• Naphcon-A (OTC)</li> <li>• Opcon-A (OTC)</li> <li>• Visine-A (OTC)</li> </ul>	1–2 gtt in eye(s) qd-qid prn	Antihistamine, decongestant
Nedrocomil 2% solution	Alocril	1–2 gtt in eye(s) bid	H <sub>1</sub> -antagonist, mast cell inhibitor
Olopatadine 0.1% solution	Patanol	1 gtt in eye(s) bid	H <sub>1</sub> -antagonist, mast cell inhibitor
Olopatadine 0.2% solution	Pataday	1 gtt in eye(s) qd	Mast cell inhibitor

<sup>1</sup>Not FDA approved for this indication.  
NSAID, Nonsteroidal antiinflammatory drug.

**Figure 3** Corneal abrasion with fluorescein stain with cobalt blue light. Reprinted with permission from American Academy of Ophthalmology: *Managing the red eye. eye care skills for the primary care physician series*. San Francisco: American Academy of Ophthalmology, 2001.

a good option for traumatic corneal abrasions. Topical ophthalmic antibiotic ointments commonly used are bacitracin (Bacticin), erythromycin (Ilotycin), and gentamicin (Gentak).

In patients who have corneal abrasions from contact lens overwear, eyes are commonly colonized with *Pseudomonas aeruginosa*. These patients should be treated with topical antibiotics such as ciprofloxacin (Ciloxan) or ofloxacin (Ocuflex) solutions.

Patching of the eye, though a common practice of the past, has not shown evidence of benefit in recent studies. It was found that eye patching can actually cause harm, so this practice is no longer recommended.

Infrequently, patients have traumatic uveitis accompanying corneal abrasion. Traumatic uveitis usually causes significantly more pain than a corneal abrasion, and, if uveitis is suspected, the clinician should consider referral to an ophthalmologist.

Patients with corneal abrasions should be reexamined in 24 hours. Corneal abrasions typically should be healed or greatly improved in 24 hours. If the abrasion is not completely healed after 24 hours, the patient should be examined again in 2 or 3 days. Referral should be considered if any worsening occurs or if the abrasion does not heal within 5 days. Corneal abrasions can be prevented by using protective eyewear.

### Other Causes of Red Eye

Other causes of red eye are somewhat less common.

#### Blepharitis

Blepharitis are inflammatory conditions of the eyelid caused by infection or obstruction of eyelid glands (Table 4).

Blepharitis may be accompanied by conjunctivitis. Staphylococcal blepharitis arises from the accessory glands to the eyelashes and causes discharge from the eyelid, often associated with erythema, induration, loss of eyelashes, and crusting of the eyelid (Figure 4). This is treated with hot, moist packs to the eyes, baby shampoo scrubs (3 oz. water and 3 drops baby shampoo used on a washcloth bid), and erythromycin ointment (Ilotycin) at bedtime. Seborrheic blepharitis, a more chronic form of blepharitis, arises from the meibomian glands and causes scaling of the eyelids (Figure 5). Seborrheic blepharitis is often associated with skin disorders such as rosacea, eczema, and seborrheic dermatitis. This is treated with hot, moist packs and baby shampoo scrubs. Resistant cases are treated with oral tetracycline (Sumycin) (or one of its derivatives).

#### Hordeolum (Stye)

A hordeolum is an acute, painful mass of the eyelid that is caused by inflammation of the glands (Figure 6). It does not usually cause the eye to become red as well. Warm compresses to the eyelid four times a day for 3 to 5 minutes typically causes resolution within 1 week. Because they arise from the same glands, hordeola and blepharitis commonly occur together.

#### Episcleritis

Episcleritis is a self-limited inflammation of the episcleral vessels and is believed to be autoimmune. It has a rapid onset and usually minimal discomfort. Redness is most often confined to a sector of the eye. Episcleritis usually resolves in 7 to 10 days. Recurrence is not uncommon. Oral NSAID drugs may be prescribed, but treatment is usually not necessary.

#### Scleritis

Scleritis is, fortunately, much less common than episcleritis. Patients with scleritis experience intense inflammation and deep eye pain. Scleritis is commonly associated with rheumatoid arthritis and inflammatory bowel disease. The patient should be promptly referred to an ophthalmologist if scleritis is suspected.

#### Acute Angle Closure Glaucoma

Acute angle closure glaucoma is characterized by acute ocular pain and is often accompanied by vomiting, blurred vision, acute photophobia, pupils unreactive to light, and circumferential redness (ciliary flush). Treatment of glaucoma with pilocarpine (Isopto Carpine), topical timolol (Timoptic), and acetazolamide (Diamox) should be started, and the patient should be given an urgent referral to an ophthalmologist.

#### Anterior Uveitis

Uveitis is the inflammation of the iris and ciliary muscle, often associated with autoimmune disease. Trauma can also cause uveitis. Signs of uveitis include ocular pain, ciliary flush, and occasionally irregularity of the pupil. Prompt referral should be arranged for a patient in whom uveitis is suspected.

In general, referral to an ophthalmologist should be considered for the following:

- Traumatic injury to the eye
- Loss of vision
- Extreme eye pain not explained by pathology
- Keratitis
- Suspected uveitis or glaucoma
- Chemical injury (especially alkali)
- Corneal abrasion not healing

**TABLE 4** Blepharitis

TYPE	SITE OF ORIGIN	CLINICAL CHARACTERISTICS	TREATMENT

## RHINOSINUSITIS

Method of

Ann M. Aring, MD

### CURRENT DIAGNOSIS

- Because inflammation of the sinuses rarely occurs without concurrent inflammation of the nasal mucosa, rhinosinusitis is a more accurate term for what is commonly called sinusitis.
- Most cases of sinusitis are caused by viral infections associated with the common cold. Viral rhinosinusitis improves in 7 to 10 days.
- Four signs and symptoms with a high likelihood ratio for acute bacterial sinusitis are double sickening, purulent rhinorrhea, erythrocyte sedimentation rate (ESR) >10mm, and purulent secretion in the nasal cavity. A combination of at least three of these four symptoms and signs has a specificity of 0.81 and sensitivity of 0.66 for acute bacterial rhinosinusitis.
- Acute rhinosinusitis lasts up to 4 weeks, subacute rhinosinusitis lasts from 4 to 12 weeks, and chronic rhinosinusitis lasts 12 weeks or longer. Recurrent acute rhinosinusitis is defined as four or more episodes per year with complete resolution between episodes.
- Radiographic imaging in a patient with acute rhinosinusitis is not recommended unless a complication or an alternative diagnosis is suspected. Computed tomography of the sinuses without contrast media is the imaging method of choice.

### CURRENT THERAPY

- Mild rhinosinusitis symptoms of less than 7 days' duration can be managed with supportive care including analgesics, saline nasal irrigation, and intranasal corticosteroids.
- Antibiotic therapy is recommended for patients with sinusitis symptoms that do not improve within 7 to 10 days or that worsen at any time.
- First-line antibiotics include amoxicillin with or without clavulanate.
- Macrolides and trimethoprim sulfamethoxazole (Bactrim) are not recommended for empiric therapy owing to high rates of resistance among *Streptococcus pneumoniae* and *Haemophilus influenzae*.
- For adults allergic to penicillin, doxycycline may be used as an alternative regimen for initial empiric therapy for bacterial rhinosinusitis. According to a recent US Food and Drug Administration (FDA) safety alert, fluoroquinolones such as levofloxacin (Levaquin) and moxifloxacin (Avelox) should be reserved for patients who do not have other treatment options.
- In adults with confirmed acute rhinosinusitis, more than 70% will clinically improve after 2 weeks with or without antibiotic therapy.
- Antibiotic use increases the absolute cure rate by 5% compared with placebo at 7 to 15 days.

### Epidemiology of Acute Rhinosinusitis and Predisposing Factors

Each year in the United States, rhinosinusitis affects one in seven adults and is diagnosed in 31 million patients. Rhinosinusitis is the fifth most common diagnosis for which antibiotics are prescribed. Rhinosinusitis has a higher frequency in the winter months and lower frequency in the summer and autumn months.

### Predisposing Factors

Predisposing factors for acute rhinosinusitis include viral upper respiratory infections and allergic rhinitis. Anatomic malformations including polyps, deviated nasal septum, foreign bodies, and tumors can also predispose to acute rhinosinusitis.

### Pathogenesis and Etiology of Rhinosinusitis

Most cases of acute rhinosinusitis are caused by viral infections associated with the common cold. The most common viruses in acute viral rhinosinusitis are rhinovirus, adenovirus, influenza virus, and parainfluenza virus. Mucosal edema occurs with the viral infection with subsequent obstruction of the sinus ostia. In addition, viral and bacterial infections impair the cilia, which help transport the mucus. The ostia obstruction and slowed mucus transport cause stagnation of secretions and lowered oxygen tension within the sinuses. This environment is an excellent culture medium for both viruses and bacteria and the infectious particles grow rapidly. The body responds with an inflammatory reaction. Polymorphonuclear leukocytes are mobilized, which results in pus formation. The most common bacteria found in acute community-acquired bacterial rhinosinusitis are *S pneumoniae*, *H influenzae*, *Staphylococcus aureus*, and *Moraxella catarrhalis*. Acute adult rhinosinusitis most commonly involves the maxillary and ethmoid sinuses. More than one of the paranasal sinuses can be affected.

### Diagnosis of Acute Rhinosinusitis

Diagnosis of acute bacterial rhinosinusitis requires that symptoms persist for longer than 10 days or worsen after 5 to 7 days. Four signs and symptoms with a high likelihood ratio for acute bacterial sinusitis are double sickening, purulent rhinorrhea, ESR >10mm, and purulent secretion in the nasal cavity. A combination of at least three of these four symptoms and signs has a specificity of 0.81 and sensitivity of 0.66 for acute bacterial rhinosinusitis. Table 1 lists the sensitivity, specificity, likelihood ratio, and odds ratio of criteria used to diagnose acute rhinosinusitis. If resistant pathogens are suspected or if the patient's immune system is compromised, bacterial culture of the secretions may be used for diagnosis and to direct therapy.

**TABLE 1** Signs and Symptoms of Acute Bacterial Rhinosinusitis

SIGN/SYMPTOM	SENSITIVITY (%)	SPECIFICITY (%)	LR +	ODDS RATIO
Symptoms after upper respiratory tract infection	99	8	1.1	2.1
Facial pain on bending forward	90	22	1.2	0.9
Nasal congestion	90	14	1.0	1.1
Purulent rhinorrhea	89	42	1.5	1.6
Bilateral facial pain, pressure, or fullness	78	32	1.2	1.4
Double sickening	72	65	2.1	*
Previous sinusitis	57	38	0.9	0.4
Upper teeth pain	50	50	1.0	1.2
Unilateral facial pain, pressure, or fullness	46	73	1.7	1.9

Abbreviation: LR = Likelihood ratio.

\*No data given in reference.

## Imaging

For uncomplicated acute rhinosinusitis, radiographic imaging is not recommended. Plain sinus radiography shows air–fluid levels in patients with both viral and bacterial rhinosinusitis. Sinus computed tomography should not be used for routine evaluation of acute bacterial rhinosinusitis. However, sinus computed tomography without contrast media can be used to identify suspected complications and define anatomic abnormalities.

## Differential Diagnosis

The signs and symptoms of acute bacterial rhinosinusitis and prolonged viral upper respiratory infection are similar, which can lead to overdiagnosis of acute bacterial rhinosinusitis. Other conditions that mimic bacterial rhinosinusitis are migraine headache, tension headache, trigeminal neuralgia, and temporomandibular joint disorders.

## Treatment of Acute Rhinosinusitis

### Symptomatic Treatment

Mild rhinosinusitis symptoms less than 7 days in duration can be managed with supportive care including analgesics, saline nasal irrigation, and intranasal corticosteroids. There are no randomized controlled trials that evaluate the effectiveness of decongestants in patients with sinusitis. Nasal saline is used to soften viscous secretions and improve mucociliary clearance. The mechanical cleansing of the nasal cavity with saline has been shown to benefit patients with rhinosinusitis. Most studies of intranasal corticosteroids are industry sponsored. A 2013 Cochrane review found that patients receiving intranasal corticosteroids were more likely to experience symptom improvement after 15 to 21 days compared with those receiving placebo (73% vs. 66.4%;  $p < .05$ ; number needed to treat [NNT]=15). Antihistamines should not be used for symptomatic relief of acute rhinosinusitis, except in patients with a history of allergic rhinitis.

### Antibiotic Treatment

Antibiotic therapy is recommended for patients with sinusitis symptoms that do not improve within 7 to 10 days or that worsen at any time. Amoxicillin with or without clavulanate is recommended as the first-line antibiotic in adults with acute bacterial rhinosinusitis. “High-dose” amoxicillin-clavulanate (Augmentin XR) is recommended for patients with high risk of *S pneumoniae* resistance, recent antibiotic use, or treatment failure. Macrolides and trimethoprim sulfamethoxazole are not recommended for empiric therapy owing to high rates of resistance among *S pneumoniae* and *H influenzae*. Fluoroquinolones are not recommended as first-line antibiotics because they do not demonstrate benefit over beta-lactam antibiotics and are associated with a variety of adverse effects. According to a recent FDA safety alert, fluoroquinolones should be reserved for patients who do not have other treatment options.

### Complications and Referral

Complications of acute bacterial rhinosinusitis are estimated to occur in 1 in 1000 cases. Patients with acute bacterial rhinosinusitis who present with visual symptoms (diplopia, decreased visual acuity, disconjugate gaze, difficulty opening the eye), severe headache, somnolence, or high fever should be evaluated with emergency computed tomography with contrast. Sinonasal cancers are uncommon in the United States, with an annual incidence of less than 1 in 100,000 patients. However, cancer should be included in the differential diagnosis. Referral to an otolaryngologist is needed if symptoms persist or progress after maximal medical therapy when computed tomography shows evidence of sinus disease. **Table 2** summarizes indications for subspecialist referral in a patient with acute bacterial rhinosinusitis.

**TABLE 2** Indications for Subspecialist Referral for Acute Bacterial Rhinosinusitis

Anatomic defects causing obstruction
Complications such as orbital involvement, altered mental status, meningitis, cavernous sinus thrombosis, intracranial abscess, Pott’s puffy tumor (osteomyelitis of front bone)
Evaluation of immunotherapy for allergic rhinitis
Frequent recurrences (3–4 episodes per year)
Fungal sinusitis, granulomatous disease, or possible neoplasm
Immunocompromised host
Nosocomial infection
Severe infection with persistent fever $>102^{\circ}\text{F}$ or $39^{\circ}\text{C}$
Treatment failure after extended antibiotic courses
Unusual or resistant bacteria

## TEMPOROMANDIBULAR DISORDERS

Method of

Jeffrey P. Okeson, DMD

Temporomandibular disorder (TMD) is a collective term that includes a number of clinical complaints involving the muscles of mastication, the temporomandibular joints (TMJs) and associated orofacial structures. Other commonly used terms are Costen’s syndrome, TMJ dysfunction, and craniomandibular disorders. TMDs are a major cause of nondental pain in the orofacial region and are considered a subclassification of musculoskeletal disorders. In many TMD patients the most common complaint is not with the TMJs but rather the muscles of mastication. Therefore the terms *TMJ dysfunction* or *TMJ disorder* are

actually inappropriate for many of these complaints. It is for this reason that the American Dental Association adopted the term *temporomandibular disorder*.

Signs and symptoms associated with TMDs are a common source of pain complaints in the head and orofacial structures. These complaints can be associated with general joint problems and somatization. Approximately 50% of patients suffering with TMDs do not first consult with a dentist but seek advice for the problem from a physician. The family physician should be able to appropriately diagnose many TMDs. In many instances the physician can provide valuable information and simple therapies that will reduce the patient's TMD symptoms. In other instances, it is appropriate to refer the patient to a dentist for additional evaluation and treatment.

### Epidemiology

Cross-sectional population-based studies reveal that 40% to 75% of adult populations have at least one sign of TMJ dysfunction (e.g., jaw movement abnormalities, joint noise, tenderness on palpation), and approximately 33% have at least one symptom (e.g., face pain, joint pain). Many of these signs and symptoms are not troublesome for the patient, and only 3% to 7% of the population seeks any advice or care. Although in the general population women seem to have only a slightly greater incidence of TMD symptoms, women seek care for TMD more often than men at a ratio ranging from 3:1 to 9:1. For many patients TMDs are self-limiting or are associated with symptoms that fluctuate over time without evidence of progression. Even though many of these disorders are self-limiting, the health care provider can provide conservative therapies that will minimize the patient's painful experience.

### Signs and Symptoms

The primary signs and symptoms associated with TMD originate from the masticatory structures and are associated with jaw function (Box 1). Pain during opening of the mouth or during chewing is common. Some persons even report difficulty speaking or singing. Patients often report pain in the preauricular areas, face, or temples. TMJ sounds are often described as clicking, popping, grating, or crepitus and can produce locking of the jaw during opening or closing. Patients commonly report painful jaw muscles, and, on occasion, they even report a sudden change in their bite coincident with the onset of the painful condition.

It is important to appreciate that pain associated with most TMDs is increased with jaw function. Because this is a condition of the musculoskeletal structures, function of these structures generally increases the pain. When a patient's pain complaint is not influenced by jaw function, other sources of orofacial pain should be suspected.

The spectrum of TMD often includes commonly associated complaints such as headache, neckache, or earache. These associated complaints are often referred pains and must be differentiated

from primary pains. As a general rule, referred pains associated with TMDs are increased with any activity that provokes the TMD pain. Therefore, if the patient reports that the headache is aggravated by jaw function, it could very well represent a secondary pain related to the TMD. Likewise, if the secondary symptom is unaffected by jaw use, one should question its relationship to the TMD and suspect two separate pain conditions. Pain or dysfunction due to non-musculoskeletal causes such as otolar- yngologic, neurologic, vascular, neoplastic, or infectious disease in the orofacial region is not considered a primary TMD even though musculoskeletal pain may be present. However, TMDs often coexist with other craniofacial and orofacial pain disorders.

### Anatomy and Pathophysiology

The TMJ is formed by the mandibular condyle fitting into the mandibular fossa of the temporal bone. The movement of this joint is quite complex as it allows hinging movement in one plane and at the same time allows gliding movements in another plane.

Separating these two bones from direct articulation is the articular disk. The articular disk is composed of dense fibrous connective tissue devoid of any blood vessels or nerve fibers. The articular disk is attached posteriorly to a region of loose connective tissue that is highly vascularized and well innervated, known as the retrodiscal tissue. The anterior region of the disk is attached to the superior lateral pterygoid muscle.

The movement of the mandible is accomplished by four pairs of muscles called the muscles of mastication: the masseter, temporalis, medial pterygoid, and lateral pterygoid. Although not considered to be muscles of mastication, the digastric muscles also play an important role in mandibular function. The masseter, temporalis, and medial pterygoid muscles elevate the mandible and therefore provide the major forces used for chewing and other jaw functions. The inferior lateral pterygoid muscles provide protrusive movement of the mandible, and the digastric muscles serve to depress the mandible (open the mouth).

When discussing the pathophysiology of TMD, one needs to consider two main categories: joint pathophysiology and muscle pathophysiology. Because etiologic considerations and treatment strategies are different for these conditions, they are presented separately.

### Pathophysiology of Intracapsular TMJ Pain Disorders

Several common arthritic conditions such as rheumatoid arthritis, traumatic arthritis, hyperuricemia, and psoriatic arthritis can affect the TMJ. These conditions, however, are not nearly as common as local osteoarthritis. As with most other joints, osteoarthritis results from overloading the articular surface of the joint, thus breaking down the dense fibrocartilage articular surface and ultimately affecting the subarticular bone. In the TMJ, this overloading commonly occurs as a result of an alteration in the morphology and position of the articular disc. In the healthy TMJ, the disc maintains its position on the condyle during movement because of its morphology (i.e., the thicker anterior and posterior borders) and interarticular pressure maintained by the elevator muscles. If, however, the morphology of the disc is altered and the discal ligaments become elongated, the disc can be displaced from its normal position between the condyle and fossa. If the disc is displaced, normal opening and closing of the mouth can result in an unusual translatory movement between the condyle and the disc, which is felt as a click or pop. Disc displacements that result in joint sounds might or might not be painful. When pain is present it is believed to be related to either loading forces applied to the highly vascularized retrodiscal tissues or a general inflammatory response of the surrounding soft tissues (capsulitis or synovitis).

### Pathophysiology of Masticatory Muscle Pain Disorders

The muscles of mastication are a very common source of TMD pain. Understanding the pathophysiology of muscle pain, however, is very complex and still not well understood. The simple explanation of muscle spasm does not account for most TMD

#### BOX 1 Common Primary and Secondary Symptoms Associated with Temporomandibular Disorders

##### Primary Symptoms

- Facial muscle pain
- Preauricular (TMJ) pain
- TMJ sounds: jaw clicking, popping, catching, locking
- Limited mouth opening
- Increased pain associated with chewing

##### Secondary Symptoms

- Earache
- Headache
- Neckache

Abbreviation: TMJ = temporomandibular joint.

muscle pain complaints. It appears that a better explanation would include a central nervous system effect on the muscle that results in an increase in peripheral nociceptive activity originating from the muscle tissue itself. This explanation more accurately accounts for the high levels of emotional stress that are commonly associated with TMD muscle pain complaints. In other words, an increase in emotional stress activates the autonomic nervous system, which in turn seems to be associated with changes in muscle nociception.

These masticatory muscle pain conditions are further complicated when one considers the unique masticatory muscle activity known as bruxism. Bruxism is the subconscious, often rhythmic, grinding or gnashing of the teeth. This type of muscle activity is considered to be parafunctional and can also occur as a simple static loading of the teeth known as clenching. This activity commonly occurs while sleeping but can also be present during the day. These parafunctional activities alone can represent a significant source of masticatory muscle pain, and certainly bruxism in the presence of central nervous system–induced muscle pain can further accentuate the patient’s muscle pain complaints.

### Etiology

Because TMD represents a group of disorders, any of several etiologies may be associated. Problems arising from intracapsular conditions (clicking, popping, catching, locking) may be associated with various types of trauma. Gross trauma, such as a blow to the chin, can immediately alter ligamentous structures of the joint, leading to joint sounds. Trauma can also be associated with a subtler injury such as stretching, twisting or compressing forces during eating, yawning, yelling, or prolonged mouth opening.

When the patient’s chief complaint is muscle pain, etiologic factors other than trauma should be considered. Masticatory muscle pain disorders have etiologic considerations similar to other muscle pain disorders of the neck and back. Emotional stress seems to play a significant role for many patients. This can explain why patients often report that their painful symptoms fluctuate greatly over time.

Although most TMD patients do not have a major psychiatric disorder, psychological factors can certainly enhance the pain condition. The clinician needs to consider such factors as anxiety, depression, secondary gain, somatization, and hypochondriasis. Psychosocial factors can predispose certain people to TMD and can also perpetuate TMD once symptoms have become established. A careful consideration of psychosocial factors is therefore important in the evaluation and treatment of every TMD patient.

TMDs have a few unique etiologic factors that differentiate them from other musculoskeletal disorders. One such factor is the occlusal relationship of the teeth. Traditionally it was thought that malocclusion was the primary etiologic factor responsible for TMD. Recent investigations, however, do not support this concept. Still, in certain instances occlusal instability of the teeth can contribute to a TMD. This may be true in patients with or without teeth. Poorly fitting dental prostheses can also contribute to occlusal instability. The occlusal condition should especially be suspected if the pain problem began with a change in the patient’s occlusion (e.g., following a dental appointment).

### History and Examination

All patients reporting pain in the orofacial structures should be screened for TMD. This can be accomplished with a brief history and physical examination. The screening questions and examination are performed to rule in or out the possibility of a TMD. If a positive response is found, a more extensive history and examination is indicated. [Box 2](#) lists questions that should be asked during a screening assessment for TMD. Any positive response should be followed by additional clarifying questions.

Patients experiencing orofacial pain should also be briefly examined for any clinical signs associated with TMD. The clinician can easily palpate a few sites to assess tenderness or pain, as well as assess for jaw mobility. The masseter muscles can be palpated bilaterally while asking the patient to report any pain

## BOX 2 Recommended Screening Questionnaire for Temporomandibular Disorder

All patients reporting pain in the orofacial region should be screened for TMD with a questionnaire that includes these questions. The decision to complete a comprehensive history and clinical examination depends on the number of positive responses and the apparent seriousness of the problem for the patient. A positive response to any question may be sufficient to warrant a comprehensive examination if it is of concern to the patient or viewed as clinically significant by the physician.

1. Do you have difficulty, pain, or both when opening your mouth, for instance when yawning?
2. Does your jaw get stuck or locked or go out?
3. Do you have difficulty, pain, or both when chewing, talking, or using your jaws?
4. Are you aware of noises in the jaw joints?
5. Do your jaws regularly feel stiff, tight, or tired?
6. Do you have pain in or about the ears, temples, or cheeks?
7. Do you have frequent headaches, neckaches, or toothaches?
8. Have you had a recent injury to your head, neck, or jaw?
9. Have you been aware of any recent changes in your bite?
10. Have you been previously treated for unexplained facial pain or a jaw joint problem?

Abbreviation: TMD = temporomandibular disorder.

or tenderness. The same assessment should be made for the temporal regions, as well as the preauricular (TMJ) areas. While the examiner’s hands are over the preauricular areas, the patient should repeatedly open and close the mouth. The presence of joint sounds should be noted along with whether these sounds are associated with joint pain.

A simple measurement of mouth opening should be made. This can be accomplished by placing a millimeter ruler on the lower anterior teeth and asking the patient to open as wide as possible. The distance should be measured between the maxillary and mandibular anterior teeth. It is generally accepted that less than 40 mm is a restricted mouth opening.

It is also helpful to inspect the teeth for significant wear, mobility, or decay that may be related to the pain condition. The clinician should examine the buccal mucosa for ridging and the lateral aspect of the tongue for scalloping. These are often signs of clenching and bruxism. A general inspection for symmetry and alignment of the face, jaws, and dental arches may also be helpful. A summary of this screening examination is shown in [Box 3](#).

### Treatment

Most recent studies suggest that TMDs are generally self-limiting, and symptoms often fluctuate over time. Understanding this natural course does not mean these conditions should be ignored. TMD can be a very painful condition leading to a significant decrease in the patient’s quality of life. Understanding the natural course of TMD does suggest, however, that therapy might not need to be very aggressive. In general, initial therapy should begin very conservatively and only escalate when therapy fails to relieve the symptoms.

When the physician identifies a patient with a TMD, he or she has two options. The physician can elect to treat the patient or refer the patient to a dentist who specializes in TMD for further evaluation and treatment. The decision to refer the patient should be based on whether the patient needs any unique care provided only in a dental office. The following are some indications for referral to a dentist:

- History of trauma to the face related to the onset of the pain condition
- The presence of significant TMJ sounds during function
- A feeling of jaw catching or locking during mouth opening

### BOX 3 Recommended Screening Examination Procedures for Temporomandibular Disorder

All patients with face pain should be briefly screened for TMD using this or a similar cursory clinical examination. The need for a comprehensive history and clinical examination depends on the number of positive findings and the clinical significance of each finding.

1. Palpate for pain or tenderness in the masseter and temporalis muscles.
2. Palpate for pain or tenderness in the preauricular (TMJ) areas.
3. Measure the range of mouth opening. Note any incoordination in the movements.
4. Auscultate and palpate for TMJ sounds (i.e., clicking or crepitus).
5. Note excessive occlusal wear, excessive tooth mobility, buccal mucosal ridging, or lateral tongue scalloping.
6. Inspect symmetry and alignment of the face, jaws, and dental arches.

Abbreviation: TMJ = temporomandibular joint.

- The report of a sudden change in the occlusal contacts of the teeth
- The presence of significant occlusal instability
- Significant findings related to the teeth (e.g., tooth mobility, tooth sensitivity, tooth decay, tooth wear)
- Significant pain in the jaws or masticatory muscles upon awakening
- The presence of an orofacial pain condition that is aggravated by jaw function and has been present for more than several months

The specific therapy for a TMD varies according to the precise type of disorder identified. In other words, masticatory muscle pain is managed somewhat differently than intracapsular pain. Generally, however, the initial therapy for any type of TMD should be directed toward the relief of pain and the improvement of function. This initial conservative therapy can be divided into three general types: patient education, pharmacologic therapy, and physical therapy.

#### Patient Education

It is very important that patients have an appreciation for the factors that may be associated with their disorder, as well as the natural course of the disorder. Patients should be reassured and if necessary, convinced by appropriate tests, that they are not suffering from a malignancy. Properly educated patients can contribute greatly to their own treatment. For example, knowing that emotional stress is an influencing factor in many TMDs can help the patient understand the reason for daily fluctuations of pain intensity. Attention should be directed toward changing the patient's response to stress or, when possible, reducing exposure to stressful conditions. Patients with pain during chewing should be told to begin a softer diet, chew slower, and eat smaller bites. As a general rule the patient should be told "if it hurts, don't do it." Continued pain can contribute to the cycling of pain and should always be avoided. The patient should be instructed to let the jaw muscles relax, maintaining the teeth apart. This will discourage clenching activities and minimize loading of the teeth and joints.

When pain is associated with a clicking TM joint, the patient should be informed of the biomechanics of the joint. This information often allows the patient to select functional activities that are less traumatic to the joint structures. For example, some patients may report that the pain and clicking are less when they chew on a particular side of the mouth. When this occurs, they should be encouraged to continue this type of chewing.

#### Pharmacologic Therapy

Pharmacologic therapy can be an effective adjunct in managing symptoms associated with TMDs. Patients should be aware that medication alone will not likely solve or cure the problem. Medication, however, in conjunction with appropriate physical therapy and definitive treatment, does offer the most complete approach to many TMD problems. Mild analgesics are often helpful for many TMDs. Control of pain is not only appreciated by the patient but also reduces the likelihood of other complicating pain disorders such as muscle co-contraction, referred pain, and central sensitization.

Nonsteroidal antiinflammatory drugs (NSAIDs) are very helpful with many TMDs. Included in this category are aspirin, acetaminophen (Tylenol), and ibuprofen. Ibuprofen (Motrin, Advil, Nuprin) is often very effective in reducing musculoskeletal pains. A dosage of 600 to 800mg three times a day for 3 to 5 days commonly reduces pain and stops the cyclic effects of the deep pain input. For patients with gastrointestinal issues, short-term use of a cyclooxygenase-2 (COX-2) inhibitor such as celecoxib (Celebrex) can also be useful.

#### Physical Therapy

In many patients with TMD, symptoms are relieved with very simple physical therapy methods. Simple instructions for the use of moist heat or cold can be very helpful. Surface heat can be applied by laying a hot, moist towel over the symptomatic area. A hot water bottle wrapped inside the towel will help maintain the heat. This combination should remain in place for 10 to 15 minutes, not to exceed 30 minutes. An electric heating pad may be used, but care should be taken not to leave it on the face too long. Patients should be discouraged from using the heating pad while sleeping because prolonged use is likely.

Like thermotherapy, coolant therapy can provide a simple and often effective method of reducing pain. Ice should be applied directly to the symptomatic joint or muscles and moved in a circular motion without pressure to the tissues. The patient will initially experience an uncomfortable feeling that will quickly turn into a burning sensation. Continued icing will result in a mild aching and then numbness. When numbness begins the ice should be removed. The ice should not be left on the tissues for longer than 5 minutes. After a period of warming a second cold application may be desirable.

The physician should be aware that many TMDs respond to the use of orthopedic appliances such as occlusal appliances, bite guards, and splints. These appliances are made by the dentist and are custom fabricated for each patient. Several types of appliances are available. Each is specific for the type of TMD present. The dentist should be consulted for this type of therapy.

#### Other Therapeutic Considerations

Sometimes TMDs become chronic and, as with other chronic pain conditions, might then be best managed by a multidisciplinary approach. If the patient reports a long history of TMD complaints, the physician should consider referring the patient to a dentist associated with a team of therapists, such as a psychologist, a physical therapist, and even a chronic pain physician. Generally, patients with chronic TMD are not managed well by the simple initial therapies discussed in this chapter. Often other factors, such as mechanical conditions within the TMJs or psychological factors, need to be addressed. The physician who attempts to manage these conditions in the private practice setting can become very frustrated with the results. It is therefore recommended that if the patient's history suggests chronicity or if initial therapy fails to reduce the patient's symptoms, referral is indicated.

### CURRENT DIAGNOSIS

- Uveitis is classified by anatomic location and etiology.
- Most forms of uveitis are due to infectious or immune-mediated disease.
- Drug-induced uveitis and masquerade disorders (neoplasms) must be excluded in diagnostic evaluations.
- Patients with first-time uveitis should have a medical history, physical examination, and targeted laboratory studies, with the possible exception of adults who have a single episode of mild anterior uveitis that responds to therapy and who have no systemic signs or symptoms.
- Diagnostic evaluation must differentiate infectious from noninfectious uveitis.
- Patients who are immunosuppressed are at higher risk of infectious uveitis and their clinical presentations may be atypical.
- Uveitis in children is uncommon and deserves a thorough medical evaluation at initial presentation.
- Uveitis is managed optimally through a collaborative multidisciplinary approach.

### CURRENT THERAPY

- Eradication of infection is the primary objective in infectious uveitis but may require judicious use of local antiinflammatory agents to mitigate structural and functional damage to intraocular tissues.
- The goal of therapy in noninfectious uveitis is to suppress and eliminate inflammation, achieving lasting remission through the stepwise implementation of therapy.
- First-time anterior uveitis in adults with negative medical history and review of systems can be treated with topical corticosteroids and cycloplegic agents and careful clinical monitoring.
- Corticosteroids can be delivered topically, through periocular and intravitreal injection, via sustained release devices implanted in the eye, and systemically.
- Immunomodulating therapy using alkylating agents, antimetabolites, biologic response modulators, or inhibitors of T-lymphocyte signaling are indicated for uveitis not responsive to systemic corticosteroids.
- A thorough history, physical examination, and select laboratory studies are required before initiating immunomodulating therapy. Subspecialty evaluations, when clinically indicated, may also be needed, such as rheumatology, neurology, or infectious disease specialists.

### Current Diagnosis

Uveitis describes a heterogeneous group of disorders that have in common inflammation of the uveal tract (i.e., iris, ciliary body, and choroid). Symptoms are nonspecific, usually involving various combinations of blurred vision, ocular discomfort, intolerance to light, and floaters. Onset may be sudden or insidious. Children may have no symptoms. The essential signs of uveitis are the presence of inflammatory cells in the aqueous humor and/or vitreous gel. Sufficient magnification with a slit lamp is required to confidently detect these inflammatory cells and avoid confusion with suspended red blood cells or pigment epithelial cells. Although the uveal tract is the conceptual epicenter of uveal inflammation, there is spillover inflammation in the aqueous humor and vitreous gel, the two anatomic

locations used to quantify the severity of inflammation and to monitor response to therapy. Grading schemes for recording the severity of anterior chamber and vitreous inflammatory cell density and protein content (flare) have been published by the Standardization of Uveitis Nomenclature (SUN) Classification Working Group.

### Clinical Features and Diagnosis

The anatomic classification of intraocular inflammation into anterior, intermediate, and posterior uveitis and panuveitis guides the diagnostic workup toward the determination of etiology. When the anterior chamber is the principal site of inflammation, the terms iritis or iridocyclitis are often used. When the vitreous is the primary focus of inflammation, the term intermediate uveitis is preferred, but posterior cyclitis or vitritis are commonly used synonyms. Pars planitis is a clinical subtype of intermediate uveitis and is characterized by clumping or a layering of inflammatory cells over the pars plana and anterior retina called “snowballs” or a “snowbank lesion.” These characteristic cells may also be seen in sarcoidosis. Posterior uveitis refers to diseases limited to the posterior segment of the eye. Comprehensive anatomical characterization includes retinitis, choroiditis, or neuroretinitis, and is clinically described as focal or multifocal. This classification is informative in developing an appropriate differential diagnosis.

Most cases of uveitis are caused by infection or immune-mediated disease. A substantial proportion of immune-mediated disease is a manifestation of systemic disease. Arriving at a diagnosis of infectious or noninfectious uveitis requires exclusion of drug-induced uveitis and so-called masquerade disorders (usually neoplasms) that mimic uveal inflammation. Most undifferentiated idiopathic forms of uveitis are localized immune-mediated disease whose pathogenesis is not yet understood. Immune-mediated and infectious uveitides may have overlapping clinical features. This is important as some diseases are diagnosed based on clinical features with supporting laboratory findings. The diagnostic evaluation for persons with noninfectious uveitis and no known systemic disorders involves a complete history, review of systems, physical examination, and select laboratory tests. There is limited consensus in the uveitis community regarding appropriate laboratory testing for specific uveitic entities; however, the general recommendation is to make case-specific determinations.

The anatomic categories of posterior uveitis and panuveitis have vastly expanded the number of potential diagnoses. The pattern and distribution of inflammatory lesions of the choroid, retina, and optic nerve, along with a host of other clinical findings (e.g., vascular or perivascular involvement, severity of overlying inflammation, color and shape of choroidal and retinal lesions, etc.) are critical to narrowing the differential diagnosis. The importance of pattern recognition in the diagnosis of posterior uveitis and panuveitis cannot be overstated. Toxoplasma chorioretinitis, the most common form of posterior uveitis, can usually be confidently diagnosed by clinical ophthalmoscopic appearance of a yellow-white retina with overlying vitreal inflammation adjacent to a hyperpigmented chorioretinal scar. On the other hand, the disorders belonging to the so-called white dot syndromes (acute posterior multifocal placoid pigment epitheliopathy, multifocal chorioretinitis with panuveitis, punctate inner choroidopathy, multiple evanescent white dot syndrome, and birdshot chorioretinopathy) require diagnostic studies such as fluorescein angiography, indocyanine green angiography, optical coherence tomography (OCT), and OCT angiography to elucidate. Most of these disorders, and a few others such as Vogt-Koyanagi-Harada disease and sympathetic ophthalmia, are clinically defined syndromes. Laboratory studies in the context of a clinically defined syndrome are used to exclude conditions that could possibly mimic their appearance.

Uveitis occurs in children substantially less often than adults. Although a majority of the same infectious and noninfectious etiologies that occur in adults also affect children, juvenile idiopathic arthritis has a relatively unique clinical presentation in young patients. All four subtypes of juvenile idiopathic arthritis are associated with anterior uveitis, but the pauciarticular category may present with anterior chamber inflammation and

advanced band keratopathy with few or no symptoms. This degree of incongruity between symptoms and clinical findings on slit-lamp examination is unusual in adults.

### Current Therapy

The heterogeneous nature of uveitis limits the generalizability of a universal therapeutic algorithm. When the cause of uveitis is infection, the goal of therapy is to eradicate the infectious organism while controlling inflammation during the process. For noninfectious uveitis, the goal of therapy is to suppress and eliminate inflammation and to achieve lasting remission. We know from published retrospective studies that early effective treatment minimizes the disease burden, so the current paradigm is the one utilized by rheumatologists, which is a treat to target approach. The severity and pattern of inflammation at presentation and the perceived risk to vision and ocular integrity guide the initial selection of therapy. Timing of treatment escalation and transition to noncorticosteroid therapy are decisions based on multiple factors, including but not limited to ocular and systemic comorbidities. Simultaneous therapies, particularly local and systemic antiinflammatory agents, are commonly used. Multidisciplinary management is ideally suited to combine the expertise needed to track the ocular response to treatment and to prescribe and monitor many of the systemic medications.

### Anterior Uveitis

Anterior uveitis, the most common subset of uveitis, is usually noninfectious. A minority of cases are attributed to viruses, most often herpes simplex virus (HSV), varicella zoster virus (VZV), and cytomegalovirus (CMV). Acute anterior uveitis associated with an underlying viral etiology is typically associated with increased intraocular pressure and iris atrophy. The diagnosis of viral anterior uveitis is typically a clinical one; when a diagnostic dilemma exists, then an anterior chamber tap with PCR analysis is recommended. In general, prompt empiric oral therapy will shorten the course, and tailored maintenance therapy may be indicated to decrease recurrences. For HSV or VZV, therapy with oral acyclovir (Zovirax),<sup>1</sup> valacyclovir (Valtrex),<sup>1</sup> or famciclovir (Famvir)<sup>1</sup> is started. Following clinical resolution of inflammation, maintenance therapy with an oral antiviral drug is recommended. The optimal treatment for anterior uveitis due to CMV is still being evaluated, with current recommendations for systemic therapy (with oral ganciclovir<sup>2</sup> or intravenous foscarnet [Foscavir]<sup>1</sup> or intravenous ganciclovir [Cytovene]).<sup>1</sup> Maintenance therapy with topical ganciclovir (Zirgan)<sup>1</sup> or oral valganciclovir (Valcyte)<sup>1</sup> should be considered. The antiviral therapy is used with concomitant topical therapy discussed in the next section. Duration of maintenance therapies for viral anterior uveitis is a clinical decision and should be individualized.

The vast majority of anterior uveitis is noninfectious, for which the mainstay of treatment is topical corticosteroids with cycloplegics (Table 1). There are nearly 20 different preparations of topical corticosteroid (e.g., dexamethasone sodium phosphate 0.1% solution; prednisolone acetate 1.0% suspension [Pred Forte]) that come in suspension or solution (and some as ointment) and in different concentrations. Dose and duration of use is tailored to the clinical setting.

Topical nonsteroidal antiinflammatory agents (e.g., diclofenac 0.1% [Voltaren]<sup>1</sup>; ketorolac 0.4% [Acular]<sup>1</sup>; flurbiprofen 0.03% [Ocufen]<sup>1</sup>) are less effective than topical corticosteroids in controlling the inflammation of anterior uveitis. Their use in combination with topical corticosteroids may be additive.<sup>1</sup>

Topical cycloplegics provide pain relief, and the mydriasis they produce reduces the risk of iridolenticular scarring. The selection of a long-acting (e.g., atropine sulfate 1% [Isopto Atropine] twice daily) versus short-acting cycloplegic agent (e.g., cyclopentolate hydrochloride 0.5%–1.0% [Cyclogyl]<sup>1</sup> two or three times a day) is based on clinical features such as severity of inflammation, presence of synechial scarring, age of patient, ability to take topical medications, and so on. Duration of action varies from 1 to 2 weeks for topical atropine to approximately half a day for cyclopentolate.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

**TABLE 1** Topical Medications for Anterior Uveitis

DRUG NAME (TRADE NAMES)	FORMULATION	STARTING DOSE SCHEDULE*
<b>Topical Corticosteroids</b>		
Dexamethasone (Decadron phosphate [Maxidex])	0.1% suspension; 0.1% solution; 0.05% ointment <sup>2</sup>	4 times per day
Difluprednate (Durezol)	0.05% emulsion	4 times per day
Fluorometholone alcohol (Flarex, FML)	0.1 and 0.25% suspensions; 0.1% ointment	2–4 times per day; 1–3 times per day
Loteprednol etabonate (Lotemax)	0.5% suspension	4 times per day
Leteprednol etabonate (Alrex)	0.2% suspension <sup>1</sup>	3 times per day
Prednisolone acetate (Pred Forte, Econopred Plus; AK-Tate)	1.0% suspension	4 times per day
Prednisolone sodium phosphate (Inflamase Forte; AK-Pred)	1.0% solution	4 times per day
Prednisolone acetate (Pred Mild; Econopred)	0.12% suspension	4 times per day
<b>Topical Cycloplegic Agents</b>		
Atropine sulfate (Isopto Atropine)	1.0%	Once or twice a day
Cyclopentolate hydrochloride (Cyclogyl) <sup>1</sup>	0.5% and 1.0%	Twice a day
Homatropine hydrobromide (Isopto homatropine)	2.0%–5.0%	Once or twice a day
Scopolamine hydrobromide (Isopto hyoscine)	0.25%	Once or twice a day
Tropicamide (Mydracil) <sup>1</sup>	0.5% and 1.0%	2–3 times a day
<b>Topical Nonsteroidal Antiinflammatory Medications</b>		
Bromfenac (BromSite; Prolensa; Xibrom) <sup>1</sup>	0.075%–0.09% solution	Once or twice daily
Diclofenac (Voltaren) <sup>1</sup>	0.1% solution	2 times per day
Flurbiprofen (Ocufen) <sup>1</sup>	0.03% solution	2 times per day
Ketorolac (Acular LS; Acular) <sup>1</sup>	0.4%–0.5%	3 times per day
Nepafenac (Ilevro; Nevanac) <sup>1</sup>	0.1%–0.3% suspension	1–3 times a day, based on formulation

\*More frequent use of corticosteroids dictated by severity of inflammation then tapered based on clinical response.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

Noninfectious anterior uveitis is commonly associated with surgical trauma and accidental blunt trauma (concussive injury). They are usually effectively managed with tapering regimens of topical corticosteroids and cycloplegics.

Oral prednisone (1 mg/kg/day) may be needed for severe or recalcitrant anterior uveitis. Strategies for therapeutic escalation beyond oral corticosteroids parallel that of intermediate or posterior uveitis.

Although topical corticosteroids and cycloplegics do not play a primary role in intermediate and posterior uveitis, they are used as adjuvant therapies for comfort and to minimize the formation of peripheral and posterior synechiae due to associated anterior inflammation/iridocyclitis.

### Intermediate Uveitis

Intermediate uveitis, characterized by inflammatory cells in vitreous, peripheral retina, and pars plana, can be associated with systemic disorders such as multiple sclerosis, sarcoidosis, syphilis, toxocariasis (in children), the HLA-B27 spondyloarthropathies and Lyme disease. Vitritis is also a presenting sign of endogenous endophthalmitis and can be mimicked by primary vitreoretinal lymphoma. Once infection, drug-related uveitis, and masquerading conditions are excluded, the approach to therapy for noninfectious forms of intermediate uveitis is similar to the step-ladder approach (described later) that typically begins with oral corticosteroids. A treat to target approach should be taken, tailored based on disease severity, ocular and systemic comorbidities, and the presence/absence of an underlying systemic rheumatologic disorder. Additionally, known chronic/progressive ocular disorders that historically requires early aggressive systemic therapy such as serpiginous or birdshot will require special considerations. (Table 2). For pars planitis recalcitrant to medical therapy, options include peripheral ablation of the snowbank lesion with indirect laser photocoagulation and pars plana vitrectomy. Their effectiveness has not been rigorously tested in clinical trials.

Adjunct periocular or intravitreal therapy (i.e., regional therapy) may be an option for noninfectious intermediate, posterior, and panuveitis. Regional therapy delivers medications closer to the site of inflammation. The currently available regional therapeutic options include periocular injections of depot corticosteroids (40 mg triamcinolone acetonide [1 mL of 40 mg/mL Kenalog-40]<sup>1</sup>); intravitreal corticosteroid injection through the pars plana (4 mg triamcinolone acetonide suspension [0.1 mL 40 mg/mL Kenalog-40<sup>1</sup>; Triescence]); and a sustained-release corticosteroid implant embedded to either a biodegradable or nonbiodegradable vehicle to achieve sustained release. The implants are injected into the vitreous or surgically fixed to the sclera. Dexamethasone (Ozurdex, 0.7 mg) has a delivery span of 6 months, and fluocinolone acetonide (Iluvien 0.19 mg<sup>1</sup>; Retisert 0.59 mg; Yutiq 0.18 mg) 18 to 36 months. Approved in 2021, a suprachoroidal route, XIPERE™ is 4 mg (0.1 mL of the 40 mg/mL triamcinolone injectable suspension), specifically approved for retinal edema associated with uveitis. In the appropriate clinical setting these options may be tried before moving to oral prednisone or other systemic immune modulator therapy. The risk of endophthalmitis and the need for repeat injections need to be considered.

### Posterior Uveitis and Panuveitis

The general diagnostic approach to posterior uveitis and panuveitis begins by excluding infection and drug-induced uveitis and not overlooking the possibility of a masquerade condition. The optimal strategy for laboratory testing to identify a culpable systemic disorder responsible for noninfectious uveitis is a matter of debate. Many posterior and pan uveitides are clinically defined syndromes. For example, Behçet disease, multifocal choroiditis with panuveitis, acute posterior multifocal placoid pigment epitheliopathy, serpiginous choroiditis, punctate inner choroidopathy, multiple evanescent white dot syndrome, Vogt-Koyanagi-Harada disease, and sympathetic ophthalmia are diagnoses based on clinical findings (e.g., ophthalmoscopy, fluorescein angiography, optical coherence tomography, etc.). These syndromes have no confirmatory laboratory tests, other than several with strong human leukocyte antigen (HLA) haplotype associations (e.g., Behçet disease [HLA-B51] and birdshot chorioretinopathy [HLS-A29]).

Management of inflammation associated with noninfectious posterior uveitis requires systemic medications. Most clinicians initiate oral corticosteroids, understanding that high-dose long-term use is associated with serious and predictable side effects. The risk of systemic side effects may be reduced with judicious use of

periocular or intravitreal corticosteroid injections, but those routes of administration also have their own potential adverse effects and complications. These range from elevated intraocular pressure and glaucoma to infectious endophthalmitis.

The optimal time to transition to corticosteroid-sparing immunomodulatory therapy is a clinical decision-making process, focused on limiting the long-term systemic side-effects of oral corticosteroids, treating inflammation recalcitrant to oral corticosteroids, and for management of specific diseases expected to fare poorly with less aggressive therapies. The guidelines for treatment escalation should be based on a treat to target approach, to minimize disease burden and improve clinical outcomes. A frequently cited reference is the SITE (Systemic Immunosuppressive Therapy for Eye Diseases) Cohort Study series, a retrospective cohort study with multiple publications detailing the use of antimetabolites, T-cell inhibitors, alkylating agents, and other immunosuppressives ascertained from medical records of approximately 9250 patients with ocular inflammation. Data are collected with up to 30 years of follow-up from five U.S. tertiary centers and analyzed by fellowship-trained ocular immunologists. Immunomodulatory therapy for the treatment of uveitis falls into four drug categories: antimetabolites, inhibitors of T-lymphocyte signaling, biologic response modifiers, and alkylating agents (Table 3). Their judicious use has been shown to reduce or eliminate the need for systemic corticosteroids, improve long-term visual prognosis, and reduce ocular complications from inflammation. Meaningful clinical responses should occur within 3 months of initiating therapy. Following achieved clinical end points, patients should be monitored and the decision to taper based on input from patients and disease-specific criteria. A thorough history, physical examination, and select laboratory tests and imaging studies should be completed prior to initiation of therapy, in conjunction with appropriate subspecialty consultation.

The most commonly used antimetabolites for the treatment of noninfectious uveitis are methotrexate (Rheumatrex),<sup>1</sup> azathioprine (Imuran),<sup>1</sup> and mycophenolate mofetil (Cellcept).<sup>1</sup> Oral methotrexate, 7.5 to 15 mg once per week with daily folic acid<sup>1</sup> 1 mg, can be increased to 20 to 25 mg/week based on clinical response. Appropriately adjusted intravenous dose can be tried for persons with gastrointestinal intolerance. Intravitreal injection of 400 µg/0.1 mL has been used for refractory inflammation. Oral azathioprine is begun at 1 mg/kg/day. Depending on clinical response, it can be incrementally increased to 2.5 mg/kg/day. Mycophenolate mofetil is started at 1 to 2 g orally per day in divided doses up to 3 g/day. The manifold side effects of antimetabolites necessitate close clinical monitoring.

Most experience in treating noninfectious uveitis with inhibitors of T-lymphocyte signaling, or calcineurin inhibitors, is with cyclosporine (Sandimmune).<sup>1</sup> Given 2.5 to 5 mg/kg/day in divided doses, cyclosporine can cause nephrotoxicity, bone marrow suppression, and hypertension.

Alkylating agents used to treat noninfectious uveitis include cyclophosphamide (Cytoxan)<sup>1</sup> and chlorambucil (Leukeran).<sup>1</sup> These immunomodulating drugs are titrated to keep white blood cell counts in the range of 3000 to 4500 cells per cubic millimeter. Chlorambucil is started at 0.15 mg/kg/day and cyclophosphamide at 1 to 3 mg/kg/day. Regular monitoring for bone marrow suppression and opportunistic infection is needed for both drugs. Risks of hemorrhagic cystitis with cyclophosphamide may be reduced by consuming generous amounts of water daily.

Biologic response modifiers, or “biologics,” have expanded the therapeutic arsenal for treating advanced or severe noninfectious uveitis. This family of medications consists of antibodies directed against key cytokines in the immune response pathway. Most experience in treating noninfectious uveitis has been with tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) inhibitors (infliximab [Remicade]<sup>1</sup> and adalimumab [Humira]). Although other biologics have been used to treat advanced or severe

<sup>1</sup>Not FDA approved for this indication.

**TABLE 2** Treatment of Infectious Uveitis

DIAGNOSIS	INFECTIOUS ORGANISM(S)	TREATMENT	COMMENT
Acute retinal necrosis	Herpes zoster virus (HZV) Herpes simplex virus (HSV) I and II	Acyclovir (Zovirax) <sup>1</sup> 13 mg/kg/dose divided every 8 h IV for 7 days, followed by 800 mg PO 5 times/day for 3–4 months or Famciclovir (Famvir) <sup>1</sup> 500 mg PO q8h or Valacyclovir (Valtrex) <sup>1</sup> 1000–2000 mg PO q8h for induction Ganciclovir (Cytovene) <sup>1</sup> 500 mg IV q12h; maintenance: (duration varies with response) Valganciclovir (Valcyte) <sup>1</sup> 900 mg PO BID for 3 weeks then 450 mg PO BID Ganciclovir <sup>2</sup> 1000 mg PO TID	Adjuvant intravitreal injection options: Ganciclovir (200–2000 µg/0.1 mL) <sup>6</sup> Foscarnet (Foscavir) <sup>1</sup> (1.2–2.4 mg/0.1 mL) <sup>6</sup> ; Possible role for prednisone (0.5–2.0 mg/kg/day po for up to 6–8 weeks)
Anterior uveitis, viral	HSV  HZV  Cytomegalovirus (CMV)	Valacyclovir <sup>1</sup> 1000 mg PO TID Acyclovir <sup>1</sup> 400 mg PO × 5/day 4 weeks Famciclovir <sup>1</sup> 250 mg PO TID Valacyclovir <sup>1</sup> 1 g PO TID Acyclovir <sup>1</sup> 800 mg PO × 5/day 5–6 weeks Famciclovir <sup>1</sup> 500 mg PO TID 5–6 weeks Ganciclovir <sup>1</sup> 5 mg/kg IV BID 2–3 weeks Valganciclovir <sup>1</sup> 900 mg PO BID × 6 weeks, then 450 mg PO BID × 6 weeks	Topical corticosteroids and cycloplegic recommended. Alternative options include an intravitreal ganciclovir (2 mg/0.05 mL). <sup>6</sup> After active infection eradicated, consider maintenance therapy for HSV and CMV  Ganciclovir ophthalmic gel (Zirgan) <sup>1</sup> 0.15% × 5/day (optional)
Cat-scratch disease	<i>Bartonella henselae</i>	Doxycycline (Vibramycin) <sup>1</sup> 100 mg PO BID 2–4 weeks	Children: antibiotic selection based on age, dental maturity.
Cytomegalovirus retinitis	Cytomegalovirus	Ganciclovir 5 mg/kg IV BID for 2–3 weeks followed by maintenance 5 mg/kg/day PO Cidofovir (Vistide) <sup>1</sup> 5 mg/kg/week IV for 2 weeks then 5 mg/kg every 2 weeks Valganciclovir 900 mg BID PO, then PO qd for maintenance. Foscarnet 90 mg/kg IV BID × 2 wks; maintenance 90–120 mg/kg IV daily	Immune reconstitution targets cause of immune compromise.
Diffuse unilateral subacute neuroretinitis (DUSN)	Possible larva of <i>Baylisascaris procyonis</i> , <i>Toxocara canis</i>	Photocoagulation of intraretinal nematode	Destruction of intraretinal larva may preserve vision.
Lyme disease	<i>Borrelia burgdorferi</i>	Doxycycline <sup>1</sup> 100 mg PO BID × 21 days (adults) Amoxicillin <sup>1</sup> 500 mg PO BID (adult); 50 mg/kg PO in divided doses × 14–21 days (children)	Alternative: cefuroxime axetil (Ceftin) 500 mg PO BID × 14–21 days (adult); 30 mg/kg/day PO (children)
Metastatic endophthalmitis (endogenous)	Numerous bloodborne bacteria and fungi	Sepsis treatment protocol; antibiotic selections based on cultures and sensitivities	Role and timing of intravitreal antibiotics and of vitrectomy less well defined
Onchocerciasis	<i>Onchocerca volvulus</i>	Ivermectin (Stromectol) 150 µg/kg single oral dose; repeat at 6 months for the lifespan of adult worm	Corticosteroids to control ocular inflammation; route of administration depends of site of inflammation
Syphilis	<i>Treponema pallidum</i>	Aqueous penicillin G 18–24 million units, IV qd divided doses for 10–14 days	Ocular syphilis is considered a subset of neurosyphilis
Toxocariasis	<i>Toxocara canis</i> or <i>Toxocara cati</i>	Prednisone 1 mg/kg/day PO; timing of antihelminthic therapy unresolved.	Laser ablation and vitrectomy depending on stage of disease. Intraocular larval death incites considerable inflammation
Toxoplasmosis	<i>Toxoplasma gondii</i>	Pyrimethamine (Daraprim): loading dose 50–100 mg PO; treatment dose 25–50 mg/day PO; and sulfadiazine: loading dose 2–4 g PO; treatment dose 1.0 g PO QID, and prednisone (0.5–1.0 mg/kg/day PO)  Trimethoprim-sulfamethoxazole (Bactrim DS) <sup>1</sup> 160 mg/80 mg PO BID, plus above regimen of prednisone	Modify doses if pregnant or immune compromised. Some recommend adding clindamycin <sup>1</sup> or azithromycin. <sup>1</sup>
Tuberculosis	<i>Mycobacterium tuberculosis</i>	For first-line therapy for active tuberculosis, follow recommendations on CDC website.	

BID, Twice a day; IV, intravenous; PO, by mouth; TID, three times a day.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States.

<sup>6</sup>May be compounded by pharmacists.

**TABLE 3** Immune Modulator Therapy for Uveitis

GENERIC (TRADE) NAME	DOSE (ROUTE)*	COMMENT/INDICATIONS <sup>†</sup>
<b>Alkylating Agents</b>		
Chlorambucil (Leukeran) <sup>1</sup>	0.15 mg/kg/day (oral)	Behçet disease; juvenile idiopathic arthritis; pars planitis; sympathetic ophthalmia
Cyclophosphamide (Cytoxan) <sup>1</sup>	1 mg/kg/day (oral)	Sclerouveitis; sympathetic ophthalmia
<b>Antimetabolites</b>		
Azathioprine (Imuran) <sup>1</sup>	1–1.5 mg/kg/day (oral) can increase to 2.5 mg/kg/day	Severe anterior uveitis; panuveitis, juvenile idiopathic arthritis; pars planitis, sarcoidosis; sympathetic uveitis; Vogt-Koyanagi-Harada disease (VKH)
Methotrexate (Otrexup, Rasuvo, Rheumatrex, Trexall) <sup>1</sup>	7.5–15 mg/week (oral)	Anterior, intermediate, and posterior uveitis; juvenile idiopathic arthritis; sympathetic uveitis
Mycophenolate mofetil (Cellcept) <sup>1</sup> ; Mycophenolate sodium (Myfortic) <sup>1</sup>	Mofetil: 1 g (oral) divided dose/day; Sodium: 360 mg (oral)/day	Anterior, intermediate, and posterior uveitis
<b>Calcineurin Inhibitors</b>		
Cyclosporine (Gengraf, Neoral, Sandimmune) <sup>1</sup>	2.5–5 mg/kg/day (oral) divided dose	Often given with prednisone 10–20 mg/day; Behçet disease; birdshot chorioretinopathy; pan uveitis; posterior uveitis; sarcoidosis; sclerouveitis; sympathetic uveitis; VKH
Tacrolimus (Prograf, Astagraf XL, Envasus XR) <sup>1</sup>	0.15–0.3 mg/kg/day (oral)	Behçet disease; birdshot chorioretinopathy; posterior uveitis
<b>Biologic Response Modifier Tumor Necrosis Factor (TNF)-<math>\alpha</math> Inhibitor</b>		
Adalimumab (Humira)	40 mg every other week subcutaneous injection	Anterior, intermediate and posterior uveitis; juvenile idiopathic arthritis; sarcoidosis
Infliximab (Remicade) <sup>1</sup>	3 mg/kg/day (intravenous) weeks 0, 2, and 6	Behçet disease; anterior uveitis; juvenile idiopathic arthritis; sarcoidosis
Certolizumab pegol (Cimzia) <sup>1</sup>	400 mg subcutaneous induction 1–3 doses; 200 mg every 2 weeks	Refractory uveitis
Golimumab (Simponi) <sup>1</sup>	50 mg subcutaneous every 4 weeks	Juvenile idiopathic arthritis; Behçet disease
<b>Biologic Response Modifier Interleukin-1 Inhibitor</b>		
Anakinra (Kineret) <sup>1</sup>	100 mg subcutaneous daily	Behçet disease
Canakinumab (Ilaris) <sup>1</sup>	150–300 mg subcutaneous every 4–8 weeks	Behçet disease; juvenile idiopathic arthritis
<b>Biologic Response Modifier Anti-Interleukin 6 Receptor</b>		
Tocilizumab (Actemra) <sup>1</sup>	4–8 mg/kg (intravenous) every 2–4 weeks	Juvenile idiopathic arthritis; Behçet disease; persistent macular edema
<b>Biologic Response Modifier Anti-Cd20</b>		
Rituximab (Rituxan) <sup>1</sup>	375 mg/m <sup>2</sup> intravenous weekly, modify accordingly	Refractory uveitis; juvenile idiopathic arthritis; refractory VKH;

\*Therapeutic doses and schedules in clinical trials have differed in loading doses and maintenance doses. Cited doses reflect lower ranges.

<sup>†</sup>Refers to reported success at controlling or eliminating inflammation as a single or as a steroid-sparing agent. Strength of recommendations will vary by level of evidence.

<sup>1</sup>Not FDA approved for this indication.

noninfectious uveitis, their equivalence or superiority to the drugs already mentioned are under study. Etanercept (Emberel)<sup>1</sup> may increase the risk of anterior uveitis in persons with ankylosing spondylitis.

Infliximab (Remicade) is given intravenously beginning with two loading doses of 3 to 5 mg/kg each given 2 weeks apart. Injections are then continued at 4-week intervals. Based on clinical response, dose can be gradually increased to 10 mg/kg. Side effects include infection from activation of latent tuberculosis or hepatitis, drug-induced autoimmune disease, and demyelinating disease. If non-melanoma skin cancer is excluded, current published data indicate that TNF-inhibitors do not increase the risk for solid malignancies. Adalimumab (Humira) is given subcutaneously starting at 40 mg/kg every 2 weeks. Children are started at a reduced dose. Its adverse risk profile is similar to that of infliximab.

Other biologics used to treat noninfectious uveitis such as anti-CD20 monoclonal antibody (Rituximab [Rituxan]<sup>1</sup>) have clinically established utility in the treatment of specific disease entities such as severe scleritis, peripheral ulcerative keratitis, ocular mucous membrane pemphigoid, and retinal vasculitis. In these cases the rheumatoid arthritis approved dosing regimen is used: two 1000 mg intravenous infusions separated by 2 weeks (cycle 1) then every 24 weeks or based on clinical evaluation, but not sooner than every 16 weeks. Interferon alfa-2a is associated with flu-like symptoms and depression, which may limit patient acceptance.

#### Complications of Uveitis

Chronic uveitis gives rise to a variety of ocular complications such as secondary glaucoma; macular edema; corneal dysfunction; neovascularization of the iris, angle, and retina; retinal tears

and detachments; cyclitic membrane formation; and uveal effusion, as well as other conditions. These ocular complications are typically approached by controlling or eliminating ocular inflammation and managing the structural/functional problems according to standards guidelines.

### Disease-Specific Recommendations

Strength of recommendations for disease-specific noncorticosteroid immunomodulatory therapy is constrained by the relative lack of prospective clinical trials, drug-to-drug comparison trials, studies that have included patients with diverse forms of uveitis, and the small size of studies. Given these limitations, the strength of recommendations is tempered by a level of evidence for most drugs of 2B or lower on the Oxford Centre for Evidence-Based Medicine level of evidence scale. Mycophenolate preparations,<sup>1</sup> azathioprine,<sup>1</sup> methotrexate,<sup>1</sup> cyclophosphamide,<sup>1</sup> cyclosporine,<sup>1</sup> sirolimus (Rapamune),<sup>1</sup> infliximab,<sup>1</sup> adalimumab, and etanercept<sup>1</sup> have demonstrated varying degrees of success in controlling inflammation, improving visual outcome, and reducing corticosteroid use in severe anterior, intermediate, and posterior uveitis and in panuveitis. Control of inflammation and improved visual acuity in Vogt-Koyanagi-Harada disease have been achieved with systemic methotrexate,<sup>1</sup> azathioprine,<sup>1</sup> mycophenolate preparations,<sup>1</sup> infliximab,<sup>1</sup> adalimumab,<sup>1</sup> and interferon alfa-2a.<sup>1</sup> The uveitis of Beçhet disease, juvenile idiopathic arthritis, pars planitis, and sympathetic ophthalmia responds to chlorambucil.<sup>1</sup> Mycophenolate preparations<sup>1</sup> have had success in various forms of anterior, intermediate, and posterior uveitis. The inflammation of Beçhet disease has been controlled with azathioprine,<sup>1</sup> infliximab,<sup>1</sup> adalimumab,<sup>1</sup> rituximab,<sup>1</sup> and interferon alfa-2a.<sup>1</sup> Sarcoid uveitis has responded to infliximab,<sup>1</sup> and adalimumab.<sup>1</sup> The systemic disease of juvenile idiopathic arthritis has been successfully managed with methotrexate, cyclosporine,<sup>1</sup> mycophenolate mofetil,<sup>1</sup> azathioprine,<sup>1</sup> and TNF- $\alpha$  inhibitors adalimumab and infliximab.<sup>1</sup> Therapeutic vitrectomy and/or laser ablation has been used in different forms of noninfectious uveitis, but evidence of long-term effectiveness is sparse.

### Systemic Drug Use in Pregnancy and in Children

Because the teratogenic potential of many immunosuppressive drugs is incompletely understood, it may be prudent to discuss contraception when they are administered to women. The largely unknown teratogenic effects of immunosuppressive agents in men should also be considered. Although prednisone is well tolerated during pregnancy, its use should be carefully comanaged with an obstetrician.

The effects of immunosuppressive drugs are less well studied in children than in adults. Children on immunosuppressive agents should not receive live virus vaccine for 3 months after immunosuppressive use has ended. This would include high-dose corticosteroids. The impact of immunosuppressive drugs and systemic corticosteroids on growth and their collateral effects on social development are not inconsequential. Osteoporosis, adrenal suppression, and heightened susceptibility to infections related to cell-mediated immunity are among the side effects that require monitoring in children. Calcium supplements and vitamin D may be beneficial in some circumstances.

<sup>1</sup>Not FDA approved for this indication.

## VISION REHABILITATION

Method of

August Colenbrander, MD; and Donald C. Fletcher, MD

### CURRENT DIAGNOSIS

- The need for vision rehabilitation needs to be considered whenever patients indicate that they have difficulty performing visual tasks.
- Sometimes, however, patients do not recognize the visual causes of their complaints, therefore:
  - Vision rehabilitation needs to be considered whenever visual acuity is reported as 20/50 or less.
  - Vision rehabilitation also needs to be considered for all patients with reported visual disorders, such as visual field deficits or contrast vision deficits, who have not received this service yet,

### CURRENT THERAPY

- Simple cases of reduced visual acuity can be addressed with a variety of magnifying devices, ranging from stronger glasses to electronic devices.
- Improved task lighting can often be helpful.
- Orientation and mobility training can be indicated for patients with visual field loss, even if their visual acuity is still adequate.
- As for any other specialized service, referral to a dedicated low vision service may be indicated.

*Vision rehabilitation* refers to the multidisciplinary effort of assisting those with various degrees of vision loss in coping with the *consequences* of that loss. To describe vision rehabilitation, the nature of vision itself must be understood. Vision is the major source of information about our environment. The eyes alone contribute as much information to the brain as all other organs combined. It is not surprising therefore that many people fear loss of vision almost as much as loss of life.

Most people will state that “we see with our eyes.” On closer examination, this is not true. An isolated eyeball cannot produce any vision; our brain, however, can produce exquisite visual imagery in our dreams, without any input from the eyes.

The ultimate goal of vision is to facilitate interaction with the environment, not just to read letters on a letter chart. To achieve this goal, the visual process goes through three distinct stages. Each stage comes with its own specific problems.

- First is the *optical stage*, where the refractive media of the eye deliver an image to the retina. Familiar problems in this area include refractive errors and cataracts.
- Second is the *receptor stage*, where the optical image is translated into neural impulses. Age-related macular degeneration (AMD) is a significant problem of the receptor stage, which is becoming increasingly common as the population ages.
- Third are various stages of *neural processing*, initially in the inner retina (glaucoma), then in the visual cortex, and finally in higher cortical centers, where the visual input gives rise to visual perception and to visually guided behaviors, actions, and interactions.

The most common visual problems vary for different ages. Today, brain-damage-related vision problems (cerebral visual impairment [CVI]) are the single most prevalent cause of visual impairment in *infants and young children*. Given that vision is so important for normal development, vision loss in infants constitutes a developmental emergency and should be detected and addressed as early as possible. When a child does not smile back at the mother, the mother may be inclined to leave the baby in its crib, instead of holding him or her to provide extra tactile stimulation to compensate for missing visual stimulation.

At *school age* and later, visual health is critical because reading becomes important for academic development. For *adults*, vision is important for maintaining independence in activities of daily living (ADL) and development of vocational skills. For *seniors*, vision loss may exacerbate other age-related dysfunctions. Studies of the elderly have shown correlations between visual impairment and depression, falls, and reduced longevity. In all of these instances, early detection and early intervention are essential; the primary care physician plays a crucial role in this respect.

### Four Aspects of Vision Loss

Vision is a complex phenomenon.

A convenient framework for discussing the various impacts of vision loss is to consider four aspects of visual functioning (Figure 1). At a basic level, we may consider how various external causes may result in *structural changes* to the eyes and

the visual pathways. For this aspect, the focus is on the tissue; an ocular pathologist is needed to describe the pathologic condition. However, structural changes alone do not determine how well the eyes actually function. Clinicians need to measure various *organ functions*, such as visual acuity, visual field, and contrast sensitivity.

Yet even knowing how the eyes function does not tell us how the person functions. In other words, the *abilities* of the person to perform tasks, such as reading, mobility, face recognition, and ADL, must be considered. Occupational therapists (OTs) and other rehabilitation professionals work with patients to teach them how residual vision can be used most effectively. OTs also assess the person in a societal context. For example, do the visual changes have an impact on the person’s *participation* in society, on his or her ability to perform necessary tasks, and on general satisfaction with one’s quality of life? It is clear that to cover all aspects of vision rehabilitation, a team approach is necessary and that the patient must be part of that team.

A single ADL may cover several of the above aspects. When reading, the aspect of minimum print size falls under organ function (retinal resolution). Reading speed (words/minute) and reading endurance (hours/day) define abilities of the person; reading endurance may be poor, even if reading acuity is adequate. Reading enjoyment, finally, falls under the aspect of quality of life.

It is helpful to draw a line between the organ side of Figure 1 on the left and the person side on the right. On the left side of the diagram, we discuss *visual functions*, which describe how each eye functions. On the right side, we speak of *functional vision*, which describes how the person functions in vision-related activities. Medical specialists are well versed in dealing with the left side of the diagram. Yet the ultimate goal of all interventions is to improve the patient’s quality of life. It is the function of vision rehabilitation to make sure that “eye” doctors become “people” doctors by extending their interest to the right side of the diagram as well.

### Comprehensive Vision Rehabilitation

Considering all of these aspects, comprehensive vision rehabilitation involves much more than the patient’s performance on a letter chart and requires teamwork by different professionals who specialize in different aspects of vision loss. All vision loss starts with some medical condition, so primary care physicians are well positioned to coordinate team activities. Primary care physicians need to be aware of what other team members can contribute and should know where to locate vision rehabilitation resources and to make appropriate referrals.

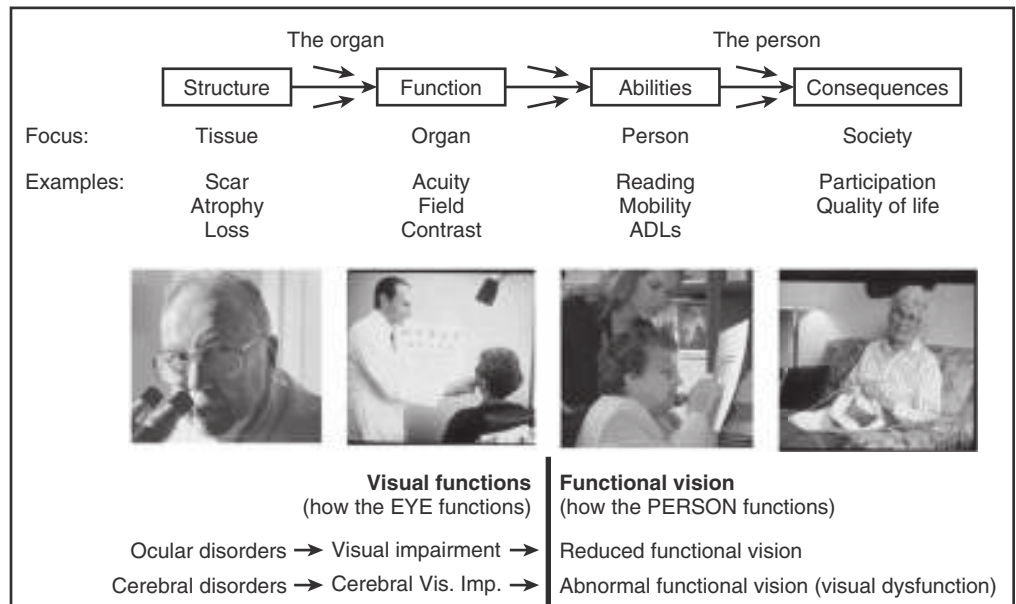

Figure 1 Aspects of vision loss.

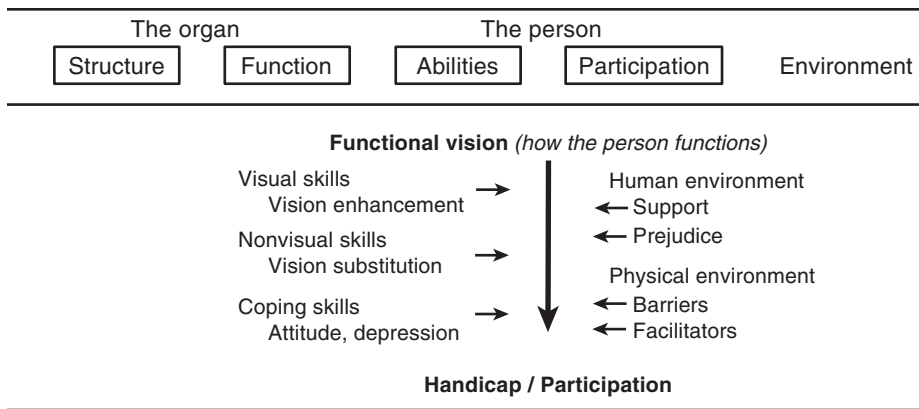

Figure 2 Comprehensive vision rehabilitation.

Figure 2 illustrates that comprehensive vision rehabilitation involves much more than the traditional optical low vision care offered in the past, and is still relevant today.

*Low vision* is a term used to describe individuals whose vision (with appropriate optical correction) is less than normal (low) but who are not blind (vision). Unfortunately, many people in this category do not yet receive the services they need. Such services should include adequate refractive, medical, and surgical care as well as rehabilitative care. The latter may include vision enhancement, vision substitution, and vision assistance as well as the honing of coping skills.

*Vision enhancement*, which is the traditional focus of low vision care, is primarily oriented at improving residual visual function through visual aids, including a wide range of magnification devices. Additionally, enhancement of contrast, illumination, and filters need to be explored.

Low vision is distinct from blindness (i.e., no vision). For blindness, the emphasis of rehabilitation is entirely on vision substitution. Patients with severe or profound low vision may combine the use of low vision rehabilitation skills with some blindness rehabilitation skills.

*Vision substitution* expands the options for rehabilitation by optimizing the use of other senses. This can range from using simple tactile markings to sense the position of a stove dial to devices such as talking books, a long cane for travel, and braille for reading. Vision enhancement and vision substitution are not mutually exclusive. A patient may use a magnifier to read price tags and may prefer talking books for recreational reading. A patient with retinitis pigmentosa, which causes reduced night vision, may have normal mobility in the daytime and need a cane at night. Digital audio books may have braille labels.

*Vision assistance*. A special form of vision substitution involves using the eyes of others. Family members, caregivers, and office personnel should be familiar with *sighted guide* techniques to effectively assist visually impaired patients with minimal embarrassment. *Guide dogs* are also a possibility. Using a guide dog requires training of the patient as well as of the dog so that they can work as a team. Dog users must also demonstrate mastery of long cane travel skills.

*Coping skills*. How different patients will accept visual aids may differ greatly. It is important to recognize that vision loss often causes a reactive depression. On the one hand, a depressed patient will be less receptive to rehabilitative suggestions. On the other hand, demonstration of rehabilitative success can be a powerful tool to lift a reactive depression and to motivate the patient for further success. It has been shown that the teaching of general problem-solving skills may improve the effectiveness of vision rehabilitation.

Many professionals may be involved in vision rehabilitation. Technicians may prescribe various magnifiers, rehabilitation workers may teach daily living skills, and psychologists may address depression. Acceptance of the work of these professionals

will be improved if the trusted primary care physician is credited with making the referrals.

Beyond the factors that directly involve the patient, the environment must also be considered.

The *human environment* is important. As patients go through the stages of adaptation, a supportive home environment is essential. As patients are counseled, it is important to include spouses, children, or significant others to make sure that they understand the condition, know what can be expected, and know how to support the patient. Answering family and caregiver questions directly is often better than leaving this to the patient, who initially may not have absorbed everything that was said. An overprotective environment, which deprives patients of opportunities to do things for themselves, can be as detrimental as an overdemanding one that puts too much emphasis on the patient's shortcomings. The same holds true for the work or school environment and for social groups.

Initially, patients often feel isolated and believe that they are the only ones experiencing these problems. *Peer support groups* can be helpful; in these groups, patients can experience how others are dealing with similar problems.

Finally, the *physical environment* needs to be considered. An uncluttered environment, where things have a defined, fixed place is helpful because it reduces the need for searching. Good general illumination and task lighting often help, because at higher illumination levels retinal cells that are damaged but not dead can still contribute to vision. Good contrast is important: Do not serve milk in a white Styrofoam cup; mark the edges of steps and stairs. The triangles and circles on men's and women's bathrooms are designed to be visible for those with very low vision; braille labels in elevators are useful for people who are totally blind.

### How Blind Is Blind?

The most common visual function test is the letter chart, developed by Snellen in 1862. That test determines how large a letter, or other symbol, must be to be recognized by the patient. That size is then compared with the size recognized by a standard observer. If the magnification requirement is 2 $\times$ , visual acuity is said to be 1/2; if it is 5 $\times$ , visual acuity is said to be 1/5, etc. That fraction can be recorded in different ways; in the United States, it is customary to use 20 as the numerator (1/2 = 20/40, 1/5 = 20/100); in the British Commonwealth, 6 is used as the numerator (6/12, 6/30); in Europe, decimal fractions are common (0.5, 0.2).

Those calculations are simple; unfortunately, the terminology used to describe various ranges of vision loss is confusing. Figure 3 shows progressively degraded pictures with examples of the terminology used to describe different degrees of visual impairment. The visual acuity level represented by each picture can be determined from the number of lines that are readable on the low vision letter chart.

**Figure 3** Ranges of vision loss.

The first picture shows the visual acuity level that is labeled as “low vision” by the World Health Organization (WHO). Although the bottom lines of the letter chart cannot be read, the appearance of the room is near normal. The next picture shows what the US Social Security Administration considers “statutory blindness” for its programs. Although reading regular print is not possible without magnification devices, it is clear that this is far from actual blindness. Other US programs use a different definition for “legal blindness,” and the WHO does not consider a person “blind” until he or she has reached the status of the last picture. At that level, reading even the special letter chart is not possible, but one can still navigate the room. Even this level of visual impairment does not constitute actual blindness.

The widespread use of the word “blindness” is unfortunate because it cannot be used with modifiers. One is either blind or sighted; one cannot be “a little bit blind.” This black-and-white thinking has hampered the acceptance of vision rehabilitation. Terms such as *vision loss* or *visual impairment* are preferred because they can be used with modifiers, including mild, moderate, severe, profound, and total vision loss. Although “legal blindness” and “severe vision loss” (ICD-9-CM) have the same definition, there is a big difference between telling a patient “you are legally blind” and “you have a severe visual impairment.” The first statement might be followed by “I am sorry, there is nothing more we can do for your eyes”; the second statement leads to the question, “What can we do to help you cope with this problem?”

### Vision Rehabilitation Techniques and Devices

Having considered the general outlines of vision rehabilitation, some details of rehabilitative interventions can be discussed. Primary care physicians should know what vision rehabilitation techniques are available so that they can make appropriate referrals.

### Optical Problems

The most commonly encountered visual problems are those involving the optical system of the eye.

*Refractive errors* are the easiest visual problems to deal with. Refractive errors can be corrected with glasses or contact lenses, and for those who hate glasses, by refractive surgery. Even if there are other causes of vision loss, determining the best refractive correction is still important.

Uncorrected refractive error accounts for about half of all visual impairment worldwide. In developed countries, the question may be why people do not avail themselves of the solutions that are available. In developing countries, availability and accessibility of eye care and of the means for correcting refractive errors often do not exist. Providing these services is a matter of infrastructure, not of individual healthcare.

*Opacities* disrupt visual image formation. Cataracts are the most familiar opacity; they can be removed by surgery. Other opacities of a temporary or permanent nature may occur in the cornea, in the anterior chamber, or in the vitreous cavity. Corneal and conjunctival infections may cause corneal scarring, as is the case in trachoma, a condition that does not exist in the developed world anymore but is still a major cause of vision loss worldwide.

*Letter chart acuity* is a good way to measure optical problems. It should be understood, however, that letter chart acuity only measures the function of the retinal area where the letter read is projected. Even for a patient with 20/200 acuity, this area is less than 1 degree in diameter. For optical problems this does not matter because foveal defocus predicts equal defocus in all other areas of the retina. For retinal problems, however, visual acuity alone is not sufficient to characterize the visual status.

*Magnification* is the primary way to compensate for reduced acuity. One way to provide magnification is to bring print closer to the eye. For older adults, this requires reading glasses with extra power. Alternatively, large print may be helpful. Larger print on medicine labels, as required in several states, can reduce medication errors by older adults, who often take several medications. Handheld magnifiers are another option; today, many have built-in LED illumination to provide more light. Video-magnifiers with a table-mounted large screen are ideal for prolonged reading; they can also enhance contrast and brightness, while some devices can even read the text out loud. Tablets, smartphone apps, and dedicated devices can provide similar advantages in a portable form. Today, these electronic means of magnification are increasingly popular because they can provide not only magnification but also contrast enhancement. They also have a larger field of view and allow a more comfortable reading distance with binocular viewing.

### Retinal Problems

While primitive forms of cataract surgery have existed for centuries, the study of retinal disorders has only been possible since the invention of the ophthalmoscope in 1851. The ability to

**Figure 4** Ring scotoma.

effectively treat some retinal disorders is even more recent. Important retinal disorders include the following.

*Age-related macular degeneration (AMD)* is the most frequent diagnosis encountered in low vision rehabilitation services in the Western world. Because the condition is age-related, its frequency will increase in the future as our population ages. This has caused profound changes in the nature of low vision care. Until the mid-20th century, most low vision care was provided by special education teachers serving young students in schools for the blind. Today, the majority of low vision patients are seniors. This has resulted in a significant influx of OTs into the field with skills in addressing multiple geriatric impairments. Yet the needs of seniors to be served still outstrip the available services.

Given that macular degeneration affects central vision and the ability to read, most patients will ultimately seek rehabilitation help. However, if only one eye is affected, AMD may go unnoticed. The patient may only complain when the second eye starts to deteriorate; at that point, the damage in the first eye may be beyond repair. Therefore, it is useful to ask patients to periodically cover each eye to see whether there is any vision difference between the eyes. If there is, this is a reason for referral.

*Glaucoma* is another age-related condition. It causes loss of peripheral vision and affects central vision only in the late stages. Glaucoma often goes undetected because patients are not spontaneously aware of visual field loss, as little as they are spontaneously aware of an increased blood pressure. Therefore, glaucoma must be sought out, primarily by measuring the intraocular pressure.

*Diabetic retinopathy* is not limited to seniors. As the incidence of diabetes is rising worldwide, so is the incidence of diabetic retinopathy. Even if treated adequately, it will cause scattered blind spots throughout the visual field.

There are many other hereditary and nonhereditary retinal conditions that may cause vision loss, but they occur in smaller numbers. They all require the help of vision rehabilitation professionals to help patients cope effectively.

*Scotomata*. Whatever the cause, retinal conditions will generally cause localized blind spots (scotomata). Therefore, when retinal damage is suspected, visual acuity alone is no longer a sufficient descriptor of visual impairment because the retinal area where the letter chart symbol is projected does not predict anything about other retinal areas. In addition to letter chart acuity, the condition of the visual field and the presence of blind spots (scotomata) must be considered (Figure 4).

Figure 4 shows a retinal image, where a word is projected across a ring scotoma that leaves only a small central island of vision. This patient will be able to recognize the central letter but will not be able to read the word. Clinicians must be careful when providing such patients with magnification because too much magnification will mean that fewer letters fit into the central area. This example also makes it clear that when retinal involvement is suspected, a reading test may be more informative than a letter chart test, given that reading requires a larger retinal area.

## Neural Processing Problems

As stated earlier, the most important stages of the visual process take place after the retinal receptors have translated the optical image into neural impulses.

The first transformations take place in the *inner retina*. Here, the input from 100 M receptors in each eye is preprocessed and compressed for transmission through 1 M nerve fibers in each optic nerve. The optic nerve fibers do not simply transmit a pixel-by-pixel image, as does a digital camera. Different retinal ganglion cells probably transmit different aspects of the image, such as edges, movement, color, brightness, and so on. These separate “movies” are transmitted in parallel. At a later stage of neural processing, these different aspects of the image are merged again to contribute to a single visual perception.

At the first synaptic station in the lateral geniculate nucleus, only 20% of the incoming connections come from the optic nerves; the other 80% come from other cortical centers and probably contribute to filtering based on attention and other factors.

In the visual cortex, the visual information is analyzed for shapes and contours. In higher cortical centers, the visual information is further processed. Here, the flow of information is no longer strictly visual because it is combined with information from other senses. This results in identification and recognition of objects through comparison to stored concepts (through the ventral stream to the temporal lobe of the brain) and in spatial location of an object (through the dorsal stream to the parietal lobe of the brain), which then result in voluntary or involuntary visually guided action.

Our knowledge of these processes is still relatively new. It has been greatly helped by new modalities for neural and retinal imaging. Today, neural processing problems are increasingly recognized in all age groups.

In young children, CVI is now recognized as the most frequent cause of visual perceptual problems. CVI is often caused by perinatal ischemia, which may cause cortical as well as subcortical changes (periventricular leukomalacia). Because this ischemia is not localized, impairments are often not limited to the visual system. Schools for the blind have increasingly developed into schools for children with multiple disabilities.

In contact sports, the results of repeated subclinical injuries are now recognized.

In veterans, traumatic brain injuries may cause problems that may be hard to define. Often visual interpretation and decision making are impaired; oculomotor system problems are often found. Traffic accidents may cause similar damage.

In older adults, strokes may cause more localized problems and agnosias for specific tasks. In all of these cases, the term *visual impairment* may be used when visual acuity and/or visual field are impaired. The term *visual dysfunction* may be more appropriate when the visual input from the eyes to the brain is normal but the processing of this information in the brain is not.

## Patient-Centered Functional Priorities

Vision problems affect all aspects of a patient’s life. It is no longer sufficient for clinicians to determine that nothing more can be done about the *causes* of vision loss, because much more can be done about the *consequences* of vision impairment.

To determine the range of services that may be appropriate for an individual with vision impairment, the American Academy of Ophthalmology recommends consideration of the following functional priority areas:

- Reading—for many patients, this is their foremost concern.
- ADL—even though reading may be the most prominent complaint, most people spend the larger part of their day performing vision-dependent activities other than reading for self-care and home management.

- Safety—Patients with visual field loss must be made explicitly aware of this loss and the problems it may cause in navigating the environment. Are they at risk for falls? How do they cross the street? Do they drive?
- Community participation—can the individual still participate in community events, including religious gatherings?
- Physical, cognitive, and psychosocial well-being—because many patients with vision loss are older, this is an important aspect that should not be overlooked. If cognitive problems exist, it may affect the recommendations to be made.

Based on these considerations, patient-centered priorities can be set and specific rehabilitation goals formulated that reflect the patient's needs and desires. The primary care physician can then make appropriate referrals for rehabilitation.

## Infectious Diseases

### AMEBIASIS

Method of

Koji Watanabe, MD, PhD

#### CURRENT DIAGNOSIS (SEE ALSO BOX 1)

- Amebiasis is transmitted by the ingestion of fecally contaminated water or food and by high-risk sexual behaviors (men who have sex with men [MSM] or oral–anal sexual contact).
- Although self-limiting mild to moderate colitis is the most common disease presentation, various severe illnesses (liver abscess, peritonitis, pleurisy, and pericarditis) can also occur.
- Diagnostic value of microscopic stool or abscess ova and parasite examination (O&P) is low. Antigen detection in stool shows high sensitivity for severely diarrheal and/or dysentery cases (amebic colitis), but shows relatively low sensitivity for mild colitis or asymptomatic cases. Serology shows high sensitivity but cannot distinguish current infection from past infection, and it is ideally used in conjunction with fecal antigen detection or polymerase chain reaction (PCR).

#### CURRENT THERAPY (SEE ALSO BOX 2)

- Infected individuals who are asymptomatic should be treated with a luminal agent (e.g., paromomycin), because they can be a source of new infection and can develop invasive amebiasis after long-term asymptomatic infection.
- Mild to severe colitis and extraintestinal disease require initial treatment with a tissue-active agent (e.g., metronidazole) followed by a luminal agent.
- Reinfection can occur frequently in endemic settings. The clinician should discuss methods to prevent re-exposure to *Entamoeba histolytica* with treated patients.

#### Epidemiology and Risk Factors for Acquisition

Amebiasis is transmitted by oral ingestion of the transmissible cyst form of *Entamoeba histolytica* in human stools. Transmission occurs by the ingestion of fecally contaminated food and water, mainly in developing countries. It also transmits directly from human to human by sexual contact or in institutions for the cognitively impaired. Food- or water-borne infection occurs in settings of poor sanitation. It is estimated to be the second most common cause of parasite infection–related mortality worldwide, accounting for 40,000 to 70,000 deaths annually. In developed countries, people who travel to or immigrate from developing countries are at higher risk for this parasitic disease. In the United States, amebiasis is the second most common cause of diarrhea in returning travelers. However, over the last two

decades amebic infection has been increasingly reported as a sexually transmitted infection in East Asian developed countries and Australia. In one report from Taiwan, men who have sex with men (MSM) and people engaging in oral–anal sex were more likely to be seropositive for *E. histolytica*. While older studies from the United States have shown that amebiasis in MSM was due to nonpathogenic *Entamoeba dispar*, more recently MSM was shown to be an independent risk factor for amebiasis-related mortality. Also, *E. histolytica* infection has been reported as a common comorbidity among HIV-infected MSM or as a sexually transmitted infection in developed European countries. It is important for primary care physicians to take detailed histories of sexual behavior as well as travel whenever amebiasis is suspected.

#### Pathophysiology and Susceptible Host Factors to Invasive Diseases

*E. histolytica* has two different forms: the tissue-invasive “trophozoite form” and the infectious “cyst form,” which is responsible for transmission. Cysts are notable for environmental stability, demonstrating considerable resistance to chlorination and desiccation, with several outbreaks resulting from the contamination of drinking water. Once cysts are ingested, excystation occurs at the terminal ileum or large intestine, forming motile trophozoites. Trophozoites bind to the mucous layer and the underlying intestinal epithelial cells via a parasite Gal/GalNAc lectin. Blockade of activity of the Gal/Gal lectin prevents contact-dependent cytolysis. Moreover, it has been shown that antilectin IgA in stool or breast milk has a protective effect against future acquisition of amebic infection in cohort studies. These results indicate that the Gal/GalNAc lectin plays a crucial role in amebic infection.

Host factors are also important for susceptibility to amebiasis. Amebiasis is more common in malnourished children, and the nutritional hormone leptin is protective, with a single nucleotide mutation of leptin receptor being the predominant genetic factor controlling amebiasis susceptibility in Bangladeshi children. Amebic liver abscess (ALA) is 10 times more common in men than in women and is uncommon in children.

#### Clinical Manifestations and Complications of Amebiasis

Asymptomatic self-limiting infection is the most common disease form of amebiasis. Up to 80% to 90% of people exposed to cysts have no or mild symptoms and clear the infection spontaneously. However, asymptomatic infection persists for a long time in some individuals who are reported as asymptomatic cyst passers or as fecal occult blood–positive, which is incidentally diagnosed by colonoscopy. These asymptotically infected individuals can be a source of a new infection in the community. Also, some develop symptomatic invasive diseases after long-term latent infection.

Symptomatic intestinal amebiasis (amebic colitis) generally has a subacute onset. Usually it takes 1 to 3 weeks from disease onset to make a diagnosis. Abdominal symptoms range from mild diarrhea to severe dysentery with abdominal pain, diarrhea, and bloody stools. Weight loss and fever are common but not universal symptoms. Intestinal fistula or perforation of the large intestine, resulting in peritonitis, is a rare but life-threatening complication of intestinal amebiasis, which is called as “fulminant amebiasis.” The very young or old, malnourished

people, pregnant women, and patients using corticosteroids are at increased risk of fulminant amebiasis. Toxic megacolon also can be caused by amebiasis. Amebic colitis sometimes mimics acute appendicitis. In this situation, appendectomy without amebicidal treatment may result in severe postoperative complications, such as abdominal sepsis, gastrointestinal fistula, or hemorrhage. Periodic acid–Schiff (PAS) stain, or ideally, immunoperoxidase with anti-*E. histolytica* antibodies, in addition to routine hematoxylin and eosin (H&E) stain can help to identify the parasite by the histopathology. Thus, intestinal amebiasis sometimes presents as severe and complicated clinical illnesses.

*E. histolytica* infection also may have extraintestinal dissemination. Liver abscess is the most common form of extraintestinal amebiasis. Patients usually present with 1 to 2 weeks of fever with or without right upper quadrant abdominal pain. Other common symptoms may include cough, sweating, malaise, weight loss, anorexia, and hiccough. Two-thirds of patients lack intestinal symptoms. Physical examination reveals hepatomegaly and tenderness over the liver in approximately half of cases. Complications can occur by direct invasion of trophozoites or the indirect effect of inflammation. Up to 10% of patients with ALA have accompanying thoracic amebiasis (pleuritic and pleural effusion). Pericarditis is the next most common form of extraintestinal amebiasis; it may result from rupture of a liver abscess in the left lobe or through extension of pleural amebiasis. Cerebral amebic abscesses are a rare form of extraintestinal amebiasis; they usually accompany other metastatic lesions, such as liver abscesses and thoracic amebiasis.

Thus, amebiasis can have various clinical presentations. The diagnosis can be very difficult to make in severe cases and in atypical clinical presentations because of secondary bacterial infection at the site of amebic invasion.

### Diagnosis

Sensitivity of each diagnostic test is shown in **Box 1**. Although microscopic stool ova and parasite examination (O&P) is frequently used in many countries including the United States, it has low sensitivity; moreover, accuracy is highly dependent on the skill of the person who carries out. Identification of trophozoites by microscope in aspirated fluid from amebic abscess is more challenging because trophozoites are present only at the edge of the abscess. Moreover, microscopic examination cannot distinguish pathogenic *E. histolytica* from nonpathogenic *E. dispar* or *Entamoeba moshkovskii* by shape.

Currently, the combination of antigen detection in stool and/or sera and serologic testing is the best diagnostic pathway. Antigen detection in feces by the TechLab *E. histolytica* II enzyme-linked immunosorbent assay (ELISA), or the TechLab *E. HISTOLYTICA* QUIK CHEK membrane enzyme immunoassay, is rapid to perform (<2 hours, or <30 minutes) and can distinguish *E. histolytica* from *E. dispar* and *E. moshkovskii*. These antigen tests have highly sensitive diagnostic value for amebic colitis, that is, Bristol stool scale 6 or 7 (60% to 95%), whereas sensitivity is relatively low for asymptomatic carrier, that is, Bristol stool scale 5 or lower (20% to 50%). In one report, when used on patients' sera, ELISA showed high sensitivity in ALA cases but only before metronidazole treatment began. Real-time polymerase chain reaction (PCR) in stool is superior in sensitivity to stool antigen detection, but is still technically complex for diagnostic use in clinical settings. Serologic tests are sensitive (approximately 90% during the convalescent phase) and noninvasive diagnostic tools for amebiasis. Antibodies are detectable in 70% or more of patients within 5 to 7 days of acute infection and persist for years after treatment. Therefore, a negative serologic result is helpful for exclusion of disease, whereas a positive result cannot distinguish between present and previous infection.

Histopathologic examination using biopsy or resected samples is sometimes useful for the diagnosis of intestinal amebiasis. As mentioned, PAS stain in addition to H&E can increase sensitivity in detection of *Entamoeba*. However, identification of *Entamoeba* in biopsy specimens is often challenging. About half of cases with gross ulcerative lesions in the large intestine, in which *E. histolytica* was proven by PCR, had a negative result on histopathology.

### BOX 1 Sensitivity of Tests for Diagnosis of Amebiasis.\*

Test	Colitis	Liver Abscess
Microscopy (stool)	25%–60%	10%–40%
Stool antigen detection (e.g., <i>E. histolytica</i> II enzyme-linked immunosorbent assay (ELISA)	80%	40%
Serum antigen detection	65%	>95%
Microscopy (abscess fluid)	N/A	<20%
Real time polymerase chain reaction	>95%	>95%
Serologic testing (indirect hemagglutination)		
Acute	70%	70%–80%
Convalescent	>90%	>90%
Histopathology by biopsy	45%	N/A

\*Before the initiation of therapy.

### BOX 2 Treatment Recommendations for Amebiasis in Adults.

#### Asymptomatically Infected Individuals

Paromomycin (Humatin) 30 mg/kg/d PO tid × 5–10 days  
or

Iodoquinol (Yodoxin)<sup>2</sup> 650 mg PO tid × 20 days

#### Mild to Severe Intestinal and Extraintestinal Disease

Metronidazole (Flagyl)\* 750 mg PO tid × 10 days  
or

Tinidazole (Tindamax) 2 g PO once daily × 5 days

Followed by

Paromomycin<sup>1</sup> 30 mg/kg/d PO tid × 5–10 days  
or

Iodoquinol 650 mg PO tid × 20 days

\*Use of intravenous form of metronidazole (500mg q8h) is limited to patients who cannot take oral medications.

<sup>1</sup>Not FDA approved for this indication.

<sup>2</sup>Not available in the United States

Modified from Mandell G, Bennett JE, Dolin R, Blaser MJ. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 7th ed. Philadelphia: Elsevier Saunders; 2009.

### Therapy

Recommended treatment regimens are shown in **Box 2**. Therapy for invasive infection differs from therapy for noninvasive infection. Noninvasive infections (treatment for asymptotically infected individuals) require treatment with luminal-active agents: paromomycin (Humatin) is currently recommended because of its high potency in asymptomatic cyst passers. Recently, it is increasingly reported that macroscopically visible colonic ulcers by *E. histolytica* are unexpectedly diagnosed from asymptomatic individuals. Treatment for asymptomatic patients with colonic ulcers is currently undetermined; however, tissue-active agents are commonly administered prior to luminal-active agents in reported cases.

For symptomatic patients, tissue-active agents should be administered before luminal-active agents. Most patients with mild to moderate colitis and uncomplicated liver abscess respond to treatment with tissue-active agents, such as metronidazole (Flagyl) and tinidazole (Tindamax). Tinidazole has the advantage of less frequent dosing than metronidazole. Treatment with tissue-active agents should be followed by luminal-active agents because parasites persist in the

intestine in up to 40% to 60% of patients who receive tissue-active agents. Broad-spectrum antibiotics and/or surgical treatment should be added to tissue-active agents in patients with fulminant colitis in which perforation and peritonitis or bacteremia are suspected. Therapeutic needle aspiration or catheter drainage is not routinely required for uncomplicated liver abscesses. Those interventions in addition to medical treatment are recommended if there is clinical deterioration or lack of response to initial medical treatment, or if alternative diagnoses need to be excluded. Also, some reports suggest that clinicians should consider those interventions for patients with a high risk of abscess rupture, as defined by a cavity with a diameter of more than 5 cm or by the presence of lesions in the left lobe, although these criteria were not conclusive in case-control studies.

Symptoms (diarrhea, dysentery, fever, pain, and tenderness) and laboratory markers (white blood cell counts, red blood cell counts, and C-reactive protein) rapidly improve after effective treatment even in patients with extraintestinal lesions. In contrast, radiologic findings, such as abscess size, often remain unchanged for months after completion of treatment.

### Monitoring After Treatment and Disease Prevention

Although routine monitoring after treating amebiasis is not recommended, it is well known that reinfection frequently occurs in endemic situations, including both water- or food-borne infections and sexually transmitted infections. In developed countries, in order to prevent reinfection, it is important for the primary physician to inform patients of behaviors that will place them at risk for acquisition of the cyst and how to avoid them, such as avoiding nonsterilized water or food in developing countries, unsafe homosexual contact, and oral-anal sexual contact. In developing countries, more than 1 billion people still have no access to safe food and water, resulting in the urgent need for an effective vaccine. Induction of acquired mucosal immunity is the current goal for vaccine development. Although there is currently no vaccine in human clinical trials, a vaccine containing the naïve or recombinant Gal/GalNAc lectin of *E. histolytica* has strong immunogenicity and protective effect against amebic colitis and liver abscess in animal models. Continuous effort will be needed to develop an effective vaccine to save the lives of affected people in endemic areas.

## ANTHRAX

Method of  
Shingo Chihara, MD

### CURRENT DIAGNOSIS

#### Cutaneous Anthrax

- Incubation period of 1 to 7 days from exposure to cattle
- Painless or pruritic lesion progresses to ulcer and eschar
- Significant swelling
- Gram stain and culture of lesion

#### Gastrointestinal

- Incubation period of 1 to 6 days after consumption of raw or undercooked meat
- Nonspecific symptoms followed by abdominal pain, ascites
- Diarrhea uncommon
- Obtain blood culture and ascitic fluid for culture and Gram stain

#### Inhalational

- Incubation period of 1 to 7 days (up to 43 days)
- Biphasic: fever, malaise, myalgia followed by dyspnea
- Widened mediastinum seen on chest x-ray and computed tomography (CT) of chest
- Blood cultures turn positive in most

#### Injection

- Injection drug use
- Significant swelling seen; eschar rare

### CURRENT THERAPY

#### Systemic Anthrax With Possible/Confirmed Meningitis

- Ciprofloxacin (Cipro) 400 mg IV every 8 hours or levofloxacin (Levaquin) 750 mg IV every 24 hours or moxifloxacin (Avelox)<sup>1</sup> 400 mg IV every 24 hours  
plus
- Meropenem (Merrem)<sup>1</sup> 2 g IV every 8 hours or imipenem/cilastatin (Primaxin)<sup>1</sup> 1 g IV every 6 hours or doripenem (Doribax)<sup>1</sup> 500 mg IV every 8 hours
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin<sup>1</sup> 3 g IV every 6 hours could be an alternative to carbapenems  
plus
- Linezolid (Zyvox)<sup>1</sup> 600 mg IV every 12 hours or clindamycin (Cleocin) 900 mg IV every 8 hours or rifampin (Rifadin) 600 mg IV every 12 hours or chloramphenicol 1 g every 6 to 8 hours

#### Systemic Anthrax When Meningitis Has Been Excluded

- Ciprofloxacin 400 mg IV every 8 hours or levofloxacin 750 mg IV every 24 hours or moxifloxacin<sup>1</sup> 400 mg IV every 24 hours  
or
- Meropenem<sup>1</sup> 2 g IV every 8 hours or imipenem/cilastatin<sup>1</sup> 1 g IV every 6 hours or doripenem<sup>1</sup> 500 mg IV every 8 hours  
or
- Vancomycin (Vancocin)<sup>1</sup> 60 mg/kg/day IV divided every 8 hours (goal trough 15–20 µg/mL)  
or
- If penicillin-susceptible strains, then penicillin G 4 million units IV every 4 hours or ampicillin<sup>1</sup> 3 g IV every 6 hours  
plus
- Clindamycin<sup>1</sup> 900 mg IV every 8 hours or linezolid<sup>1</sup> 600 mg IV every 12 hours  
or

- Doxycycline 200mg IV×1, then 100mg IV every 12 hours, or rifampin<sup>1</sup> 600mg IV every 12 hours

#### Oral Treatment for Cutaneous Anthrax Without Systemic Involvement

- One of the agents below for 7 to 10 days in naturally-acquired cases and for 60 days in bioterrorism-associated cases
- Ciprofloxacin 500mg PO every 12 hours
- Doxycycline 100mg PO every 12 hours
- Levofloxacin 750mg PO daily
- Moxifloxacin<sup>1</sup> 400mg PO daily
- Clindamycin<sup>1</sup> 600mg PO every 8 hours
- If penicillin-susceptible strain
- Amoxicillin<sup>1</sup> 1g PO every 8 hours
- Penicillin VK 500mg PO every 6 hours

<sup>1</sup>Not FDA approved for this indication.

Anthrax has been described for centuries and the name is derived from Greek for “burnt coal” owing to eschar formation from cutaneous anthrax. Anthrax is rarely seen in developed countries, including the United States, but it is important to be aware of this condition because of its potential as a bioterrorism agent. When anthrax is suspected, the clinician needs to contact the local or state health department immediately. Anthrax has historical significance because it was the agent used in Koch’s postulate during the 19th century when Koch proved that *Bacillus anthracis* is responsible for anthrax in cattle.

#### Background

*B. anthracis* is the bacterium responsible for anthrax. It forms spores that can survive in soil for years. It is hyperendemic in the Middle East and in sub-Saharan Africa. Systemic anthrax is primarily a disease of grazing animals. In naturally-acquired anthrax, humans are accidentally infected from exposure to the animal or its products.

#### Epidemiology

Since the mid-20th century, there has been a precipitous decline in anthrax owing to animal and human vaccines, improvement in factory hygiene, sterilization procedures for imported animal products, and increased use of alternatives to animal hides or hair. Cutaneous anthrax comprises over 95% of naturally-acquired human anthrax and there are an estimated 2000 cases annually. Between 1900 and 2001 there were 18 cases of inhalational anthrax in the United States, of which 16 were fatal. Over the last decade, there have been several cases of inhalational and cutaneous anthrax related to African drum makers. In late 2001, there were 22 cases of anthrax in the United States from spores delivered in the mail, of which five were fatal. In 1979, accidental release of dried anthrax spores from a biologic weapons facility in Sverdlovsk in the former Soviet Union resulted in 68 deaths from inhalation anthrax.

#### Pathophysiology

*B. anthracis* is a gram-positive, encapsulated, spore forming, nonhemolytic, nonmotile rod-shaped bacterium. Infection with anthrax requires three components: the edema factor, the lethal factor, and protective antigen. The edema factor combines with protective antigen and becomes edema toxin, which causes edema and impairment of the immune system. The lethal factor combines with protective antigen and becomes lethal toxin, which causes lysis of macrophages. For cutaneous anthrax, these exotoxins result in extensive edema and tissue necrosis locally. In inhalation anthrax, spores that reach the

alveoli or alveolar ducts are phagocytized by the alveolar macrophage and transported to the mediastinal lymph nodes where they replicate and cause hemorrhagic mediastinitis. With gastrointestinal tract infection, *B. anthracis* is transported from the gastrointestinal tract to mesenteric lymph nodes where they multiply and cause mesenteric lymphadenitis, ascites, and sepsis.

#### Clinical Manifestations

There are four distinct clinical presentations: cutaneous, inhalation, gastrointestinal tract, and injection anthrax, depending on the site of entry. Meningitis is a devastating complication that could occur with any of the four infections.

#### Cutaneous Anthrax

Cutaneous anthrax is the most common form and seen in developing countries as a result of contact with infected animals or animal products such as wool, hair, or hides. Spores invade through either skin abrasions or hair follicles. Subsequently, they germinate and multiply. The incubation period is commonly 5 to 7 days with range of 1 to 19 days. The lesions appear in exposed areas such as head, neck, forearms, and hands and begin as a small, painless papule. They are pruritic at times and form blisters. Subsequently, they evolve into painless necrotic ulcers with a black, depressed eschar with extensive edema and lymphadenopathy.

#### Inhalation Anthrax

Inhalation anthrax occurs when spores are aerosolized while working with contaminated animal products or when they are released intentionally in bioterrorism. The incubation period is 1 to 7 days but could be as long as 43 days. The course of disease is usually biphasic. Initially, nonspecific symptoms such as fever, malaise, and myalgia are present, resembling influenza. These symptoms last for several days before the bacteremic phase starts. The manifestations include rapidly, fulminant progressive respiratory symptoms such as severe dyspnea, as well as hypoxemia and shock. Once in this phase, the patient dies within a few days despite support in the intensive care unit. Therefore it is important to suspect anthrax in the prodromal phase, which is difficult owing to its rarity and lack of specific symptoms. Widening of the mediastinum on a chest x-ray may be helpful in establishing the diagnosis. This finding was seen in 7 out of 10 cases of inhalation anthrax from 2001. Hilar abnormalities, pulmonary infiltrates, or consolidation and pleural effusion may be seen.

#### Gastrointestinal Tract Anthrax

Gastrointestinal tract anthrax occurs after ingestion of raw or undercooked meat from an animal infected with anthrax. Gastrointestinal infection is relatively common and has been reported from mouth to ascending colon. The incubation period is 1 to 6 days. Initially, nonspecific symptoms such as asthenia, headache, low-grade fever, facial flushing and conjunctival injection occur. They are followed by abdominal pain, abdominal distention from ascites, nausea, and vomiting. Diarrhea occurs less frequently. As the disease progresses, abdominal pain becomes severe and findings of hypotension and intravascular depletion are seen. When the infection occurs in the oropharynx, necrotic ulcers with pseudomembranes cause pain and edema.

#### Injection Anthrax

An outbreak of injection anthrax was described in 2009. It was reported in Scotland among injection heroin users. Among the 47 confirmed cases, typical eschar formation seen in cutaneous anthrax was not seen in all but one case. Prominent edema was seen in most patients and some developed compartment syndrome.

## Meningitis

Meningitis is a complication seen with all forms of anthrax. About half of patients with inhalation anthrax develop hemorrhagic meningitis. Symptoms such as altered mental status, seizures, cranial nerve palsies, and myoclonus may be seen. When anthrax is suspected, lumbar puncture should be done on presentation unless there are contraindications.

## Diagnosis

When diagnosis of anthrax is suspected, the provider must notify the local department of health and the clinical microbiology laboratory. There has been reported transmission of anthrax to laboratory personnel handling *B. anthracis* and specimen handling in biosafety level 3 facilities is recommended. Because the genus *Bacillus* is part of the normal skin flora, it is crucial for the microbiology laboratory to distinguish *B. anthracis* from other non-*anthracis* species of *Bacillus*. Conventional culture and staining are used for distinction. *B. anthracis* is nonmotile and nonhemolytic and those characteristics are used to distinguish it from non-*anthracis* species of *Bacillus*. Most microbiology laboratories have the ability to make a presumptive identification of an organism, and the identification is confirmed by a reference laboratory.

## Specimen Collection

When collecting clinical specimens for suspected anthrax, proper personal protective equipment such as disposable gloves, disposable aprons, and boots, should be used. When there is any potential of aerosolization of spores, then face shields and respirators are recommended. Hand washing with soap and water will reduce the endospore contamination of the skin, but alcohol handrubs are not effective against these endospores. For cutaneous anthrax, the edge of the eschar should be lifted, and two specimens of vesicular fluid should be collected by rotating a swab. One swab will be used for culture and Gram stain while the other would be used for polymerase chain reaction (PCR). Punch biopsy of the cutaneous lesion is an alternative. When inhalational anthrax is suspected, blood cultures must be obtained prior to use of antibiotics. If pleural fluid is present, then thoracentesis should be performed for Gram stain, culture, and PCR. For alimentary tract anthrax, blood cultures must be obtained. If there are oral lesions, then specimens could be collected with swabs similar to a cutaneous lesion. If ascites is present, then paracentesis should be performed for Gram stain, culture and PCR. For meningitis, cerebrospinal fluid (CSF) should be collected for culture, Gram stain and PCR.

There are unique findings observed in routine laboratories with systemic anthrax. Marked hemoconcentration may be seen in the complete blood count, and the initial white blood cell count is frequently within normal limits. In chemistry, decreased sodium, increased blood urea nitrogen, mild transaminitis and hypoalbuminemia are seen. Inflammatory markers such as erythrocyte sedimentation rate and C-reactive protein are elevated in most cases except in cases of injection anthrax, when C-reactive protein is low.

## Treatment

### Supportive Care

Hospitalization is required for all patients with systemic infections. Only uncomplicated cutaneous anthrax could be treated on an outpatient basis. Close monitoring is warranted because the patient status may deteriorate rapidly. Hemodynamic support should be given, including fluids, vasopressors, blood products, and invasive hemodynamic monitoring. Mechanical ventilation may be needed because of respiratory distress, airway protection for altered mental status, or for airway edema. Adjunctive corticosteroids may be indicated in four situations: patients with history of endocrine or corticosteroid therapy; edema of head or neck; anthrax meningitis; or

vasopressor-resistant shock. Pleural fluid and ascites should be drained aggressively. Surgery is indicated in certain situations. Surgery for cutaneous anthrax has led to dissemination and poor outcome. Therefore, in cutaneous anthrax, indication for surgery is limited to tracheotomy for airway obstruction and surgery for compartment syndrome. In gastrointestinal anthrax, surgery might be considered for complications such as bowel ischemia or infarct and perforation. In injection anthrax, removal of necrotic nidus would help reduce the toxin and spore reservoir.

### Antimicrobial Treatment for Systemic Disease with Possible Meningitis

At least three intravenous antibiotics with good penetration to the central nervous system are recommended. At least one drug should have bactericidal activity, and at least one drug should inhibit protein synthesis. These should be continued for at least 2 weeks or until clinically stable, whichever is longer. The fluoroquinolone class is bactericidal, has good penetration to the central nervous system, and has no reported resistance by *B. anthracis*. Intravenous ciprofloxacin (Cipro) is the primary bactericidal component in the treatment of systemic disease. Levofloxacin (Levaquin) and moxifloxacin (Avelox)<sup>1</sup> are considered to be alternatives. The carbapenem class has good central nervous system penetration, and meropenem (Merrem)<sup>1</sup> is the preferred second antibiotic in treatment of systemic disease with possible meningitis. Imipenem/cilastatin (Primaxin)<sup>1</sup> and doripenem (Doribax)<sup>1</sup> are considered alternatives. Penicillin G or ampicillin<sup>1</sup> could be used in place of carbapenems when the isolate is known to have a minimum inhibitory concentration (MIC) of less than 0.125 µg/mL. As for protein synthesis inhibitor, linezolid (Zyvox)<sup>1</sup> is preferred because it provides good central nervous system penetration. If there is contraindication to linezolid use such as drug-drug interaction or myelosuppression, then clindamycin (Cleocin)<sup>1</sup> is the alternative. When both linezolid and clindamycin cannot be used, rifampin (Rifadin)<sup>1</sup> could be used for synergistic effect in combination with the bactericidal drugs. Chloramphenicol is another antibiotic that is a protein synthesis inhibitor. It could be used if linezolid, clindamycin, and rifampin are unavailable. Doxycycline (Vibramycin) is an inhibitor of protein synthesis but does not adequately penetrate the central nervous system. Therefore doxycycline should not be used when meningitis is not ruled out. If the patient had been exposed to aerosolized spores, then the patient should be transitioned to oral antibiotics after completion of initial intravenous combination therapy to prevent relapse from spores.

### Antimicrobial Treatment for Systemic Disease when Meningitis is Ruled Out

At least two antimicrobial agents are recommended for systemic anthrax without meningitis. At least one should be bactericidal and at least one should be a protein synthesis inhibitor. This combination should be administered intravenously for at least 2 weeks or until clinically stable, whichever is longer. For penicillin-susceptible strains, penicillin G is considered equivalent to ciprofloxacin. Vancomycin (Vancocin)<sup>1</sup> is an acceptable alternative bactericidal agent. Clindamycin<sup>1</sup> and linezolid<sup>1</sup> are equivalent first choices for protein synthesis inhibitors. Doxycycline is an alternative agent. If the patient had been exposed to aerosolized spores, then the patient should be transitioned to oral antibiotics after completion of initial intravenous combination therapy to prevent relapse from spores.

### Treatment for Cutaneous Anthrax without Systemic Involvement

A single oral antibiotic is adequate to treat cutaneous anthrax without systemic involvement. Fluoroquinolones and doxycycline are considered first-line agents. Clindamycin<sup>1</sup> is a second-line agent when first-line agents are unavailable or

<sup>1</sup>Not FDA approved for this indication.

contraindicated. Penicillin or amoxicillin<sup>1</sup> may be used if the isolate is found to be sensitive *in vitro*. It is important to give an adequate dose because resistance may develop when underdosed.

### Antitoxins

There are three antitoxins in the Centers for Disease Control and Prevention (CDC) Strategic National stockpile: raxibacumab, obiltoximab, and anthrax immune globulin intravenous (AIGIV). These agents are not readily available to the public. They inhibit binding of protective antigen to the anthrax toxin receptor and translocation of lethal factor and edema factor into cells. There are human and animal data from the pre-antibiotic era that suggest that there is lower mortality in those who received the antitoxin in cutaneous anthrax compared with those who did not. Whether this agent should be given for systemic anthrax is controversial owing to lack of data. Because the mortality rate with systemic anthrax is high whereas the complication of antitoxin treatment is low, the potential benefit from antitoxins outweighs the potential risk from the antitoxins in systemic anthrax. This agent should be given in addition to appropriate antibiotics when systemic anthrax is suspected.

### Pregnancy

Overall management is similar to that in the nonpregnant patient. In pregnancy, ciprofloxacin is preferred over doxycycline for both treatment and prevention. Newer fluoroquinolones such as levofloxacin and moxifloxacin<sup>1</sup> are not preferred because embryo toxicity has been observed in animal studies. This was not seen with ciprofloxacin. Transplacental transmission of anthrax is known to occur. Ciprofloxacin, levofloxacin, meropenem,<sup>1</sup> ampicillin,<sup>1</sup> penicillin, clindamycin,<sup>1</sup> and rifampin<sup>1</sup> are known to have adequate concentration in the placenta and at least one agent should be used with treatment.

### Prognosis

Uncomplicated cutaneous anthrax has a mortality rate of less than 2% with treatment. Injection anthrax has a mortality rate of 28%, and gastrointestinal anthrax has a mortality rate of 40%. Inhalational anthrax has mortality of 45% despite antibiotics and modern intensive care. Meningitis from anthrax is almost always fatal.

### Prevention

Postexposure prophylaxis should be started as soon as possible after exposure. Sixty days of antibiotics for immediate protection and a three-dose series of Anthrax Vaccine Adsorbed (AVA, BioThrax) for long-term protection are recommended by the United States Advisory Committee on Immunization Practices. Ciprofloxacin and doxycycline are recommended as first-line antibiotic therapy for postexposure prophylaxis and are FDA-approved for this indication. Alternative agents include levofloxacin, moxifloxacin, amoxicillin, or penicillin VK (if sensitive); and clindamycin. AVA should be administered at diagnosis and at 2 and 4 weeks. AVA is not FDA-approved for postexposure prophylaxis. Raxibacumab and obiltoximab, which are two monoclonal antibodies held in the United States Strategic National Stockpile, have been approved for prevention of inhalation anthrax when alternative preventive therapies are not available or not appropriate.

<sup>1</sup>Not FDA approved for this indication.

## BABESIOSIS

Method of

Cheston B. Cunha, MD; and Burke A. Cunha, MD

### CURRENT DIAGNOSIS

- Suspect babesiosis in patients from Ixodes tick-endemic areas who present with a malaria-like illness (MLI) with fever, chills, headache, fatigue, and malaise.
- Clinically, babesiosis usually presents as an acute febrile illness with high fevers (>102°F), relative bradycardia, and shaking chills accompanied by fatigue and myalgias.
- Myalgias may suggest an influenza-like illness (ILI).
- Severe headaches may suggest an alternate diagnosis, e.g., meningitis.
- Some patients with babesiosis may be short of breath and may go on to develop acute respiratory distress syndrome (ARDS).
- Consider babesiosis for unexplained fevers following blood transfusion.
- In prolonged fevers that meet the definition of fever of unknown origin (FUO), consider babesiosis in patients from endemic areas.
- With babesiosis, there are usually no localizing signs except for splenomegaly. Importantly, no rash is present. If rash is present, consider an alternate diagnosis.
- In babesiosis, nonspecific laboratory test results, considered together, are helpful in excluding or narrowing diagnostic possibilities.
- Common nonspecific laboratory findings of babesiosis include a normal/slightly decreased white blood cell count, relative lymphopenia, atypical lymphocytes, thrombocytopenia, elevated total bilirubin, and high lactate dehydrogenase levels. Sera are mildly elevated.
- The erythrocyte sedimentation rate is usually highly elevated (>90 mm/h) as are serum ferritin levels.
- Definitive babesiosis diagnosis is by peripheral blood smears (thick and thin); thick smears are best for the detection of babesia and thin smears are best to assess the degree of parasitemia.
- In normal hosts, the degree of parasitemia is usually low (1%–5%), but high in compromised hosts (>10%). Severe babesiosis may occur in asplenic individuals (Howell-Jolly bodies reflect the degree of splenic dysfunction), the immunosuppressed, the elderly, and those with coinfections, e.g., ehrlichiosis, Lyme disease.
- If present, babesiosis is diagnosed by peripheral stained blood smears demonstrating the characteristic (but uncommon) “Maltese cross” in tetrads (four merozoites).
- In nonmalarious areas, babesiosis may be diagnosed by demonstrating intraerythrocytic ring forms on the peripheral smear.
- Babesiosis, like malaria, has intracellular ring forms, but babesiosis, unlike malaria, has no intracellular pigment (hemozoin).
- Alternatively, *Babesia microti* serology in the Northeastern United States is diagnostic if IgM titers are highly elevated (>1:64).
- Polymerase chain reaction to detect *Babesia* is more sensitive than blood smear review. It is particularly useful in patients with a low level of parasitemia.

## CURRENT THERAPY

- Preferred therapy is atovaquone (Mepron)<sup>1</sup> plus azithromycin (Zithromax).<sup>1</sup>
- Alternatively, clindamycin (Cleocin)<sup>1</sup> plus quinine<sup>1</sup> may be used.
- In addition to antibabesiosis therapy, exchange transfusion may be lifesaving in severe cases.
- For severe cases, continue therapy until degree of parasitemia is <5%.
- Recurrent or persistent babesiosis should be treated for >2 weeks after resolution of parasitemia.
- Doxycycline is not effective in babesiosis.
- Coinfection with other tick-borne pathogens is rare, but possible.

<sup>1</sup>Not FDA approved for this indication.

## Epidemiology

Babesiosis is a tick-borne zoonosis that clinically presents as a malaria-like illness (MLI). There are many *Babesia* species, but only five are pathogenic in humans. The geographic distribution of babesiosis mimics that of hard-bodied *Ixodes dammini* (*I. scapularis*) ticks and their vertebrate hosts, e.g., dogs, cats, cattle, and rodents. The primary reservoir for babesiosis in the Northeastern United States is the white-footed mouse (*I. dammini* nymphs) and the white-tailed deer (*I. dammini* adults). Sporadic cases of babesiosis also occur in states with the tick vector/vertebrate hosts. Babesiosis may also be acquired by blood/blood product transfusions.

## Clinical Features

In the Northeastern United States, babesiosis is usually *B. microti* and clinically manifests as an MLI. Babesiosis may be asymptomatic (IgG seropositive) or a mild, self-limited influenza-like illness (ILI). The incubation period for naturally acquired babesiosis is 1 to 6 weeks and 6 to 9 weeks for transfusion-acquired babesiosis. Clinical presentations in normal hosts are subacute with fever, fatigue, headache, malaise, and anorexia often mimicking Epstein-Barr virus infectious mononucleosis (with false-positive Monospot test results). Babesiosis presenting in patients with prolonged fevers of unknown origins (FUOs) and anorexia/weight loss may mimic a lymphoreticular malignancy. Presentation may be acute in those with impaired splenic function, those on immunosuppressives, or the elderly. Babesiosis may be viewed clinically as the “malaria of Long Island/Nantucket” as it presents with many malarial features, e.g., fever, chills, headache, sweats, myalgias. Excluding epidemiologic considerations, babesiosis differs in geographic distribution from malaria. Clinically, babesiosis differs from malaria in two important aspects. The clinical hallmarks of malaria are acute onset, intermittent fevers, and the classic “malaria paroxysm.” *Babesia* reproduce by asynchronous asexual budding, which is clinically manifest as constant/nonintermittent fever. With malaria, fevers are intermittent with fever periodicity related to the *Plasmodium* species. Only *P. falciparum* has no fever periodicity and like babesiosis has no hepatic phase. Malaria and babesiosis both have extraerythrocytic ring forms, but babesiosis has two distinct morphologic features: extracellular merozoites (tetrads), known as “Maltese crosses,” and no extraerythrocytic pigment, which malaria does have.

Unless the liver or spleen is enlarged, the physical features in babesiosis are limited to the fever. The fever curve of babesiosis is remittent without periodicity; fever is between 102 °F and 105 °F and accompanied by relative bradycardia. Rash is not a feature. When babesiosis is suspected, the presence of a rash is either indicative of coinfection, e.g., Lyme disease, or an alternative cause, e.g., viral or drug exanthem. Babesiosis should

<sup>1</sup>Not FDA approved for this indication.

not be in the differential diagnosis of Rocky Mountain spotted fever with rash on the wrists/ankles. Babesiosis may clinically resemble ehrlichiosis. Peripheral blood smears are the best way to differentiate babesiosis from ehrlichiosis. Nonspecific laboratory abnormalities in babesiosis include normal/decreased white blood cell (WBC) count (leukopenia). Relative lymphopenia is usually present. Atypical lymphocytes are frequently present in the peripheral smear. Thrombocytopenia is a constant finding. The erythrocyte sedimentation rate (ESR) is highly elevated (usually >90 mm/h and often >100 mm/h) as is C-reactive protein (CRP). Since the pathophysiology of babesiosis is that of an acute hemolytic anemia, like malaria, intravascular hemolysis in babesiosis is manifested by increased lactate dehydrogenase (LDH)/total bilirubin. Increased LDH and total bilirubin are the most sensitive indicators of the degree of intravascular hemolysis in babesiosis. The hemoglobin/hematocrit is decreased later in more severe cases. Ferritin levels are highly elevated and prolonged (higher/longer) than would occur with acute-phase ferritin elevations. Since babesiosis impairs T cell function, as in malaria, serum protein electrophoresis often shows polyclonal gammopathy reflecting compensatory B cell hyperactivity. Serum transaminases are mildly elevated, but alkaline phosphatase is unelevated. Cold agglutinins are not a feature of babesiosis. In patients with decreased/absent splenic function, Howell-Jolly bodies are present in the peripheral smear. The number of Howell-Jolly bodies present is inversely proportional to the degree of splenic dysfunction.

Diagnosis of babesiosis is microscopic or serologic. Like malaria, babesiosis may be diagnosed on Giemsa stained blood smears. If malaria is not a diagnostic consideration (geographic distribution, blood transfusion), the presence of intraerythrocytic ring forms is diagnostic. Less common, but more specific, are pathognomonic tetrads (Maltese crosses) of babesiosis in peripheral smears. Also, unlike malaria, there is no extraerythrocytic pigment in babesiosis. Alternatively, elevated IgM *Babesia* species titers are diagnostic.

## Therapy

The preferred therapy of babesiosis consists of 7 days combination therapy of azithromycin (Zithromax)<sup>1</sup> plus atovaquone (Mepron).<sup>1</sup> Alternatively, clindamycin (Cleocin)<sup>1</sup> plus quinine<sup>1</sup> for 7 days may be used (Table 1).

Treatment failure may occur in those with impaired T cell function, e.g., patients with HIV or with decreased splenic function. In such cases, exchange transfusion may be lifesaving.

<sup>1</sup>Not FDA approved for this indication.

## BACTERIAL MENINGITIS

Method of

Martha Muller, MD

### CURRENT DIAGNOSIS

#### Patient age often determines clinical presentation:

- Neonates: nonspecific symptoms
- Classic features: Fever, headache, neck stiffness, altered mental status
- Cerebrospinal fluid (CSF) evaluation
- Elevated opening pressure
- Elevated white blood cell count
- Decreased glucose: CSF-to-blood glucose ratio <0.60
- Elevated protein

### CURRENT THERAPY

#### Neonates <2 months

- Most common organisms: *Streptococcus agalactiae* (GBS), *Escherichia coli* or other gram-negative enteric organism, occasional *Listeria monocytogenes*
- Empiric therapy: Ampicillin, cefotaxime, or ceftriaxone (should be discussed with a pharmacist to determine risk factors for use)

#### Infants and Children >2 months

- Most common organisms: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* type B
- Empiric therapy: Ceftriaxone and vancomycin (used for potential penicillin-resistant *S. pneumoniae*)

#### Adults

- Most common organisms: *S. pneumoniae*, *N. meningitidis*
- Empiric therapy: Ceftriaxone and vancomycin

#### Adults >50 years of age

- Most common organisms: *S. pneumoniae*, *N. meningitidis*, *L. monocytogenes*
- Empiric therapy: Ceftriaxone, vancomycin and ampicillin

Bacterial meningitis is a serious, life-threatening infection of the central nervous system. This inflammation of the meninges and subarachnoid space, including the cerebrospinal fluid (CSF), may potentially affect the brain cortex and parenchyma. Bacterial meningitis can occur via several pathophysiologic mechanisms (Table 1). In the neonatal period, most of the offending organisms have colonized mucosal surfaces after contact and aspiration of maternal intestinal and genital tract secretions during the delivery process. The most common mechanism noted outside of the neonatal period involves nasopharyngeal colonization, penetration of the nasopharyngeal mucous membrane barrier with entrance to the interstitial space, and entrance into the capillary bloodstream with subsequent delivery to the meninges or choroid plexus. Once organisms penetrate the CSF, an advantage in their favor exists. In a usual physiologic state, there is essentially an absence of capsule-specific immunoglobulins, complement factors, polymorphonuclear lymphocytes, and other plasma cells within the CSF, making the environment conducive to bacterial proliferation. Available host defenses are apparently ineffectual against encapsulated organisms. The cerebral vasculature is the primary mark for inflammation. Inflammatory changes result in blood-brain barrier disruption, edema, vasospasm and potential arterial thrombosis, as well as cerebral vein occlusions.

Additionally, bacterial and neutrophil-associated inflammatory products may traverse the pial barrier, potentially resulting in neuronal necrosis or cranial nerve compression.

The majority of bacterial meningitis cases occur sporadically. Globally, reported cases of bacterial meningitis increased between 2006 and 2016, with poverty strongly correlated to incidence. Incidence reported in higher-resourced countries has decreased to 0.5 to 1.5 per 100,000 population. Africa continues to bear a significant burden of bacterial meningitis, with incidence reaching 1000 per 100,000 population. Worldwide, bacterial meningitis is linked with significant morbidity and mortality, evidenced by approximately 16 million reported cases in 2013, associated with 1.6 million years lived with disability annually. Although dependent on many factors, including etiologic agent, age, risk factors, and so on, case fatality rates for bacterial meningitis have been reported to be between 17% and 40%.

A disease formerly dominated by *Haemophilus influenzae* in infants has now transitioned to one caused by *Streptococcus pneumoniae*, largely affecting older adult patients. On the whole, *S. pneumoniae* meningitis causes meningitis in children older than 5 years of age and in adults older than 65 years of age. Contrastingly, *Neisseria meningitidis* tends to cause meningitis in older children and young adults. *Streptococcus agalactiae* dominates as the most common organism implicated in bacterial meningitis in neonates and young infants.

Many intrinsic and extrinsic factors increase the risk for developing bacterial meningitis as well as affect the potential offending bacteria (Table 1). Additionally, general factors such as poor living conditions and crowded daycare centers influence the potential development of bacterial meningitis.

### Diagnosis

The clinical presentation of bacterial meningitis is greatly influenced by patient age. Neonates and infants generally present with

**TABLE 1** Pathophysiologic Mechanisms Associated with the Development of Bacterial Meningitis

MECHANISM	EXAMPLES
Hematologic	Nasopharyngeal colonization with penetration
Traumatic	Skull fractures
Iatrogenic	Cochlear implantation; ventriculoperitoneal shunt placement
Congenital	Dermal sinus
Contiguous infection	Sinuses; middle ear

nonspecific signs and symptoms, including poor feeding, respiratory distress, fussiness, general weakness, and irritability. Although not universal in babies with bacterial meningitis, fever may also be present in <40% and seizures may be present in 15% to 34%. Similarly, hypothermia may be a presenting symptom. In general, patients with bacterial meningitis beyond the neonatal period present with more classic symptoms, including fever, neck stiffness, photophobia, significant headache, nausea, and vomiting. Those patients with associated systemic compromise have higher potential for poor disease outcome.

Physical examination findings are also associated with age, generally displaying more characteristic findings with increasing age. Meningeal irritation may be demonstrated by neck stiffness, the Brudzinski sign (hips and knees reflexively flex when the neck is flexed), and the Kernig sign (flexion of the thigh with the hip and knee at 90 degree angles results in pain on knee extension). A high degree of suspicion for bacterial meningitis in the appropriate clinical setting should be maintained despite physical examination findings as they are not always indicative of the disease. An adult prospective study demonstrated that the classic signs of meningeal irritation demonstrated a sensitivity of only 5% to 30%. Older adult patients >65 years of age may present without typical symptoms. Additionally, patients with bacterial meningitis in this population may frequently present with nonspecific confusion. These older adult patients may also have nuchal rigidity that is not associated with bacterial meningitis.

In general, lumbar puncture should be sought without delay, with few contraindications to suggest otherwise. Contraindications include shock, respiratory compromise, and coagulopathy. Indications for obtaining neuroimaging before conducting a lumbar puncture include the presence of focal neurologic findings in children and immunocompromised condition, previous history of central nervous system disease, new-onset seizure, and focal neurologic findings in adults. CSF examination is crucial to the diagnosis of bacterial meningitis. CSF obtained for suspected bacterial meningitis should routinely be evaluated for cell count (red blood cells; white blood cells, with differential as appropriate), glucose, protein, Gram stain, and culture (Table 2). CSF culture serves as the gold standard for diagnosis, with reported positivity in 50% to 90% of patients. CSF should be evaluated as soon as possible after obtaining it as white blood cells deteriorate within 30 minutes, and elevated white blood cell counts have the potential to metabolize CSF glucose. In general, characteristic CSF findings include elevated white blood cells, low glucose, and elevated protein values (Table 2). It is important to note that the CSF white blood cell count may infrequently be normal,

especially very early in the course of illness. Blood cultures should also be obtained for patients with concerns for bacterial meningitis, with reported positivity in 50% to 80% of cases.

The receipt of antibiotics before CSF evaluation may lend to decreased organism recovery via culture. Effective antibiotic therapy can result in sterile cultures within 2 hours for *N. meningitidis* and begin the sterilization process within 4 hours for *S. pneumoniae*. Additional factors that may adversely affect CSF diagnostic utility include the potential for 24 to 48 hour or longer before obtaining culture results, inadequate CSF specimen volumes, fastidious organisms requiring special growth parameters, and inappropriate specimen attainment and transportation to the laboratory. Although CSF glucose and protein values in children may rarely be affected (in general, irregular values tend to persist for many days despite appropriate therapy), a diagnosis of bacterial meningitis may often still be made based on the CSF analyses in the setting of antibiotic pretreatment. Polymerase chain reaction (PCR) is a promising tool in the arsenal for diagnosis of bacterial meningitis, especially in the setting of antibiotic pretreatment, and its evaluation and clinical use are expanding. Notably, the World Health Organization endorses the utilization of real-time PCR when considering *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type B for patients with potential meningitis. The diagnostic precision of PCR has been most widely evaluated for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* and has been reported to be as high as 95% to 100% in cases of culture-proven bacterial meningitis. A prospective study from Sweden reviewing CSF from repeat lumbar puncture demonstrated PCR positivity in 89% of samples taken on days 1 to 3; 70% of samples taken on days 4 to 6; and 33% of samples taken on days 7 to 10. In contrast, all CSF cultures taken from the same samples were negative. With its increasing utilization, PCR sensitivity has been reported as 61% to 100%, 88% to 94%, and 72% to 92% for *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, respectively. Additionally, false-negative PCR results are rare, occurring in approximately 5% of cases. Latex agglutination and coagglutination techniques, best for detection of bacteria that are actively proliferating and shedding polysaccharide, are infrequently used for the diagnosis of bacterial meningitis.

Complications of bacterial meningitis may occur any time during the course of the illness and include circulatory collapse, disseminated intravascular coagulation, gangrenous digits, focal neurologic findings, seizures, and subdural effusions.

The differential diagnosis of bacterial meningitis in infants and young children includes otitis media, pharyngitis, pneumonia, retropharyngeal abscess, and lymphadenopathy. Additional diagnoses include brain abscess, tuberculous meningitis, aseptic meningitis, meningitis caused by atypical organisms, and sinusitis.

**TABLE 2** Anticipated Cerebrospinal Fluid Findings in Bacterial Meningitis

CSF PARAMETER	TYPICAL FINDINGS
White blood cell count	>1000 cells/mm <sup>3</sup> (may be affected by immunosuppression, neutropenia, atypical pathogens)
Glucose	<40 mg/dL (CSF-to-blood glucose ratio <0.60)
Total protein	>100 mg/dL (increased above normal values for age)
Gram stain	Positivity depends on bacterial burden. Stains positive 97% of the time when cultures grow >10 <sup>5</sup> CFU Specific yield of 70% to 90% for <i>Streptococcus pneumoniae</i> Specific yield of 30% to 90% for <i>Neisseria meningitidis</i> Sensitivity low for <i>Listeria monocytogenes</i> as few organisms are generally present in CSF
CSF opening pressure	>200 mm/CSF (may be >300 mm/CSF. Continued elevation for first 24 to 48 hours before decrease)

CFU, Colony-forming units; CSF, cerebrospinal fluid.

### Antibiotic Management

Successful treatment is characterized by a delicate balance between prompt antibiotic administration and host inflammatory response regulation. Underscored by an almost 100% mortality noted for untreated bacterial meningitis, prompt, appropriate antibiotic administration is paramount, generally increasing the chances of survival. This is particularly notable for infants and children in whom case fatality rates are decreased to <10% and <5%, respectively, for meningococcal meningitis in the setting of appropriate therapy.

Empiric antibiotic therapy should be chosen based on a variety of factors, including most likely bacterial etiology (local antibiograms and resistance patterns should be considered) (Tables 3 and 4), ability to penetrate the blood-brain barrier and achieve adequate CSF levels, and bactericidal mechanism of action. Beta-lactam antibiotics are frequently used to treat bacterial meningitis and are generally effective against the most commonly associated bacteria. CSF concentrations of these antibiotics, even in the setting of minimal meningeal inflammation, are generally adequate for the minimal inhibitory concentrations for susceptible bacteria. Bacterial resistance patterns also greatly influence empiric antibiotic therapy. Worldwide, penicillin resistance in *S. pneumoniae* has affected recommendations to utilize vancomycin as part of the empiric antibiotic regimen. Antibiotics should be provided parenterally at maximal clinically indicated doses (Table 5). Antibiotic therapy should not be delayed by the

**TABLE 3** Empiric Antibiotic Therapy Based on Contributing Factors\*

CONTRIBUTING FACTOR	POTENTIAL ORGANISMS	ANTIBIOTIC THERAPY
Age	<i>S. agalactiae</i> , <i>E. coli</i> (gram negative enteric organisms), <i>L. monocytogenes</i>	Ampicillin and cefotaxime or ceftriaxone (discuss use in this population with pharmacist)
<1 month		Ceftriaxone or cefotaxime and vancomycin
1–2 years	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>H. influenzae</i> type B, <i>S. agalactiae</i> , <i>E. coli</i>	Ceftriaxone or cefotaxime and vancomycin
2–50 years		Ceftriaxone or cefotaxime, ampicillin and vancomycin
>50 years	<i>S. pneumoniae</i> , <i>N. meningitidis</i> <i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i>	
Head trauma	<i>S. aureus</i> , coagulase-negative <i>Staphylococci</i> , aerobic gram-negative organisms (including <i>P. aeruginosa</i> )	Vancomycin with either cefepime <sup>1</sup> or meropenem
Penetrating trauma		
Neurosurgery	<i>S. aureus</i> , coagulase-negative <i>Staphylococci</i> , aerobic gram-negative organisms (including <i>P. aeruginosa</i> )	Vancomycin with either cefepime <sup>1</sup> or meropenem
CNS shunt placement	<i>S. aureus</i> , coagulase-negative <i>Staphylococci</i> , aerobic gram-negative organisms (including <i>P. aeruginosa</i> )	Vancomycin with either cefepime or meropenem

**TABLE 4** Special Patient Characteristics Associated with Specific Organisms

BACTERIA	PATIENT CHARACTERISTICS
<i>Streptococcus pneumoniae</i>	Immunocompromised status
<i>Neisseria meningitidis</i>	Complement deficiencies, asplenia, smoking, antibody deficiency
<i>Haemophilus influenzae</i> type B	Native American children; Alaskan Native children
<i>Listeria monocytogenes</i>	Immunocompromised status
<i>Staphylococcus aureus</i>	Neurosurgical procedures, shunt device placement, trauma, underlying disease (e.g., diabetes mellitus), human immunodeficiency virus, cardiovascular disease, intravenous drug use

need to obtain neuroimaging. Once a specific organism is isolated, antibiotic therapy should be tailored to treat the organism, completing an appropriate duration of therapy (Table 6).

### Adjunctive Therapy

With a goal of decreasing inflammation leading to neuronal death and brain damage, dexamethasone (Decadron)<sup>1</sup> administration is the cornerstone of adjunctive therapy for bacterial meningitis. Data from studies evaluating the effect of steroids on outcomes of infants and children with bacterial meningitis have demonstrated improved meningeal inflammatory indices and decreased audiologic and neurologic sequelae compared with those receiving placebo; this benefit is most notable for *H. influenzae* meningitis. The data for dexamethasone use to treat *S. pneumoniae* meningitis in children is less vigorous. Additionally, animal models of bacterial meningitis demonstrated decreased vancomycin concentrations and penetration rates in the CSF for those animals receiving dexamethasone. This is important given the potential need to utilize vancomycin in the treatment of penicillin-resistant *S. pneumoniae* bacterial meningitis.

The American Academy of Pediatrics Committee on Infectious Diseases does endorse the use of dexamethasone for *H. influenzae* type B meningitis. However, the committee does not make a recommendation for routine dexamethasone use in *S. pneumoniae* meningitis. They do provide a consideration of its use in children >6 weeks of age after risks and benefits have been reviewed. There are inadequate data to make a recommendation for dexamethasone use during the neonatal period. The available data demonstrating

decreased unfavorable outcomes in adults when using dexamethasone have prompted the Infectious Diseases Society of America to routinely recommend dexamethasone for adults with suspected or proven pneumococcal meningitis. When given, dexamethasone should be provided at a dose of 0.15 mg/kg every 6 hours for 2 to 4 days. It should be given 10 to 20 minutes before or concurrent with the first dose of antibiotic therapy.

### Vaccination Prevention

Between 1990 and 2013, global mortality caused by *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type B decreased by 29%, 25%, and 45%, respectively. Conjugate vaccination strategies have played an important role in improving that landscape. The introduction of *H. influenzae* type B and *S. pneumoniae* conjugate vaccines during the 1990s and 2000s contributed to reports of a decrease in bacterial meningitis in both vaccinated and non-vaccinated populations. The additional benefit of whole-population herd immunity was also described with the introduction of pneumococcal conjugate vaccines. The introduction of conjugated *H. influenzae* type B vaccination programs provided a significant contribution to reducing bacterial meningitis, wherein bacterial meningitis caused by this organism has decreased by almost 100%. Interestingly, initiation of the 7-valent pneumococcal conjugate vaccine (Prevnar 7) in the United States was accompanied by a noted decrease in meningitis caused by vaccine serotypes, initially in children followed by a decrease in adults. However, a concurrent increase in non-vaccine serotypes was noted in response. Likewise, the introduction of the 13-valent pneumococcal conjugate vaccine (Prevnar 13) has also been met with an increased prevalence of non-vaccine serotypes causing bacterial meningitis. Since 2015 there has been a brisk increase in incidence of invasive pneumococcal disease, including meningitis, secondary to non-PCV13 serotypes. Despite the concerns regarding serotype replacement, receipt of several pneumococcal conjugate vaccines in the United States led to a 66% and 33% decrease in rates of pneumococcal meningitis for children <2 years of age and adults >65 years of age, respectively. Vaccination against *N. meningitidis* has also resulted in a decrease in bacterial meningitis, demonstrating a rate decrease from 13.5 per 100,000 in 1968 to 5.2 per 100,000 in 1989 to 2011. Many higher resourced countries have seen a significant decrease in the incidence of serogroup-C meningitis related to vaccination. Serogroup-B meningitis rose with the decline of serogroup-C meningitis in higher-resourced countries. In 2015, the United Kingdom introduced serogroup-B vaccine 4CMenB (Bexsero), reporting an overall 75% decline in invasive disease.

Immunization against *H. influenzae* type B, *S. pneumoniae*, and *N. meningitidis* has been incorporated into the routine childhood vaccination schedule in the United States. The Advisory Committee on Immunization Practices provides specific vaccine recommendations.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 5** Antibiotics Commonly Used to Treat Bacterial Meningitis

ANTIBIOTIC	ADULT DOSING	PEDIATRIC DOSING
Ampicillin	2 g every 4 hours	300–400 mg/kg/day divided every 4–6 hours; maximum daily dose: 12 g/day.
Cefotaxime <sup>2</sup>	2 g every 4–6 hours	225–300 mg/kg/day divided every 6–8 hours
Ceftriaxone	2 g every 12 hours	50 mg/kg/dose every 12 hours
Cefepime	2 g every 8 hours	50 mg/kg/dose every 8 hours
Meropenem	2 g every 8 hours	40 mg/kg/dose every 8 hours
Vancomycin*	15–20 mg/kg/dose every 8–12 hours	15 mg/kg/dose every 6 hours

<sup>2</sup>Not available in the United States.

\*Appropriate loading and level monitoring should be performed by a pharmacist.

**TABLE 6** Duration of Antibiotic Therapy for Uncomplicated Infections Caused by Specific Organisms

PATHOGEN	DURATION OF THERAPY
<i>Streptococcus agalactiae</i> (GBS)	14 days
<i>Escherichia coli</i> (gram-negative enteric organisms)	21 days
<i>Listeria monocytogenes</i>	21 days
<i>Streptococcus pneumoniae</i>	10–14 days
<i>Neisseria meningitidis</i>	7 days
<i>Haemophilus influenzae</i> type B	7–10 days

### Outcomes/Sequelae

The consideration of patient outcomes is multifactorial, including patient age; time to antibiotic administration, especially as it relates to symptom onset; host factors such as immune response to infection; and time to CSF sterilization. In general, the greatest morbidity and mortality are seen at the extremes of ages (i.e., neonates and older adults). Mortality associated with bacterial meningitis has been 20% to 25% for numerous decades. Pneumococcal meningitis is associated with the highest case fatality rates, reported as 20% to 37% in high-income countries and as high as 51% in low-income countries. This is in contrast with case fatality rates reported as 3% to 10% worldwide for meningococcal meningitis. Zainel et al. reported that risk factors implicated in the development of neurologic complications in the pediatric population include age <12 months; bacterial etiology, especially *S. pneumoniae*; altered level of consciousness on presentation; delayed presentation; and delayed antibiotic administration.

An important immediate complication related to bacterial meningitis in pediatric patients is the development of subdural effusions. Subdural effusions are described in 20% to 39% of pediatric patients with bacterial meningitis and is notably more common in infants <1 year of age compared with their older peers. Importantly, although there is the potential for infection, most subdural effusions in this clinical scenario are asymptomatic, demonstrating spontaneous resolution.

Neurologic difficulties have been reported in 20% to 30% of bacterial meningitis events. Similarly, longstanding neuropsychological sequelae have been reported in as many as 50% of those who survive bacterial meningitis. When compared with their well siblings who did not have bacterial meningitis, infants and children with bacterial meningitis are more likely to experience seizures, hearing loss, cognitive disturbances, and behavioral concerns. Similarly, there have been reports of disturbed executive functioning, memory, and intelligence in adults who have recovered from bacterial meningitis.

Seizures, hearing loss, and cognitive impairment are the most commonly reported disabilities after a diagnosis of bacterial meningitis.

Seizures complicate bacterial meningitis and have an individual link to increased morbidity. In children, the development of longstanding neurologic complications is less concerning when associated seizures that occur early during the course of illness are easily controlled. In contrast, prolonged or difficult-to-control seizures and seizures developing 72 hours after admission are more likely to be associated with neurologic sequelae and are often indicative of a cerebrovascular event. Neurologic complications have been reported in as many as 50% of those who survive bacterial meningitis. Hearing loss is a common complication of bacterial meningitis. In fact, sensorineural hearing loss has been described as the most broadly reported neurologic sequelae of bacterial meningitis. Hearing loss has the potential to be transient or permanent and is often associated with *S. pneumoniae* meningitis. Sustained hearing loss is generally sensorineural, with incidence reported as 14% for mild hearing loss and 5% for severe hearing loss. The hearing loss typically occurs during the initial days of the infection and can be transient or permanent, underscoring the need for formal hearing evaluation to occur in all patients diagnosed with bacterial meningitis.

## BRUCELLOSIS

Method of

Xinghong Yang, PhD

## CURRENT DIAGNOSIS

- The diagnosis of brucellosis relies on the serologic reaction of antibodies to *Brucella*'s lipopolysaccharide (LPS) located on the cell surface of smooth *Brucella melitensis*, *Brucella abortus*, and *Brucella suis*.
- Although the rough species, *Brucella canis*, does not have an intact LPS layer, its detection requires the antigens specifically prepared from *B. canis*.
- Rose Bengal test is regularly used to diagnose infection with smooth *Brucella* spp.
- When patients with brucellosis symptoms test negative by Rose Bengal test, the microagglutination test and 2-mercaptoethanol rapid slide agglutination test are used to determine whether the patient is infected with rough *Brucella* spp.

## CURRENT THERAPY

- Three aspects of therapy are critical when using antibiotics to treat brucellosis:
  - The antibiotics must be able to penetrate macrophages to take effect because *Brucella* spp. are intracellular pathogens and normally reside within professional and nonprofessional phagocytes.
  - Multiple antibiotics are typically used to minimize relapses commonly seen when only a single antibiotic is used.
  - In complicated cases, in addition to antibiotic treatment, surgical intervention may be required to remove infected tissues.

Brucellosis is an ancient disease recorded by the Romans more than 2000 years ago. Since *Brucella* was identified as the cause of brucellosis in sick soldiers in 1887 by Sir David Bruce, brucellosis has been defined as an emerging disease. *Brucella* is a zoonotic bacterial pathogen, causing approximately 500,000 new cases annually worldwide. Although rarely fatal (<5% mortality rate), it causes an undulating fever leading to a dramatic decrease in the quality of life. Its incubation time can vary between 1 and 8 weeks, and often infection is asymptomatic; however, serious complications can lead to disability or death. Because no human vaccine is available, antibiotic therapy is the only option for treatment.

A total of ten *Brucella* species have been identified to date (Table 1). Four of these—*Brucella melitensis*, *Brucella abortus*, *Brucella suis*, and *Brucella canis*—commonly cause human brucellosis, and their genomes have been sequenced.

## Epidemiology

Wildlife and domesticated animals can serve as natural reservoirs for *Brucella* spp. Humans acquire brucellae by exposure to contaminated foods or aerosols or by direct contact. Often contaminated or unpasteurized animal products, such as milk, soft cheese, and butter are consumed, causing oral exposure. *Brucella* spp. can spread via contaminated aerosols or by aerosolization of contaminated animal by-products, resulting in lung infection. *Brucella* can also infect by direct contact of skin cuts or abrasions with sick animals or their products and enter into the blood or lymphatic system and, regardless of route, produce infection,

**TABLE 1** *Brucella* Species, Preferred Animal Hosts, and Human Infection Potential

SPECIES	HOST ANIMALS OR RESERVOIR	HUMAN INFECTION?*
<i>B. melitensis</i>	Goats, sheep, camels	Yes
<i>B. abortus</i>	Cows, bison, camels, yaks	Yes
<i>B. suis</i>	Pigs, wild hares, caribou, reindeer, wild rodents	Yes
<i>B. canis</i>	Dogs	Yes
<i>B. cetaceae</i>	Seals, harbor porpoises	Yes
<i>B. inopinata</i>	Unknown	Yes
<i>B. microti</i>	Common voles, red foxes, soil	Unknown
<i>B. neotomae</i>	Rodents	No
<i>B. ovis</i>	Sheep	No
<i>B. pinnipedialis</i>	Minke whales, dolphins	No

\*“Yes” and “no” mean *Brucella* spp. are able or unable to infect humans, respectively; “unknown” indicates that it is not confirmed whether *Brucella* spp. are able to infect humans.

causing a bacteremia. Among the three routes, food ingestion and aerosol inhalation can result in brucellosis. Aerosolized brucellae can be used as a bioweapon because the dosage required for infecting 50% of the population is as little as 1885 colony-forming units (CFUs).

Currently, brucellosis is endemic to Latin America, Africa, the Mediterranean rim, the Middle East, and Central Asia. To prevent human infection, animal immunization campaigns were adopted by many countries, including the United States and the former Soviet Union. The campaigns successfully curbed animal infection and consequently reduced human infection in these areas. When the programs were stopped, the incidence of brucellosis rapidly increased. Thus maintenance of animal immunization programs is essential for protecting humans from infection.

Although transmission of brucellae among humans occurs rarely, several cases have been reported. It may be disseminated via sexual contact, milking, and organ transplantation. *B. melitensis* is the most commonly isolated species from brucellosis patients, followed in descending order by *B. abortus*, *B. suis*, and *B. canis*. *B. melitensis* and *B. abortus* can cause acute brucellosis and display the most severe symptoms, which can lead to complications. *B. suis* can cause extended duration of illness and results in suppurating lesions in infected tissues. Patients with *B. canis* infections display mild to moderate illness and rarely develop complications.

## Risk Factors

The susceptible population includes those who live or travel in the endemic areas, particularly veterinarians, microbiologists, and those who work with or process livestock. The current animal vaccines are all infectious to human, and consequently veterinarians who administer these vaccines are at high risk for being infected. Microbiologists or laboratory workers also can acquire brucellosis through close contact, and indeed laboratory outbreaks are frequently reported. Thus *Brucella* is also considered an occupational disease or a laboratory-acquired disease.

## Pathophysiology

*Brucella* can be phagocytized by nonprofessional and professional phagocytic cells to establish an intracellular replication niche. Once inside host cells, brucellae stay in early-formed phagosomes, where they prevent phagosomes from fusing with late-formed endosomes and lysosomes and survive intracellularly. Antibiotics must be able to penetrate the host cell membrane to kill brucellae or inhibit their growth.

*Brucella* uses numerous mechanisms to evade detection by the immune system. Unlike LPS from other gram-negative bacteria, *Brucella* LPS does not trigger an inflammatory response or activate the alternative complement system, so it helps brucellae avoid recognition. *Brucella*'s LPS endows brucellae with a phenotype highly resistant to cationic bactericidal peptides. The intracellular brucellae do not cause cell death in macrophages or apoptosis in respiratory epithelial cells. Thus the LPS reduces the chances of exposure to the immune system, which aids brucellae survival and meanwhile diminishes the stimulation of the host immune system. *Brucella* inhibits the macrophage response to interferon- $\gamma$  (IFN- $\gamma$ ), a critical cytokine for stimulating innate and adaptive immunity. Additionally, to maintain vigorous intracellular survival and replication, brucellae equip their outer membranes with phosphatidylcholine and synthesize cyclic  $\beta$ -1,2-glucans to preclude fusion between phagosome and lysosome.

## Diagnosis

Accurate diagnosis of brucellosis is always a challenge because brucellosis exhibits symptoms similar to numerous other febrile illnesses (Table 2). In many patients, the symptoms are mild and

**TABLE 2** Symptom Pattern of Human Brucellosis

\*Percentage based on 500 patients.

<sup>†</sup>Percentage based on 290 male patients.

moderate; thus in a number of cases the diagnosis might not be even considered.

Isolation of brucellae from blood, bone marrow, urine, cerebrospinal fluid, or joint aspirate serves as the gold standard for diagnosing brucellosis. However, under many circumstances, brucellae cannot be cultured from patients' samples. The rate of blood culture positivity ranges from 16% to 90%. Hence, other indices are used to identify brucellosis. Testing for antibodies against *Brucella* is commonly used. *Brucella* agglutination titer of 1:160 is considered a clear diagnostic index as long as the patient presents signs and symptoms of the disease. Recommended tests are the Rose Bengal test, the serum agglutination test alone or with 2-mercaptoethanol or dithiothreitol reduction, Coombs' antiglobulin, the complement-fixation test, and the enzyme-linked immunosorbent assay (ELISA). The results of a combination of tests such as the serum agglutination test and Coombs' antiglobulin can be used to assess the stage of evolution of the disease at the time of diagnosis. In the blood sample, infection may also be associated with low levels of red and white blood cells, low platelets, and elevated liver function. A biopsy of body tissues can also assist in making the diagnosis because patients can experience bone marrow hypoplasia or liver fibrosis and cirrhosis.

Depending on the patient's symptoms and severity of the illness, an investigation may be undertaken. Examinations may include computed tomography (CT) scan or magnetic resonance imaging (MRI) to identify signs of inflammation or abscesses in the brain or other tissues. Electrocardiogram (ECG) may be performed to investigate heart infection or damage, and x-rays can show bone and joint deformations.

## Differential Diagnosis

Because human brucellosis mimics the symptoms of many other diseases, disease complications vary from patient to patient, and the latency time between exposure and the occurrence of symptoms is irregular and relatively long, making the differential diagnosis tedious and difficult. Therefore, before diagnosis, answers to three questions can help narrow the focus to brucellosis:

- Did the patient have direct contact with large or small ruminants, their carcasses, or their products?
- Did the patient consume unpasteurized dairy products?
- Does the patient live in or travel to areas where brucellae are endemic in humans or epidemic in animals?

In spite of the difficulties in diagnosing brucellosis, some clinical features can still be used to distinguish brucellosis from other infectious diseases. If left untreated, fever of brucellosis displays an undulating pattern. In about 50% of patients, the fever of brucellosis is associated with musculoskeletal symptoms; however, these symptoms are rarely observed in typhoid and malaria fevers.

In patients with hepatosplenomegaly or lymphadenopathy, the differential diagnosis includes glandular fever-like illnesses, such as cytomegalovirus (CMV) infection, Epstein-Barr virus (EBV) infection, HIV infection, toxoplasmosis, and tuberculosis (TB). CMV patients can develop antibodies to the virus. Also, in the active infection phase, CMV can be detected from the blood, saliva, urine, or other body tissues. These indices can be used to differentiate CMV infection from the brucellosis. EBV patients have an elevated white blood cell count, an increased total number of lymphocytes, and greater than 10% atypical lymphocytes, but brucellosis patients usually show a decrease in the white blood cell count.

HIV infection can induce antibodies against HIV, and virologic tests can detect HIV antigens or RNA. HIV infection can be further confirmed by a supplemental antibody test, such as Western blot and indirect immunofluorescence assay. Brucellosis patients' sera do not display any reaction in these tests. For toxoplasmosis patients, serum immunoglobulin (Ig)G and IgM titers can be used to detect whether the patient is infected by *Toxoplasma*.

For TB patients, a skin test or a special TB blood test can be used for diagnosis, and other tests such as chest x-ray and a sample of sputum coughed up from deep in the lungs may be used for confirmation. In patients with osteomyelitis or septic arthritis, the most important alternative diagnosis is TB.

In patients with acute epididymo-orchitis, the differential diagnosis includes mumps and surgical problems, such as torsion. For mumps patients, buccal swab specimens are collected for viral detection via culturing virus in cell lines or using real-time polymerase chain reaction (RT-PCR) to detect mumps viral RNA. For testicular torsion in men, an ultrasound examination of the spermatic cord can provide valuable information regarding whether the patient requires emergency surgery.

### Treatment

To date, the only option for treating brucellosis is by means of antibiotics. However, in cases of complications, such as heart brucellosis and spinal brucellosis, antibiotic treatment in combination with surgical intervention may be needed. Antibiotics commonly used are doxycycline (Vibramycin), rifampin (Rifadin),<sup>1</sup> streptomycin, cotrimoxazole (TMP-SMX [Bactrim]),<sup>1</sup> and gentamicin (Garamycin)<sup>1</sup> (Table 3). Regimens of a combination of 2 or 3 antibiotics are recommended to reduce the unacceptably high relapse rates with monotherapy. Antibiotic regimens vary and depend on the patient's age, the severity of the disease, pregnancy, cost of the medicine, and availability of the medicine.

Doxycycline combined with rifampin<sup>1</sup> for a full 6-week course is a commonly used therapy recommended by the World Health Organization. It is considered the most effective regimen, particularly when combined with an aminoglycoside. In patients with spondylitis or sacroiliitis, doxycycline plus streptomycin is an effective combination. For pediatric patients older than 8 years, doxycycline plus gentamicin<sup>1</sup> is the recommended therapy. For children younger than 8 years, trimethoprim-sulfamethoxazole (TMP-SMX) therapy for 3 weeks followed by a 5-day course of gentamicin<sup>1</sup> is most effective. TMP-SMX<sup>1</sup> is also effective in treating pregnant women, either as a single agent or in combination with rifampin<sup>1</sup> or gentamicin<sup>1</sup> (see Table 3).

Once brucellosis is diagnosed, immediate therapy is critical because it can alleviate symptoms and also prevent the development of complications. Nevertheless, even when treatment is executed according to the doctor's prescription, rates of relapse can still reach up to 5% to 10%. Depending on the severity or

complications of the illness and the treatment time applied, the recovery time can last from several weeks to several months.

### Monitoring

After antibiotic therapy is initiated, patients are periodically monitored by doctors to evaluate whether the therapeutic regimen is effective and whether relapse occurs. Because relapse is indicated by the recurrence of a positive blood culture result during the post-therapy period or signs and symptoms of brucellosis infection, routine examination of the patient includes serum culture for *Brucella* organism and assessment for brucellosis symptoms after the treatment phase. In addition to monitoring brucellosis symptoms, both doctors and patients should monitor any adverse effects of medication. For instance, adverse reactions to TMP-SMX occur in 50% to 100% of patients with AIDS compared with about 14% of patients without AIDS. Up to 57% of AIDS patients treated with TMP-SMX<sup>1</sup> require a change in therapy owing to the adverse effects.

Generally, brucellosis patients should be followed up clinically for up to 2 years to detect relapse. Patients should be monitored for regaining of body weight. IgG antibody should be checked by serum agglutination test for levels that remain in the diagnostic range for more than 2 years. Complement fixation titers should fall to normal within 1 year of treatment. Relapse should respond to a prolonged course of the same therapy originally used.

### Complications

Brucellae are transported into the lymphatic system and can replicate in spleen, liver, kidney, breast tissue, and joints to cause both localized and systemic infections. Infection of the reproductive system can cause fetal abortion. Owing to the low virulence, low toxicity, and multiple mechanisms to protect them from the immune system, brucellae can survive and reproduce in nearly any tissues or organs. At 1 year after infection, the disease can develop into chronic brucellosis that can further cause one or multiple complications in one organ or the whole body.

There are seven major types of complications from *Brucella* infection.

- Endocarditis: Brucellae can infect the heart's inner lining, which can destroy the heart valves and, if left untreated, will lead to death of the patient.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 3** Treatment for Brucellosis

MEDICATION	ADULT DOSAGE	DOSAGE ADJUSTMENT			ADVERSE EFFECTS
		PEDIATRIC DOSAGE	RENAL FAILURE	HEPATIC INSUFFICIENCY	
Doxycycline (Vibramycin)	100 mg PO q12h	2.2–4.4 mg/kg <sup>3</sup> PO div q12h (>8 y)	No change	No change	Dizziness, headache, photosensitivity, nausea, diarrhea, hemolytic anemia, hepatotoxicity
Rifampin (Rifadin) <sup>1</sup>	600–900 mg PO qd	20 mg/kg PO qd (do not exceed 600 mg qd)	No change	Moderate: caution Severe: avoid	Heartburn, epigastric distress, anorexia, nausea, flatulence, cramps, liver dysfunction, jaundice
Streptomycin	15 mg/kg IM q24h or 1 g IM qd × 2–3 wk	20–40 mg/kg IM qd (do not exceed 1 g/d)	Necessary	No change	Nausea, vomiting, vertigo, face paresthesias, rash, fever, urticaria, angioedema, eosinophilia
Trimethoprim-sulfamethoxazole (TMP-SMX) (Bactrim) <sup>1</sup>	1 DS tab PO q12h (160 mg TMP/800 mg SMX)	8–12 mg/kg TMP PO given in divided doses q12h	Necessary Avoid use in CrCl <15 mL/min	No change	Nausea, vomiting, anorexia, rash, urticaria
Gentamicin (Garamycin) <sup>1</sup>	2 mg/kg <sup>3</sup> IM/IV q8h or 5 mg/kg IM/IV q24h <sup>1</sup> or 240 mg q24h	2.5 mg/kg q8–12h IM/IV	Necessary	No change	Nephrotoxicity, dizziness, vertigo, tinnitus, hearing loss, numbness, skin tingling, muscle twitching, convulsions

Abbreviations: CrCl = creatinine clearance; DS = double strength.

<sup>1</sup>Not FDA approved for this indication.

<sup>3</sup>Exceeds dosage recommended by the manufacturer.

- Meningitis and encephalitis: Brucellae can infect the central nervous system to cause an inflammation of the brain, the membranes surrounding the brain, and the spinal cord. This is fatal if the patient is not treated in time.
  - Arthritis: Osteoarthritis caused by *Brucella* infection is typically associated with pain, stiffness, and swelling of the joints, such as the knees, hips, ankles, wrists, spine, shoulder, elbow, sternoclavicular, and small joints. Spondylitis caused by brucellae is characterized by joint inflammation between the vertebrae bones of the spine or between the spine and pelvis. Spondylitis is difficult to treat and can cause lasting damage. These osteoarticular complications are the clinical forms most commonly observed.
  - Epididymitis and epididymoorchitis: Brucellae can infect the epididymis to cause swelling and pain of the testicle.
  - Cutaneous complications: Brucellae can infect skin to cause lesions, rashes, nodules, erythema nodosum, papules, petechiae, and purpura.
  - Respiratory complications: Inhalation of brucellae can result in lung infection, which can lead to pneumonia, bronchopneumonia, pleural effusion with a predominance of monocytic or lymphocytic infiltrates, and paroxysmal dry cough.
  - Hematologic complications: Aspartate aminotransferase (AST) or alanine aminotransferase (ALT) levels can be elevated and are associated with pain in the right upper quadrant or jaundice.
- Complications are common in brucellosis patients. Young patients tend to have cutaneous, hematologic, and respiratory complications. Adult patients tend toward osteoarticular and cardiac complications. Middle-aged patients tend to develop genitourinary, neurologic, and gastrointestinal complications.

### Prevention

Maintaining hygienic habits is very important for avoiding *Brucella* infection. These include consuming only pasteurized milk and cheese. Meat must be cooked thoroughly before consumption. In these regards, education is beneficial for preventing infection by this pathogen. People who handle animals or animal products should wear personal protective equipment, including glasses, rubber gloves, and clothing to protect skin and eyes from exposure or direct contact. Laboratory workers should use a Biosafety Level 3 (BSL-3) facility to handle the *Brucella* organisms and work according to the laboratory's standard operating procedures. Animal immunization programs must be maintained all over the world to cut off the transmission chain from livestock to humans. In addition, primary care physicians should be familiar with the clinical and laboratory findings of brucellosis symptoms and complications.

## CLOSTRIDIOIDES DIFFICILE COLITIS

Method of

Jeffery D. Semel, MD

### CURRENT DIAGNOSIS

- *Clostridium difficile* (renamed *Clostridioides difficile*) infection is diagnosed by a combination of clinical and laboratory findings.
- Diagnosis requires a positive test for the presence of *C. difficile* toxins.
- GDH, or glutamate dehydrogenase, produced by *C. difficile*, can be detected in stool. However, it is not specific and can be produced by non-toxicogenic *C. difficile*.
- Enzyme immunoassay testing for toxin A and or B has a variable sensitivity and specificity and a turnaround time of about 24 hours and correlates well with disease activity.
- Polymerase chain reaction testing has a high sensitivity and specificity and a turnaround time of less than 4 hours; correlates less with disease activity, thus identifying patients with colonization as well as active infection. Increasingly, combination testing is being employed to improve diagnostic accuracy.
- Laboratory testing for *C. difficile* toxins should only be performed on patients with  $\geq 3$  unformed stools per 24 hours, who are not on laxatives and is not useful as a test of cure.
- Pathologic findings can help to confirm diagnosis.

### CURRENT THERAPY

- If possible, the clinician should first consider discontinuing concurrent antibacterial therapy.
- Treatment should be initiated only after a positive test result for *C. difficile* toxin unless the patient is at high risk for *C. difficile* infection or is severely ill, in which case empirical therapy is justified.
- Treatment recommendations depend on the severity of the disease and whether the patient has a first-time diagnosis or recurrence.
- Clinical parameters that guide treatment include increasing age, leukocytosis, elevation of serum creatinine, and presence of hypotension, shock, ileus, or megacolon.
- Taken orally, fidaxomicin (Dificid) is preferred for initial therapy and recurrences, although it is much more costly than vancomycin, which remains an acceptable choice. Metronidazole (Flagyl)<sup>1</sup> oral, can be used for non-severe disease if these are not available.
- Intravenous metronidazole and or rectal vancomycin (enema)<sup>1,6</sup> can be added for severe disease.
- FMT (fecal microbiota therapy) is a safe and effective option for recurrent disease that does not respond to oral therapies, and has shown promise in studies of severe or fulminant *C. difficile* infection.
- Antimicrobial stewardship programs are a safe and cost-effective method of reducing the burden of *C. difficile* infections.

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

Pseudomembranous colitis is an inflammatory disease of the colon that is almost always associated with the toxin-producing bacteria *Clostridioides difficile*. In very rare cases, other organisms can be responsible. In this article I discuss *C. difficile* as an important cause of pseudomembranous colitis.

## Epidemiology and Risk Factors

*C. difficile* is the most common infectious cause of health care-associated diarrhea. Studies in US hospitals showed that mortality rates related to *C. difficile* infection nearly quadrupled from 1999 through 2004. An active population and laboratory based study done by the US Centers for Disease Control and Prevention in 2011 suggested that 453,000 new cases occur in the United States annually; with a 30-day mortality rate of 6.4%. Higher rates of infection were found in whites, females, and those >65 years of age. A Canadian study in 2011 prospectively followed 5422 hospitalized patients and showed that 7.4% had asymptomatic colonization only (60% of these were positive at the time of admission); 2.8% developed *C. difficile* infection during hospitalization. Another study by the CDC found decreased hospital-associated infection rates in US hospitals between 2011 and 2015 but no change in the rate of *C. difficile* infections. Colonization of asymptomatic hospitalized patients with *C. difficile* ranges from 0%–22% and is higher in residents of long-term care facilities.

Additional risk factors for the development of *C. difficile* infection include antimicrobial or chemotherapeutic drug exposure, severe underlying illness, prior hospitalization (acute or long-term care), use of feeding tubes, recent gastrointestinal surgery, and gastric acid suppression. Exposure to antibiotics has been shown to lead to an alteration in the type and quantity of bacterial species found in the normal human intestinal microbiome. Most antibiotics have been associated with *C. difficile* infection. Increased antimicrobial duration and dosage appear to be associated with higher risk of *C. difficile* infection.

Epidemic strains have been described by pulsed-field gel electrophoresis (NAP1,4,7,11 etc.) that are associated with decreased regulatory gene function and increased toxin production. The risk and severity of infection are increased after exposure to the NAP1 strains. Failure of standard first-line therapy for *C. difficile* infection may increase to 10% to 35% during infection with NAP strains.

*C. difficile* infection occurs rarely without prior antibiotic exposure. Healthy peripartum women, children, and postsurgical patients rarely have *C. difficile* infection develop after a single dose of an antibiotic. Newborns have a higher rate of colonization but generally a low rate of *C. difficile* infection.

## Microbiology and Pathophysiology

*C. difficile* is a gram-positive, spore-forming, anaerobic rod. *C. difficile* can exist as either a spore or vegetative form. The vegetative form is highly oxygen sensitive; slight exposure can kill the bacteria. The spore form is highly heat-stable and can survive harsh conditions such as the high acidity of the stomach. Spores have been shown to resist many commercial disinfectants. *C. difficile* reproduces in intestinal crypts and releases exotoxins A and B, leading to severe inflammation. Toxin A (enterotoxin) attracts neutrophils and monocytes, and toxin B (cytotoxin) degrades colonic epithelial cells. Most strains of *C. difficile* produce both toxin A and B; however, toxin production, and thus detection may fluctuate during infection. Toxins disrupt cell membranes and cause shallow ulcerations on the intestine mucosal surface. Ulcer formation leads to the release of proteins, mucus, and inflammation manifesting as a pseudomembrane. A pseudomembrane is virtually pathognomonic for *C. difficile* infection.

Transmission occurs via the fecal–oral route, person to person, or via fomites. Following exposure to antibiotics, the normal gut flora is altered (“dysbiosis”), allowing *C. difficile* to become more dominant. Exposure to *C. difficile* spores may result in no acquisition, asymptomatic colonization, mild diarrhea, or infection. Evidence showing colonization occurring during hospitalization as opposed to prior to hospitalization poses an increased risk for *C. difficile* infection, suggests that colonization in some patients induces immunity, and that more virulent strains are present in the hospital.

In addition, the host immune response to spore exposure is important in determining the clinical outcome. Approximately 60% of people have detectable levels of antibodies to toxin A and B. It is likely that prior exposure to *C. difficile* spores or related clostridial

species and subsequent colonization stimulates antibody production and immunity. *C. difficile* has been found to be capable of creating a biofilm in vitro, which may impair the antibacterial activity of antibiotics such as metronidazole (Flagyl). Various studies are attempting to define the role of active or passive immunotherapy, including vaccination with nontoxicogenic *C. difficile*, to prevent *C. difficile* infection. Another factor favoring *C. difficile* growth is the loss of gut microbiome members with bile metabolizing capacity leading to enrichment of primary conjugated bile acids, which can promote germination of *C. difficile* spores and decreased binding to toxins.

## Clinical Features

*C. difficile* infection is diagnosed by a combination of clinical and laboratory findings. Diarrhea is defined as the passage of three or more unformed stools in a 24-hour period. Symptoms include fever, diarrhea, and cramplike abdominal pain. Patients can have nausea, vomiting, or hematochezia. In severe cases, abdominal tenderness and distention are present. Signs of septic shock can develop. The extent of leukocytosis frequently correlates with disease severity. Plain abdominal radiographs might show distended loops of bowel, ileus, or, in severe cases, toxic megacolon. Computed tomography (CT) image findings include colonic wall thickening and dilatation, mesenteric edema, and, rarely, perforation. Endoscopy can reveal pseudomembranes. However, sigmoidoscopy or colonoscopy may be complicated by perforation in severely ill patients and should be performed with caution.

## Differential Diagnosis

The differential diagnosis includes bacterial causes such as *Shigella*, *Salmonella*, or *Campylobacter* species, protozoan infections such as *Entamoeba histolytica* or *Strongyloides stercoralis* (immunosuppressed patients), inflammatory disorders such as ulcerative colitis or Crohn’s disease, drug toxicity (e.g., chemotherapeutic agents), and vascular disorders such as ischemic bowel disease.

## Diagnosis

Various tests have been developed for the diagnosis of *C. difficile* infection. Glutamate dehydrogenase (GDH) is a protein produced by *C. difficile* and can be detected in stool. It is very sensitive for *C. difficile* but can be produced by non-toxicogenic *C. difficile* and thus is non-specific.

Enzyme immunoassays (EIA) for toxin A and or B detect toxin production. The sensitivity is 63%–94% and specificity is 75%–100%. GDH and toxin assays correlate well with clinical disease activity, but may not detect the presence of small amounts of toxin.

Molecular tests such as polymerase chain reaction (PCR) can be performed in less than 4 hours. The sensitivity is approximately 93% and specificity is 97%. These tests target toxin genes and do not always correlate with clinical disease. Since the introduction of PCR, the number of cases diagnosed has increased further (though some may represent colonization). Thus positive *C. difficile* testing must be correlated with clinical disease activity to determine if treatment is indicated. Increasingly, authors have recommended two-step testing using PCR, or, GDH/toxin EIA, followed by PCR when GDH/toxin EIA are discordant.

## Treatment

If possible, the clinician should first consider discontinuing concurrent antibacterial therapy, unless there is a compelling clinical indication to continue. Antimotility agents should be avoided because decreased gut motility can increase the potential for tissue toxin exposure and toxic megacolon. Treatment for *C. difficile* infection should be initiated only after a positive *C. difficile* test result unless the patient is at high risk for *C. difficile* infection or is severely ill, in which case empirical therapy is reasonable even with negative test results.

Antibacterials used to treat *C. difficile* infection can be administered orally, intravenously, or rectally. Oral therapies are preferred. Oral vancomycin (Vancocin) is not absorbed in the gastrointestinal tract and is eliminated in the feces.

Fidaxomicin (Dificid), a macrocyclic antibiotic, has been shown to have equal efficacy to vancomycin but with a potentially lower rate of *C. difficile* recurrence. Fidaxomicin is approved for patients 18 years or older. Oral metronidazole (Flagyl), a nitroimidazole antibiotic, is eliminated primarily in the urine, although 6% to 15% is eliminated in the feces, and may be less active as inflammation subsides.

Recommendations for the treatment of *C. difficile* infection depend on the severity of the disease. Clinical parameters that correlate with severity include increasing age, leukocytosis, and elevation of the serum creatinine.

A white blood cell count of at least 15,000 cells/ $\mu$ L or a serum creatinine at least 1.5 times the premorbid level suggests the possibility of severe infection. The Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA) published treatment guidelines in 2018 and a “focused” update in 2021. Fidaxomicin 200 mg by mouth twice daily for 10 days is now considered the treatment of choice for an initial episode. The average retail price (USD, Singlecare.com, February 2022) of a 10-day course of fidaxomicin is \$5262.00, compared with vancomycin, \$491.00. In view of significant cost differences between fidaxomicin and vancomycin, the guidelines state that “implementation depends upon available resources and vancomycin remains an acceptable alternative”. If these drugs are not available, metronidazole (Flagyl)<sup>1</sup> 500 mg three times daily by mouth can be used but should be avoided if the disease is severe.

Patients with an initial episode that is complicated by hypotension, shock, ileus, or megacolon should be treated with vancomycin 500 mg PO or via nasogastric tube 4 times per day, plus metronidazole<sup>1</sup> 500 mg IV every 8 hours. If the patient has a complete ileus, the clinician may consider adding a rectal instillation of vancomycin<sup>1,6</sup> 500 mg every 6 hours. It is recommended that trained personnel administer the enema to decrease the chances of rectal perforation if the rectal route is chosen.

### Monitoring

The response to therapy should be monitored clinically. Reversal of hemodynamic instability, decreasing stool frequency, and a declining white blood cell count are objective measures of response. Stool tests for *C. difficile* toxin are not valuable for monitoring disease elimination, because these tests can remain positive after improvement.

### Complications and Recurrence

Another challenging problem in *C. difficile* infection is recurrence. Recurrence is defined as another episode that occurs within eight weeks following resolution of the initial episode. Recurrence occurs in approximately 20% to 30% of cases. Continued use of antibacterials (other than treating agents), increased age, female sex, use of proton pump inhibitors or corticosteroids, living in a nursing home, longer hospitalization, severe underlying disease, and inadequate antitoxin antibody response are risk factors for relapse. Even though treatment failure and relapse are common, resistance to metronidazole or vancomycin is uncommon.

The 2021 IDSA/SHEA guideline update now recommends fidaxomicin in one of two strategies, 200 mg oral twice daily for 10 days or 200 mg twice daily for 5 days followed by once every other day for 20 days as the treatment of choice for *C. difficile* recurrences. Alternatively, vancomycin can be prescribed in a tapered and pulsed regimen (vancomycin 125 mg PO 4 times per day for 2 weeks, followed by 125 mg PO 2 times per day for 1 week, followed by vancomycin 125 mg PO once daily for 1 week, followed by 125 mg PO once every 2 to 3 days for 2 to 8 weeks). Cost considerations apply as discussed in treatment of the initial episode. The updated guidelines also suggest that bezlotoxumab (Zinplava), a monoclonal antibody directed against *C. difficile*, given as a single intravenous infusion with standard of care antibiotics, be considered after a recurrence for

high risk patients. Bezlotoxumab should be used with caution in patients with congestive heart failure. The average retail cost is \$4561.00.

Fidaxomicin may be considered as an alternative to vancomycin for an initial recurrence.

Another option for recurrent *C. difficile* infection is fecal reconstitution or fecal microbiota therapy (FMT). The goal is to reverse dysbiosis and restore normal colonic flora. Healthy donor stool is infused via colonoscopy, intraduodenal, or by frozen capsule. Numerous studies have shown the efficacy of FMT, although the exact place, timing and mode of installation continue to be under evaluation. A second FMT installation may improve efficiency. Donor stool must be screened for infectious agents prior to installation.

Probiotics<sup>7</sup> are live organisms that seek to restore the normal gastrointestinal microflora. Most studies have used *Lactobacillus* species or *Saccharomyces boulardii* in an effort to prevent, or treat *C. difficile* infection. A recent Cochrane analysis has shown that the use of probiotics during antimicrobial administration may decrease the subsequent development of *C. difficile* colitis. The optimal probiotic formula, dosing, and side effect profile remains to be determined. Probiotics have not shown benefit during active infection. Occasional cases of fungemia or bacteremia have been reported in immunocompromised patients and those with central venous catheters treated with probiotics. Probiotics should be avoided in these patients.

Recently, Fischer et al. have reported promising results using fecal microbiota transplant with oral vancomycin in the treatment of severe or fulminant *C. difficile* colitis as a possible option to avoid surgery in critically ill patients. Total colectomy is often considered as a last measure for patients who remain critically ill despite standard therapy. The exact indications for surgery are not clear, although refractory shock, signs of peritonitis, megacolon, and multiorgan failure are most often cited. As expected, the mortality rate after total colectomy is high, ranging from 35% to 80%. Neal and colleagues reported that in a series of 42 patients, performance of a diverting loop ileostomy and intraoperative colonic lavage with polyethylene glycol, followed by postoperative antegrade vancomycin flushes, resulted in 19% mortality and 93% colon preservation.

### Prevention

Given the difficulties in controlling the spread of *C. difficile*, prevention is critical. *C. difficile* spores resist desiccation and can survive in the hospital environment for months. Environmental contamination is highest in and around the rooms of patients with *C. difficile* infection. The risk of hospital-associated *C. difficile* has been found to be increased for patients occupying the bed of a previous patient who received antibiotics. Items that have been found to harbor *C. difficile* spores include clothing, blood pressure cuffs, telephones, toilets, doorknobs, oral and rectal thermometers, and other medical equipment. In addition, the hands of health care workers have been found to be a vehicle of transmission.

Current recommendations for prevention of transmission of *C. difficile* include the following. Careful hand hygiene with soap and water is essential. Programs to monitor the compliance and technique of hand hygiene are recommended. Alcohol-based hand rubs, which are widely used, have been shown to be less effective at removing spores than conventional hand washing. Thus alcohol-based hand rubs should not be used for *C. difficile* isolation when *C. difficile* outbreaks are present. Barrier precautions with gowns and gloves should be used. Programs to ensure adequate and effective cleaning of health care facilities after use are recommended. Disposable electronic thermometers are recommended. Antimicrobial stewardship programs aimed at promoting the judicious

<sup>1</sup>Not FDA approved for this indication.

<sup>6</sup>May be compounded by pharmacists.

<sup>7</sup>Available as a dietary supplement.

use of antibacterial therapy have been found to be effective in reducing *C. difficile* infection rates and are encouraged. Finally, should continued antibiotic therapy be required in a high risk patient, prophylaxis with vancomycin<sup>1</sup> 125 mg daily may decrease the risk of colitis.

<sup>1</sup>Not FDA approved for this indication.

## CAT SCRATCH DISEASE

Method of

Ronen M. Ben-Ami, MD

## CURRENT DIAGNOSIS

- The combination of a compatible clinical syndrome of regional lymphadenopathy with a primary inoculation lesion and cat contact is highly suggestive of cat scratch disease.
- Results of *Bartonella henselae* serology are helpful in confirming the diagnosis; however, up to 20% of patients remain seronegative throughout their disease.
- Detection of *B. henselae* DNA by polymerase chain reaction from pus obtained by needle aspiration or lymph node biopsy is a highly sensitive diagnostic modality and may be particularly useful in seronegative patients.

## CURRENT THERAPY

- Typical cat scratch disease is a self-limiting disease; therefore systemic antimicrobials are not routinely indicated in immunocompetent patients with uncomplicated cat scratch disease.
- Indications for antimicrobial therapy include an immunocompromised host, endocarditis, retinitis, and other atypical syndromes.
- Treatment may also be considered for patients who have typical cat scratch disease and who have extensive or bulky lymphadenopathy and are highly symptomatic.
- Suppurative lymph nodes should be drained by large-bore needle aspiration.

Cat scratch disease is a worldwide zoonotic infection caused by *Bartonella henselae*, an intracellular, pleomorphic, gram-negative bacillus. Other *Bartonella* species have rarely been implicated. The disease typically manifests as benign regional lymphadenopathy, but atypical disease can involve almost any organ system and is associated with significant morbidity.

## Epidemiology

*Bartonella henselae* infection is widespread among domestic cats and other felids worldwide, and serologic studies indicate a higher prevalence in warm, humid climates. Transmission among cats occurs via an arthropod vector, the cat flea *Ctenocephalides felis*. *B. henselae* bacteremia is detected at higher rates in feral cats than in domesticated cats and in kittens compared with adult cats, explaining the higher infectivity of these animals. Cats infected with *B. henselae* are asymptomatic. Transmission to humans occurs via a scratch, bite, or lick; contamination of cat scratches by flea feces may enhance *Bartonella* transmission.

Cat scratch disease has been estimated to occur in the United States at a rate approaching 10 per 100,000 population. There is some seasonality, with incidence peaking between September and January. Although traditionally considered a disease of childhood, epidemiologic surveys have found a similar incidence of cat scratch disease in adults, and 6% of patients are 60 years of age or older. Cat contact is the most important risk factor: Almost all patients are cat owners or were otherwise exposed to cats, and about one-half can recall a recent bite or scratch, most commonly by a kitten.

## Clinical Manifestations

Cat scratch disease is divided into two clinical syndromes. Typical cat scratch disease is a subacute, self-limiting regional lymphadenopathy and constitutes 80% to 90% of cases. Atypical cat scratch disease encompasses Parinaud oculoglandular syndrome and other clinical entities with systemic extranodal involvement. Bacillary angiomatosis and bacillary peliosis are manifestations of *B. henselae* infection in immunocompromised persons and are not discussed here.

## Typical Cat Scratch Disease

A primary skin lesion, usually a papule or pustule, appears at the site of inoculation 3 to 10 days after cat contact and persists for 1 to 3 weeks. Regional lymphadenopathy develops within 1 to 7 weeks and resolves spontaneously after 2 to 4 months. The primary lesion is still present in about two-thirds of patients when they present for evaluation of lymphadenopathy. The most commonly involved lymph nodes are, in descending order of frequency, axillary and epitrochlear nodes, head and neck nodes, and femoral and inguinal nodes. One-third of patients develop lymphadenopathy at multiple sites. Lymph nodes are often painful and red; suppuration occurs in 10% of nodes. Mild constitutional symptoms, including low-grade fever and malaise, are noted in about one-half of the cases. Rash, night sweats, anorexia, and weight loss are uncommon. Infection results in lifelong immunity.

### Atypical Cat Scratch Disease

Parinaud oculoglandular syndrome, the most common form of atypical cat scratch disease, is a specific type of regional lymphadenopathy that occurs following conjunctival inoculation of *B. henselae*. The syndrome includes granulomatous conjunctivitis and preauricular lymphadenopathy. Endocarditis and encephalitis represent severe forms of *B. henselae* infection and are more common in older adult patients. Encephalitis manifests with various degrees of altered mental status, agitation, headache, and seizures. Cerebrospinal fluid lymphocytic pleocytosis occurs in only one-third of cases, and brain imaging studies usually fail to show any abnormalities. Neuroretinitis manifests as sudden unilateral loss of visual acuity. The diagnosis is suspected on the basis of typical findings on fundoscopic examination: papilledema and macular exudates in a starlike configuration. However, these findings are not pathognomonic of cat scratch disease. Other ocular findings include uveitis, optic neuropathy, and retinal vessel occlusion. Infrequent manifestations are self-limiting granulomatous hepatitis and splenitis and osteoarticular disease. Prolonged fever of unknown origin has been described in children and adolescents, taking the form of relapsing fever in one-half of the cases.

### Diagnosis

A compatible clinical syndrome in a person with a positive history of cat exposure suggests cat scratch disease. The diagnosis is most commonly confirmed with specific serologic assays. The immunofluorescence assay and the enzyme-linked immunosorbent assay are comparably sensitive, although cross-reactivity can occur with other organisms such as *Chlamydia* species, *Coxiella burnetii*, and non-*henselae* *Bartonella* species. A single elevated titer of immunoglobulin (Ig)M or IgG in the acute phase or a fourfold increase of IgG in convalescent serum supports the diagnosis.

Biopsy and histopathologic examination of lymph nodes are usually only performed when malignancy is suspected. Necrotizing granulomas are typically observed. The pleomorphic gram-negative bacilli are best visualized with the Warthin-Starry stain; however, the sensitivity of this method is too low to be clinically useful. Similarly, culture lacks sensitivity and requires prolonged incubation, making it impractical for routine use.

Polymerase chain reaction assays for the detection of *B. henselae* in pus aspirated from suppurative lymph nodes or primary skin lesions are highly sensitive and specific, and they can be performed with a rapid turnaround time. However, these assays are not widely available in most clinical microbiology laboratories.

### Differential Diagnosis

Cat scratch disease should be differentiated from other infectious and noninfectious causes of regional lymphadenopathy.

Importantly, lymphoma and solid tumors with metastases to lymph nodes may be confused with cat scratch disease. Malignancy should be suspected in patients who have marked constitutional symptoms, who are seronegative, or whose lymphadenopathy fails to resolve spontaneously after more than 6 months. Unlike cat scratch disease, pyogenic lymphadenitis manifests with rapid progression, high-grade fever, and a septic-appearing patient. Mycobacterial infection, syphilis, bubonic plague, tularemia, histoplasmosis, and sporotrichosis should be considered based on the presence of specific risk factors and endemic exposures. *Bartonella* endocarditis must be differentiated from other causes of culture-negative endocarditis, specifically Q fever and brucellosis.

### Treatment

Because of the self-limiting course of typical cat scratch disease, patients usually only require observation and reassurance of its benign nature. The goals of therapy are alleviation of symptoms in patients with bulky lymphadenopathy and drainage of suppurating lymph nodes to prevent spontaneous formation of chronic sinus tracts. If drug treatment is initiated, azithromycin (Zithromax)<sup>1</sup> is the agent of choice based on a small randomized placebo-controlled study that showed more-rapid resolution of lymphadenopathy in the azithromycin arm as determined by ultrasonography. Suppurative nodes should be drained by large-bore needle aspiration. Incisional drainage is best avoided because it can promote sinus tract formation.

Atypical cat scratch disease syndromes usually require treatment, but there are scant data to support specific regimens, and treatment duration is not well defined. For patients with endocarditis, treatment with an aminoglycoside for at least 14 days is associated with a higher likelihood of recovery and survival. Uncontrolled data suggest that, for patients with neuroretinitis, treatment with antibiotics and corticosteroids is associated with better visual outcomes than treatment with antibiotics alone (Table 1).

### Prevention

Flea control in domestic cats can reduce the likelihood of *Bartonella* bacteremia and transmission to humans. Bites and scratches should be promptly rinsed. HIV-infected patients and other immunocompromised persons should be cautioned about the risks of cat exposure because they are susceptible to disseminated visceral *B. henselae* infection as well as other zoonotic infections such as toxoplasmosis.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Antibiotic Treatment Regimens for Cat Scratch Disease

CLINICAL SYNDROME	FIRST CHOICE	SECOND CHOICE	COMMENTS
Typical cat scratch disease	Not indicated*	Azithromycin (Zithromax) <sup>1</sup> 500 mg PO on day 1, then 250 mg PO × 4 days	Drain suppurative nodes using large-bore aspiration
Endocarditis	Gentamicin <sup>1</sup> 1 mg/kg IV q8h × >14 days plus doxycycline 100 mg IV/PO bid × 6 weeks	Doxycycline 100 mg PO bid plus rifampicin (Rifadin) <sup>1</sup> 300 mg PO bid × 6 weeks	Some experts recommend extending oral doxycycline treatment × 3–6 months Surgical valve excision may be required
Neuroretinitis	Doxycycline 100 mg PO bid plus rifampicin <sup>1</sup> 300 mg PO bid × 4–6 weeks	NA	Spontaneous resolution is the rule; the utility of treatment remains unproven
Other atypical cat scratch disease	As for neuroretinitis	NA	Treatment duration should be individualized

<sup>1</sup>Not FDA approved for this indication.

\*Treatment may be considered for patients with bulky or extensive lymphadenopathy and for immunocompromised patients.  
NA, Not available.

## CHIKUNGUNYA

Method of

Scott Kellermann, MD, MPH; and Rick D. Kellerman, MD

### CURRENT DIAGNOSIS

- Clinically, chikungunya is a diagnosis of exclusion, particularly when laboratory testing is not available. Accurate diagnosis depends on the patient's clinical symptoms and the epidemiology of endemic disease.
- Acute symptoms include incapacitating relapsing bilateral symmetrical polyarthralgia accompanied by high fever, headache, backache, and fatigue. Some may have a pruritic maculopapular rash at onset.
- Chronic symptoms include episodic incapacitating symmetrical polyarthralgia. Many have long-term asthenia and depression.
- From 0 to 7 days of infection, Chikungunya virus can be detected via real-time reverse-transcription polymerase chain reaction (RT-PCR).
- For individuals presenting 8 or more days following onset of symptoms, chikungunya virus serologic testing via ELISA or IFA should be performed.
- Immunoglobulin (Ig)M anti-chikungunya virus antibodies are detectable starting about 5 days (range 1–12 days) and persist for several weeks to 3 months.
- Immunoglobulin M antibody levels peak 3 to 5 weeks after the onset of illness and persist for approximately 2 months.
- IgG antibodies begin to appear about two weeks following onset of symptoms and persist for years.
- A positive IgG antibody indicates prior chikungunya infection; it does not delineate whether arthritic symptoms are a consequence of prior infection.

### CURRENT THERAPY

- Medical treatment is primarily supportive.

The word “chikungunya” is a derivation of the Kimakonde (a Mozambique dialect) word “kungunyala” meaning “to become desiccated or contorted.” In the Democratic Republic of the Congo, it is called “buka-buka,” translated as “broken-broken,” reflecting the incapacitating arthralgias that are common manifestations of Chikungunya fever.

## Epidemiology

Chikungunya, first diagnosed in Tanganyika in 1952, is found in a large percentage of countries in Africa, Asia, and Southeast Asia and is prevalent in India. Chikungunya virus often causes large outbreaks with high attack rates, affecting one-third to three-quarters of the population. Dense human populations and lack of herd immunity likely contribute to the explosive nature of chikungunya epidemics in many regions. In India during 2006, more than 1,250,000 cases of chikungunya were reported, with *Aedes aegypti* implicated as the vector. In late 2013, the first locally acquired cases were reported on Caribbean islands. By the end of 2017, more than 2.6 million suspected cases had been chronicled in the Americas. From 2010 through 2013, 110 cases of chikungunya were documented among US travelers. Following the outbreak in the Americas, there were >4,000 cases reported in US travelers from 2014 to 2017, 13 of which were locally acquired in the continental United States. In 2020 there were 33 travel associated cases of chikungunya, no cases were acquired in the continental US or its territories.

A 2014 study, undertaken by the Puerto Rico Department of Health and the CDC, demonstrated that chikungunya cases are vastly underreported in Puerto Rico. In passive surveillance of 250 participants, 70 (28%) tested positive for past or current chikungunya virus infection. However, only two of 25 participants (8%) with chikungunya infection who sought care had been reported to health authorities.

It is believed that chikungunya virus originated in Africa and migrated to Asia 200 years ago. Evidence derived from molecular genetics suggests it evolved around 1700; the first recorded outbreak of this disease was probably in 1779.

Interestingly, some medical historians believe that a pandemic of chikungunya occurred in the western hemisphere in the 1800s but was diagnosed as dengue fever. The 21st-century researchers who have examined the accounts of this pandemic now speculate that it was caused by chikungunya because the cases exhibited severe joint arthritis, which is more indicative of chikungunya than dengue. The virus then disappeared from the Americas until it reemerged during the last decade. Chikungunya epidemics appear suddenly and unpredictably and proceed explosively.

## Risk Factors

Individuals at the highest risk of contracting chikungunya and suffering from more-severe symptoms are those who have chronic arthritis, underlying chronic medical conditions, those over the age of 65 years, and pregnant women. Travelers who spend extended periods of time in endemic areas are at greater risk. These include missionaries, humanitarian aid workers, and those who frequently work outdoors.

## Pathophysiology

Chikungunya is an arthropod-transmitted disease caused by a single-stranded RNA arbovirus. Patients develop viremia within a few days of infection. The virus invades and replicates within the joints. Animal models of chikungunya virus pathogenesis suggest the virus directly infects the synovium, tenosynovium, and muscle, leading to production of proinflammatory cytokines and chemokines and recruitment of leukocytes. Typically, infectious virus is cleared from the circulation within days and from joints within a couple of weeks. Chronic arthritis due to chikungunya virus develops in up to approximately 60% of infected individuals. Why some patients develop chronic joint pain while others do not is not well understood. Three hypotheses have been proposed to explain chronic arthritis: persistent

viral replication, persistent viral RNA driving an inflammatory response, and autoimmunity. Persistent T cell activation has been reported in chronic arthritis due to chikungunya virus, but rheumatoid factor and anticyclic citrullinated peptide testing are typically negative.

As with dengue fever and yellow fever, chikungunya cycles from mosquito to human to mosquito. The mosquito *Aedes aegypti* is the usual vector for transmission of chikungunya. *A. aegypti* is well adapted to urban settings and is widely distributed in the tropics and subtropics worldwide. It prefers the human host and breeds readily in flowerpots and in trash. It often enters homes and will feed indoors and outdoors. A single *A. aegypti* mosquito can infect more than one human since this species may feed on another host if its blood meal is interrupted.

*Aedes albopictus*, the Asian tiger mosquito, is also a vector. Both species are found in the southeastern United States and limited parts of the southwest. The risk of person-to-mosquito transmission is highest during the viremic first week of illness. Human and nonhuman primates are the main amplifying reservoirs for the virus. Transmission is possible through a needle stick, the handing of blood, and through aerosol laboratory exposure. No transfusion-related cases have been identified. Previous infection will convey permanent immunity.

### Prevention

Currently, no vaccine or preventive drug is available. Several candidate vaccines, including mRNA vaccines, are in various stages of development. The best preventive measures are wearing permethrin-treated, bite-proof long sleeves and trousers and using a mosquito repellent such as 30% DEET, 20% oil of lemon eucalyptus, or 30% picaridin. Screening windows and doors has only a limited effect, because most contacts between the *Aedes* mosquitoes and humans occur outside. The CDC's website has excellent information regarding preventive measures: <https://www.cdc.gov/chikungunya/prevention/index.html>.

Standing water, a breeding ground for mosquitoes, should be drained. *Aedes aegypti* breeding sites are associated with human habitation and are seemingly innocuous (i.e., flower vases, water storage vessels and birdbaths). Customary blood handling procedures are recommended.

If a Chikungunya epidemic were to occur in the United States, the standard public health measures of avoidance and mosquito control would be major lines of defense. To prevent local spread, the patient diagnosed with chikungunya should use mosquito repellent for 1 week after onset of fever.

### Clinical Manifestations

Chikungunya virus infection should be considered in patients with acute onset of fever and polyarthralgia, especially in travelers who have recently returned from areas with endemic chikungunya. Joint pain may precede fever; in one outbreak in 2017 among more than 1300 patients in Dhaka, Bangladesh, joint pain preceded fever in 90 percent of cases.

The incubation period of the chikungunya virus ranges from 1 to 12 days, most typically 3 to 7 days. Chikungunya infection may be divided into an acute phase (<3 months) and chronic phase (>3 months). The acute phase may be further subdivided into viremic (1–3 weeks) and subacute post-viremic (4–12 weeks) phases.

The viremic phase is characterized by sudden onset of high-grade fever (often >39°C), severe, incapacitating polyarthralgia/polyarthritis, myalgias, conjunctivitis, and exanthema. Polyarthralgia is reported in 87% to 98% of cases and represents the most characteristic symptom. The joint pain is mostly polyarticular, bilateral, and symmetrical and occurs mainly in peripheral joints (wrists, ankles, and phalanges) and some large joints (shoulders, elbows, and knees). Joint swelling is less frequent, occurring in 25% to 42% of cases. Typically, the fever lasts for 2 days and then will defervesce abruptly. Headache and an extreme degree of prostration may persist for a variable period, usually about 5 to 7 days. Symptoms typically resolve in 7 to 10

days. Rare complications include uveitis, retinitis, myocarditis, hepatitis, nephritis, hemorrhage, and neurologic problems such as myelitis, meningoencephalitis, Guillain-Barré syndrome, and cranial nerve palsies. In 40% to 50% of cases, skin involvement is present, consisting of a pruritic maculopapular rash, predominantly on the thorax, localized petechia, and facial edema.

In the subacute phase, fever settles but articular symptoms and fatigue persist. Polyarthritis is usually symmetrical and involves small and large joints. Tenosynovitis and bursitis can also occur, which are usually very painful. Patients who have concomitant comorbidities such as osteoarthritis, heart failure, respiratory disease, renal disease, and diabetes are likely to have more severe manifestations of acute infection. Chikungunya infection may also exacerbate underlying rheumatic diseases and relapses of autoimmune arthritis in patients who were in remission prior to infection.

The chronic phase of the disease may follow a pattern similar to rheumatoid arthritis, peripheral spondylarthritis, undifferentiated arthritis, and fibromyalgia. The ankles, knees, hips, wrists, elbows, and metacarpal-phalangeal joints are mainly involved. In a 2016 meta-analysis including approximately 5700 patients in 18 studies, chronic inflammatory rheumatism (defined as new-onset arthritis, musculoskeletal pain, or arthralgia) occurred in approximately 40 percent of individuals; symptoms persisted beyond 18 months in 56 percent of these patients.

Factors such as an age older than 45 years, high viral load (>10<sup>9</sup>/mL) during the acute phase, and severe immunologic response in post-viremic phase are predictors of development of chronic symptoms.

About 20% of patients with chronic chikungunya infection may have chronic pain with neuropathic features including paresthesia, tingling, numbness, and itching.

A study of pregnant women conducted on the island of Réunion during 2005–2006 epidemic showed that the mother to child (vertical) transmission rate was approximately 50% when chikungunya infection occurred in the intra-partum (2 days either side of delivery) period. Delivery by cesarean section did not prevent the transmission of virus. The babies were born healthy; however they developed fever, weakness, and thrombocytopenia between 3 to 7 days. Neurocognitive outcome was poor in children with perinatal transmission from infected mothers.

The case fatality ratio is approximately 1 per 1000, with most deaths occurring in newborns, the elderly, and the infirm.

### Diagnosis

In humans, chikungunya viremia may exceed 10<sup>9</sup> RNA copies/mL plasma; in addition, viremia may be present prior to onset of symptoms. In the setting of symptomatic infection, viremia usually disappears after 6 to 7 days of illness; however, the virus has been isolated after 8 days, and chikungunya genomic products can be detected as late as day 17 of illness. Instructions for serum diagnostic testing are found on the Centers for Disease Control and Prevention's website: <https://www.cdc.gov/chikungunya/hc/diagnostic.html>.

Chikungunya virus RNA can be detected by RT-PCR during the first 5 days following onset of symptoms with excellent sensitivity and specificity (100% and 98%, respectively). For individuals presenting 8 or more days following onset of symptoms, chikungunya virus serologic testing via ELISA or IFA should be performed. A positive result establishes a diagnosis of chikungunya virus infection.

Immunoglobulin (Ig)M anti-chikungunya virus antibodies (detected by direct ELISA) are present starting about 5 days (range 1 to 12 days) following onset of symptoms and persist for several weeks to 3 months. IgG antibodies begin to appear about 2 weeks following onset of symptoms and persist for years. A positive IgG antibody test result indicates prior chikungunya infection; it does not delineate whether arthritic symptoms are a consequence of prior infection. The time between possible exposure and clinical history should be evaluated carefully when making a diagnosis of chronic chikungunya viral arthritis in a patient with a positive IgG test.

Viral culture is a research tool.

A complete blood count may show lymphopenia and thrombocytopenia. Liver enzymes may elevate, and the serum creatinine might also increase. There are no pathognomonic radiologic findings, and biologic markers of inflammation are normal or modestly elevated.

In many parts of the world, chikungunya is a clinical diagnosis of exclusion, particularly when laboratory testing is not readily available. The probability of accurate clinical diagnosis is predicated on the epidemiology of endemic diseases and the patient's clinical symptoms.

### Differential Diagnosis

The differential diagnosis for chikungunya includes influenza, malaria, rickettsia, and a multitude of viruses, especially dengue fever. Dengue and chikungunya viruses are transmitted by the same mosquitoes, may have similar clinical features, and can occasionally coinfect the same individual. Clinically differentiating chikungunya from dengue may be difficult; however, in chikungunya the onset of fever is typically more abrupt and shorter lived, with severe arthralgia, rash, and lymphopenia more prevalent, whereas infection with dengue is more likely to present with neutropenia, thrombocytopenia, hemorrhage, shock, and death. Seasonally, chikungunya is more likely to be seen in the summer months when *Aedes* mosquitos proliferate.

### Treatment

Most chikungunya infections are self-limiting and will improve with supportive care, hydration, and analgesia. There is no specific antiviral therapy for acute chikungunya virus infection.

In the acute viremic phase (1–3 weeks), acetaminophen (up to 500 to 1000 mg 3 times daily) is useful. If acetaminophen is inadequate for symptom relief and once dengue is excluded, any nonsteroidal antiinflammatory drug (NSAID) may be used.

In the subacute phase (4–12 weeks), if there is evidence of severe synovitis and joint swelling, prednisone 10 to 20 mg daily for 5 days tapered over 10 days can be efficacious. The lowest effective glucocorticoid dose possible with a short trial is usually sufficient; however, the individual response to therapy varies substantially. More severely affected patients may require higher doses (0.5 mg/kg daily), and some patients require up to 1 to 2 months of glucocorticoid therapy. Adding oral steroids to NSAIDs will aid in ameliorating symptomatology. Weak opioids like codeine or tramadol may be also considered at the lowest dose for the shortest duration necessary.

In the chronic phase (>3 months) of chikungunya arthritis with ongoing synovitis or tenosynovitis, disease-modifying antirheumatic drugs (DMARD) can be used. The most commonly used DMARD is methotrexate<sup>1</sup> as a single dose at 7.5 to 15 mg/wk, along with folic acid<sup>1</sup> 1 mg/day. Renal function should be assessed. There is limited experience using sulfasalazine.<sup>1</sup> In patients with a complete response for at least 6 months, discontinuation of DMARD therapy should be attempted. In patients who are nonresponsive to methotrexate,<sup>1</sup> a tumor necrosis factor (TNF)-alpha inhibitor is an appropriate consideration.

### Monitoring

Chikungunya is a nationally notifiable disease. Cases should be immediately reported to state or local health department officials to facilitate diagnosis and mitigate the risk of local transmission.

### Complications

During the 3 years following the 2006 La Reunion outbreak, 60% of patients experienced ongoing symptoms of arthralgia, most reporting episodic relapses and recovery periods. Long-term arthralgias were typically polyarthralgia (70%), symmetrical (90%), and highly incapacitating (77%). They were

often associated with local swelling (63%), asthenia (77%), or depression (56%). The age older than 35 years and the presence of arthralgia 4 months after the disease onset are risk factors of long-term arthralgia. Chikungunya is one of the agents researched as a potential biologic weapon.

## CHOLERA

Method of

Mark Pietroni, MD, MBA

Cholera affects about 3 million people per year and kills approximately 100,000. It can kill within hours of the onset of symptoms, and even today the impact of an outbreak of cholera can be catastrophic in locations in which the water and sanitation infrastructure is weak, especially in crisis or war situations. The 21st century has already seen large-scale cholera epidemics in Haiti, Zimbabwe, Pakistan and Yemen, as well as many smaller outbreaks in countries and areas in which cholera is endemic. When cholera is untreated, mortality can be as high as 60% to 70%, but even in epidemics, with appropriate management and well-run diarrhea treatment centers, mortality can be reduced to well below 1%.

Oral rehydration therapy (ORT) is now the mainstay of treatment (Table 1). Developed in the 1960s in Dhaka, Bangladesh, ORT was used to great effect during the Bangladesh Liberation War of 1971. Cholera broke out in the refugee camps outside Calcutta, and the medical services ran out of intravenous fluid. ORT was not accepted as routine therapy by the medical profession at that time. The courageous decision to treat people with ORT saved thousands of lives and convinced the world of the effectiveness of ORT in the management of cholera.

### Pathophysiology

Cholera is caused by a gram-negative, comma-shaped bacterium called *Vibrio cholerae*. Clinical disease is caused by two serogroups: *V. cholerae* O1 (which has two biotypes: classical and El Tor) and *V. cholerae* O139. Humans are the only known natural host, and asymptomatic human carriage is rare. *V. cholerae* is rapidly killed by boiling water, but it can lie dormant for months in blue-green algae, crustaceans, and copepods in brackish water, especially in estuaries. The Ganges delta provides an ideal habitat and is believed to be the place cholera first emerged.

<sup>1</sup>Not FDA approved for this indication.

**TABLE 1** Composition (mEq/L) of Common Solutions Used for Rehydration

SOLUTION	NA <sup>+</sup>	K <sup>+</sup>	CL <sup>-</sup>	HCO <sub>3</sub> <sup>-</sup>	CITRATE	CA <sup>2+</sup>	GLUCOSE OR CARBOHYDRATE
<b>Intravenous Solution</b>							
Normal saline	154	—	154	—	—	—	—
Ringer's lactate	130	4	109	28	—	3	—
Ringer's lactate + D <sub>5</sub>	130	4	109	28	—	3	278
Cholera saline (Dhaka solution)	133	13	98	48	—	—	140
<b>Oral Solution</b>							
Standard ORS	90	20	80	—	10	—	111
Hypo-osmolar ORS	75	20	65	—	10	—	75
ReSoMal*	45	40	76	—	7	—	125

Abbreviations: D<sub>5</sub> = 5% dextrose; ORS = oral rehydration solution; ReSoMal = reduced osmolarity ORS for malnourished children.

\*Also contains Mg 6 mmol/L, Zn 300 μmol/L, Cu 45 μmol/L.

Human infection is caused by ingestion of contaminated food or drink or from poor hand hygiene in epidemic situations. Relative or absolute achlorhydria facilitates passage through the stomach. Proliferation occurs in the small intestine, where a number of toxins are released. This results in massive secretion of isotonic fluid into the gut. The fluid passes out of the anus full of vibrios to perpetuate the cycle of transmission. Killing the host does not appear to interrupt this cycle!

The cholera toxin is secreted only by the O1 and O139 serogroups. It has two subunits: A (active) and B (binding). Subunit B binds to receptors in the small intestine and subunit A activates adenylate cyclase. This causes the active secretion of a number of ions into the gut, which drags water by osmosis and also blocks the reabsorption of sodium from the gut. The net result is a massive loss of water, sodium chloride, and bicarbonate. This cannot be replaced by drinking a sodium solution because sodium reabsorption is blocked. However, the addition of glucose to a solution of sodium activates a sodium–glucose co-transporter; sodium is absorbed and water follows by osmosis. This is the basis of oral rehydration therapy for diarrhea today.

### Clinical Presentation and Diagnosis

Cholera manifests as an acute watery diarrhea without blood in the stool or (usually) abdominal cramps. The majority of cases are clinically indistinguishable from other causes of watery diarrhea. About 10%-20% will develop dehydration but most require only oral rehydration fluid as treatment. However, some will progress to classic or severe cholera.

The classic picture is of the rapid onset of profuse watery diarrhea (rice-water stool) and vomiting, which is painless and can result in circulatory collapse within hours without effective treatment. The history is usually less than 24 hours, although it may be longer if the patient is taking oral rehydration solution. Abdominal cramps can occur. Fever is absent. Patients usually remain alert, but severe electrolyte abnormalities such as hypoglycemia and hyponatremia can cause a reduced level of consciousness or convulsions, especially in children. Acidosis is often severe and results in tachypnea, which is commonly misdiagnosed as pneumonia. Patients should be reassessed for the presence or absence of pneumonia 1 to 2 hours after adequate rehydration. The diagnosis of cholera can be confirmed by the presence of rapidly motile vibrios detected by dark-field microscopy or by stool

or rectal swab culture. However, the classic history, appearance of the stool, and rapid presentation mean that the diagnosis is usually clinical.

### Treatment

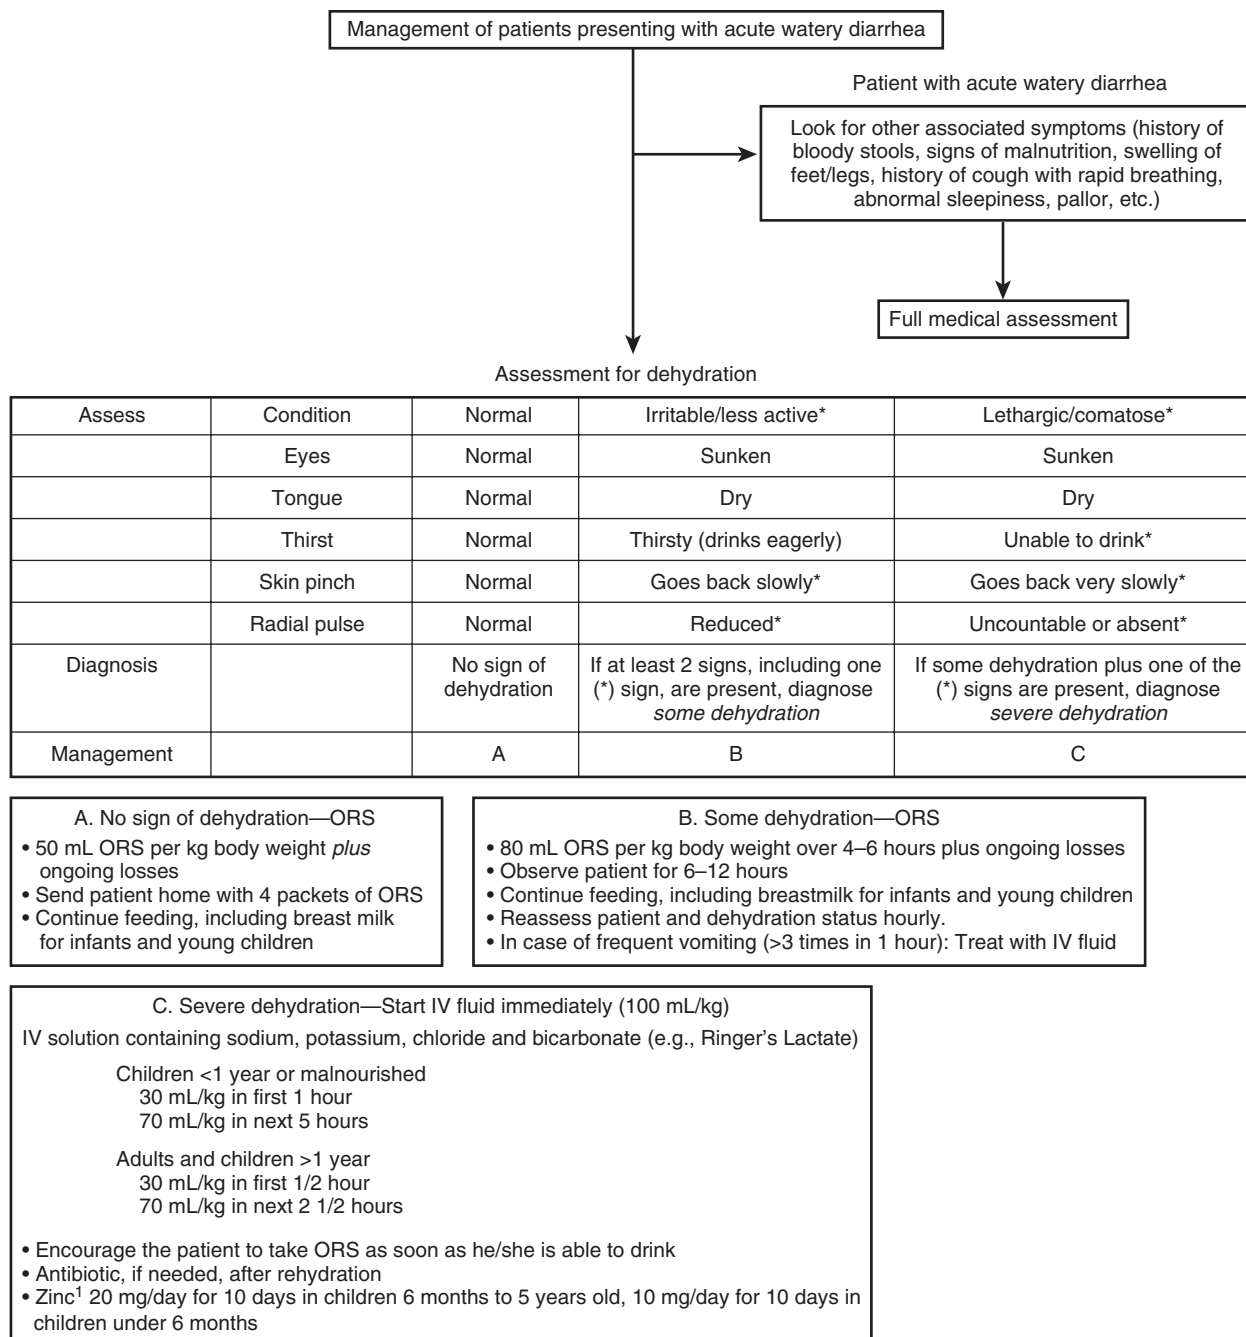

A clinical syndrome of acute watery diarrhea (three or more watery stools in the last 24 hours) of short duration (24–48 hours) with or without vomiting associated with dehydration in anyone older than 2 years in an endemic or epidemic situation should be treated as cholera. Children younger than 2 years may be managed in the same way, but other diagnoses such as rotavirus should be considered. The mainstay of management (whatever the causative organism) is appropriate early rehydration, and time should not be wasted worrying about investigations or which antibiotic to use (Figure 1).

The initial assessment should be brief but must:

- Confirm the diagnosis of acute watery diarrhea
- Assess the level of dehydration
- Assess the presence or absence of malnutrition
- Recognize any other comorbidities

Accurate assessment and rapid, appropriate treatment of dehydration is critical to the management of cholera. A simple scoring system based on five clinical signs is sufficient and can accurately predict patients with 5% to 10% (some) dehydration and greater than 10% (severe) dehydration. Common mistakes include overreliance on individual clinical signs and giving too little intravenous fluid during the initial phase and too much during the recovery phase. Patients with less than 5% (no) dehydration and 5% to 10% (some) dehydration can be managed with oral rehydration alone (Box 1) unless there is a reduced level of consciousness or inability to take fluids by mouth. Those with 5% to 10% (some) dehydration must be reassessed every 1 to 2 hours to make sure that hydration is improving.

Patients with severe dehydration require an immediate intravenous fluid bolus of 100 mL/kg given over 3 hours with one third in the first 30 minutes (double the duration in children who are younger than 1 year or have malnutrition). If possible, the intravenous fluid should contain sodium, potassium, and bicarbonate—Ringer's lactate or cholera saline—but normal saline with 5 to 10 mmol/L of potassium may also be used. Oral rehydration should start at the same time. Once the intravenous fluid bolus has finished, further intravenous fluids are usually not required.

**Figure 1** Quick identification of cholera cases can be made using a standard case definition. During an outbreak, cholera should be suspected in any patient who is older than 2 years, is attending a health facility, and has a history of acute watery diarrhea (passage of at least three stools in the last 24 hours) of a short duration (less than 24 hours), with or without vomiting, and with signs of dehydration. (Flow chart modified from International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B) internal treatment protocol.) *Abbreviation:* ORS = oral rehydration solution.

Patients are best managed using a cholera cot, especially in an epidemic situation. The cholera cot is a bed (or sometimes a chair) covered with a nonabsorbent sheet with a hole that allows the passage of stool and urine directly to a bucket under the bed (Figure 2). The sheets and bucket should be replaced three times a day and between patients. They may be washed, sterilized, and reused. Patients do not need to use a toilet (which can be several times an hour), linen is not soiled, and body fluids are prevented from running on the floor. This system enables adequate infection control to be maintained with limited resources.

After an initial assessment has been made and fluids started, a fuller clinical assessment can take place. Patients with significant comorbidities can require individually tailored treatment plans.

Antibiotics reduce the length of stay and fluid requirement in patients with severe dehydration due to cholera (Box 2). A single dose is sufficient, but this should be repeated if the dose is vomited back. The choice of antibiotic should be guided by local sensitivities where these are available. If not, a single dose of azithromycin (Zithromax)<sup>1</sup> 1 g in adults and 20 mg/day for

<sup>1</sup>Not FDA approved for this indication.

**BOX 1** Fluids for Patients without Signs of Dehydration**Acceptable**

Oral rehydration solution (optimal for both repletion and maintenance)  
 Salted drinks (salted rice water or salted yogurt drink)  
 Broth or soup (salted vegetable or meat soup)  
 Water  
 Rice water  
 Coconut water (unsweetened)  
 Weak tea (unsweetened)  
 Fresh fruit juice (unsweetened)

**Unacceptable**

Carbonated beverages  
 Sweetened juices  
 Coffee

**Medicinal teas or infusions**

Fluids containing salt should be encouraged. Unacceptable fluids include carbonated beverages and sweetened juices; the sugar in these fluids may worsen diarrhea. Coffee and medicinal teas or infusions are also unacceptable since they can have diuretic and purgative effects.

**BOX 2** Antibiotics in Cholera

Antibiotics should be given to all patients with severe dehydration. Choice of antibiotic depends on local sensitivity pattern. If ciprofloxacin is used a 3-day course is now needed due to rising MICs.

**First-Line Drug (If Susceptibility Report Is Not Available)****Adults**

Azithromycin (Zithromax)<sup>1</sup> 1 g (500 mg × 2) PO as a single dose after correcting severe dehydration

**Children**

Azithromycin<sup>1</sup> 20 mg/kg PO as a single dose after correction of dehydration and cessation of vomiting (if any)

**Second-Line Drug (Not Recommended for Children < 5 Years or Pregnant Women)****Adults**

Ciprofloxacin (Cipro)<sup>1</sup> 1 g (500 mg × 2) PO for 3 days after correction of severe dehydration

**Children**

Ciprofloxacin<sup>1</sup> 20 mg/kg PO for 3 days after correction of dehydration and cessation of vomiting (if any)

**Third-Line Drugs**

Doxycycline (Vibramycin) 300 mg as a single dose after food (not in children or pregnant women)

<sup>1</sup>Not FDA approved for this indication.

**Figure 2** Cholera cot.

10 days in children 6 months to 5 years old, 10 mg/day for 10 days in children under 6 months. All children between 6 months and 5 years of age should receive zinc<sup>1</sup> 20 mg/day for 10 days because this reduces subsequent mortality and further episodes of diarrhea.

Recovery from cholera is rapid, and mortality is extremely low if the dehydration is treated appropriately. The Cholera Hospital run by the International Centre for Diarrhoeal Disease Research, Bangladesh (ICDDR,B), in Dhaka treats around 120,000 patients a year. The average length of stay is 16 hours, and the mortality rate is zero.

**Prevention**

Because the transmission of cholera is feco-oral, cholera can be prevented by good hand hygiene and by providing safe

drinking water and appropriate sanitation. Standard food and hygiene precautions should be followed by people travelling in endemic areas (e.g., eat only boiled or fried foods; drink only boiled or bottled water). The FDA recently approved a single-dose live oral cholera vaccine, called Vaxchora in the United States. Vaxchora is indicated for adults 18–64 years old who are traveling to an area of active cholera. Two other oral inactivated cholera vaccines, Dukoral and ShanChol, are not available in the United States. These two cholera vaccines provide around 60% to 80% efficacy for 6 months. They are not recommended for the occasional traveler or tourist but may be given to people working in high-risk situations, such as aid workers in a cholera outbreak. The World Health Organization recommends the use of oral cholera vaccine in endemic areas as part of disease control programmes and maintains a global cholera vaccine stockpile for use in epidemic situations.

CURRENT DIAGNOSIS

- Coronavirus disease 2019 (COVID-19), the illness caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), presents with a broad spectrum of multisystem clinical manifestations, including fever, dry cough, dyspnea, fatigue, sore throat, gastrointestinal symptoms, headache, chills, myalgias, anosmia, and ageusia, that can lead to severe illness and death in a minority of cases.
- Transmission of SARS-CoV-2 occurs most commonly through droplet and aerosol contact and less commonly by surface contamination.
- Diagnosis is based on detection of SARS-CoV-2 by viral testing of a respiratory sample, usually a nasopharyngeal swab. Serologic tests can detect antibodies from past infection or vaccination.
- Other factors critical for diagnosis and treatment include exposure history, computed tomography (CT) findings, laboratory tests, and clinical manifestations of SARS-CoV-2 infection.
- Different variants have demonstrated different clinical presentations, severity of illness, and incubation periods.

CURRENT THERAPY

- Prevention and protection via utilization of a SARS-CoV-2 vaccine are paramount and offer the best possibility of containing COVID-19 worldwide.
- Other pragmatic recommendations focus on prevention of person-to-person transmission and infection control, which are accomplished by social distancing, hand washing, source control measures, screening, quarantine, contact tracing, and personal protective equipment (PPE) for healthcare workers.
- For nonhospitalized adults with mild to moderate COVID-19 at high risk of disease progression, several effective therapeutic options should be utilized including oral antiviral therapy, intravenous antiviral treatment, and monoclonal antibody (mAb) therapy.
- Patients with moderate or severe disease may require hospitalization, respiratory support, and intensive care. Treatment in hospitalized patients includes supportive care and directed treatment to moderate the inflammatory response.
- Older adults and individuals with underlying chronic medical conditions are at higher risk for morbidity and mortality from COVID-19.
- Efficacy of specific mAbs has been dependent on the infecting variant.

Epidemiology

A novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) was first recognized in December 2019 as the etiologic agent of a serious respiratory illness soon designated *coronavirus disease 2019* (COVID-19). This potentially fatal disease has led to enormous human casualties and a tragic worldwide economic impact. Since COVID-19 was first reported in Wuhan, the capital of Hubei, China, it has reached a pandemic level, spreading over the world and multiplying more hurriedly than any infectious disease of recent memory, with more than

610 million confirmed cases and more than 6,522,381 deaths, according to the latest figures (September 15, 2022) from the Johns Hopkins Coronavirus Resource Center. The outbreak has spread throughout the world, and in the United States there have been more than 95 million confirmed cases and over 1 million deaths as of September 2022.

This new, highly contagious coronavirus causes a respiratory illness with such symptoms as fever, cough, shortness of breath, and, in some cases, a deadly acute respiratory syndrome that can lead to pneumonia, respiratory failure, or septic shock. Infected persons have shown a range of symptoms from mild to severe illness and death. Symptoms may appear in as few as a couple of days to as long as 14 days after exposure, with variation depending upon the variant. Genetic analysis of the virus indicates that it originated in bats, although it is still unclear whether it jumped directly from bats or an intermediary host existed. It appears similar to other zoonotic coronaviruses, like SARS-CoV, which emerged in 2002. Although there is a near-consensus view that the causative agent of COVID-19 has a natural zoonotic origin, several of its characteristics are not easily explained by this hypothesis and suggest the possibility of an alternate hypothesis of a laboratory leak origin. There remains much to be learned about the possible source and evolutionary path of this emerging disease.

In many countries, healthcare facilities have been stressed by a surge in recurrent cases, especially by patients requiring ventilatory support and intensive care. To slow disease spread and allow more time for public health and hospitals to become better prepared, public health efforts initially focused on flattening the epidemic curve with recommendations for physical distancing (referred to by some as *social distancing*) to minimize person-to-person transmission. Closure of schools and workplaces occurred, especially early in the pandemic, as well as cancellation of public events and services such as public transport. Classic public health strategies, including isolation and quarantine, were also implemented as effective countermeasures. However, limited data exist on the comparative effectiveness of these varied policy interventions. The brisk emergence of this devastating pandemic caused by a previously unknown pathogen underscores the perpetual challenges facing modern public health of emerging infectious diseases and the necessity of sustained preparedness.

The availability of safe and effective SARS-CoV-2 vaccines has saved numerous lives and assisted the control of COVID-19 both in the United States and worldwide. However, the emergence of several new variants of the original virus have been recognized that appear to cause significant changes in the way the pathogen behaves, including alterations to its transmissibility. The current vaccines have a limited duration of maximal efficacy, necessitating booster doses to maintain maximal protection. The evolution of variants has rendered vaccines less effective at preventing viral replication, but the protective effects of preventing severe illness have remained robust. Infection with SARS-CoV2 yields immunity roughly on par with vaccine-induced immunity.

Risk Factors

Exposure history to individuals with COVID-19 is the essential risk factor. Individuals who have had close contact with a known positive patient or who have traveled to or live in an area with high community transmission should be screened if they are symptomatic. Individuals with known exposure should be tested for SARS-CoV2 at least 5 days from initial exposure. Employment as a healthcare worker engaged in the direct care of patients is also a risk factor. Individuals at higher risk of morbidity and mortality if infected are adults older than 65 years of age, especially those in long-term care facilities and those with chronic illnesses such as hypertension, diabetes, obesity, chronic kidney disease, chronic obstructive pulmonary disease (COPD), asthma, immunocompromised conditions, pregnancy, heart failure, and sickle cell disease. Studies have also revealed that a disproportionate percentage of COVID-19 hospitalizations and deaths occurs in minority and lower-income populations. Disease in children is

typically mild, but severe disease from COVID-19 and multisystem inflammatory syndrome in children (MIS-C) occurs, causing over 1400 deaths among children in the United States.

### Pathophysiology

Coronaviruses (CoVs) are enveloped, positive-sense single-stranded RNA viruses, which are characterized by clublike glycoprotein spikes on their surface that mediate receptor binding and cell entry during infection. These spikes on the envelope give coronaviruses a *crownlike* appearance under an electron microscope, which is the source of its name, *corona* being the Latin term for “crown.” They are the largest group of viruses belonging to the Nidovirales order, which includes Coronaviridae, Arteriviridae, Mesoniviridae, and Roniviridae families. The Coronavirinae comprise one of two subfamilies in the Coronaviridae family. Coronaviruses possess an unusually large RNA genome and cause a wide spectrum of multisystem diseases in birds and mammals ranging from upper respiratory infections in chickens to enteritis in pigs and cows to potentially fatal human respiratory disease. To date, only seven human coronaviruses have been identified. Several cause common colds and self-limiting upper respiratory infections. However, at least three have caused widespread deadly outbreaks, including the highly pathogenic severe acute respiratory syndrome coronavirus (SARS-CoV), Middle East respiratory syndrome coronavirus (MERS-CoV), and most recently SARS-CoV-2.

Genomic analyses indicate that SARS-CoV-2 probably originated and evolved from a strain found in bats. Most researchers suggest that there probably was an amplifying mammalian host, intermediate between bats and humans. However, it is not certain whether an intermediary exists, as the original strain’s mutation could have directly jumped from bats to humans. Although animal-to-human transmission was first presumed, the main exposure mechanism appears to be human-to-human transmission, with symptomatic individuals the most frequent source of spread, although presymptomatic and asymptomatic individuals also contribute to this spread. Transmission is believed to occur primarily through respiratory droplets spread by coughing, sneezing, or talking and via aerosol transmission, especially in closed spaces. Studies also reveal that SARS-CoV-2 can contaminate objects and surfaces for hours and days.

Like other coronaviruses, SARS-CoV-2 is sensitive to ultraviolet rays and heat. These viruses can be effectively inactivated by lipid solvents including ether, ethanol, chlorine-containing disinfectants, and peroxyacetic acid.

### Prevention

Vaccination is the most effective way to prevent SARS-CoV-2 infection and severe illness and is recommended for everyone 6 months of age and older. Boosters are recommended for everyone 5 years of age and older, if eligible. Although there are numerous COVID-19 vaccines in various stages of development across the world, three vaccines were authorized for emergency use by the US Food and Drug Administration (FDA) and have been used extensively in the United States: Comirnaty/Pfizer-BioNTech, Spikevax/Moderna, and Johnson & Johnson’s Janssen. For primary and booster vaccination for all populations, the mRNA vaccines (Pfizer-BioNTech and Moderna) are preferred over the Janssen vaccine. Novavax, a two-dose vaccine series utilizing SARS-CoV-2 spike protein with an adjuvant, is available under EUA for patients 12 years of age and older, but only as a primary series.

The Pfizer-BioNTech COVID-19 vaccine, which is marketed as Comirnaty, was the first FDA-approved vaccine for the prevention of COVID-19 disease. This vaccine has full FDA approval for patients 12 years of age and older. The FDA has provided an EUA for a three-dose series in children 6 months through 4 years and a two-dose series for children 5 to 11 years old. Individuals 5 years and older with certain forms of immunosuppression should receive three doses to complete the primary series. Prior to September 2022, booster doses were recommended to supplement immunity. As of September 2022, a new formulation of a bivalent

Pfizer booster dose is authorized for patients 12 years and older 2 months after any primary series or previous booster dose.

The Moderna COVID-19 vaccine, which is marketed as Spikevax, is also an mRNA vaccine and is FDA approved for use in individuals 18 years of age and older. It is authorized under EUA for children 6 months to 17 years old. The vaccine consists of two shots given 4 weeks (28 days) apart, with full effect achieved 2 weeks after the second shot. (As with the Pfizer vaccine, the second shot may be given up to 6 weeks or beyond after the first dose, if necessary.) For patients with underlying immunodeficiency, the initial series consists of three doses. Prior to September 2022, booster doses were recommended to supplement immunity derived from this vaccine. As of September 2022, a new formulation of a bivalent Moderna booster dose was authorized for patients 18 years of age and older 2 months after any primary series or previous booster dose.

Recommended COVID-19 vaccines and schedules are constantly evolving. For the latest updates, please visit the CDC and FDA websites.

Heterologous dosing, or using different mRNA vaccines for booster dosing, is an approved strategy. For example, a patient receiving a primary series with Pfizer may receive booster doses with Moderna and vice versa. Evidence demonstrates more broad-based immune responses when the heterologous approach is used.

With the mRNA COVID-19 vaccinations, mild side effects are common within 7 days of being vaccinated, and there has been a rare association recognized with myocarditis, especially in young adult and adolescent males, for whom the illness is typically mild and self-limiting. Extensive studies, including among pregnant women, have demonstrated a strong safety profile with nonadverse consequences for pregnant women or their babies. In contrast, COVID-19 has demonstrated major health hazards for pregnant women including an increased risk of miscarriage, adverse infant outcomes, and maternal hospitalization and death.

The third authorized vaccine, Johnson & Johnson’s Janssen (J&J/Janssen) COVID-19 vaccine, is an adenoviral vector vaccine that is allowed for use through EUA in individuals 18 years of age and older. This vaccine consists of one shot, with full vaccination occurring 2 weeks after the shot. Mild side effects were common within 7 days of being vaccinated, and a plausible causal association emerged between the vaccine and thrombosis with thrombocytopenia syndrome (TTS). Because of this rare but serious adverse event, and lesser efficacy, the mRNA vaccines are recommended over the Janssen vaccine. However, offering the Janssen vaccine is preferable to not providing any vaccine, and it may be considered in individuals who have experienced an anaphylactic reaction after receiving an mRNA vaccine. A booster dose with an mRNA vaccine is recommended 2 months after receiving a Janssen vaccine. A second booster is recommended 4 months later for certain groups as outlined earlier.

These three vaccines provided strong protection against early COVID-19 variants, with less protection against milder illness and viral shedding for those infected with the Omicron variant. Booster doses, given 5 months or more after the initial series, have proven to be over 90% effective at preventing severe illness or death. The duration of maximal protection is variable and begins to wane after 3 to 4 months.

Evusheld (tixagevimab/cilgavimab), an mAb product against COVID-19, is approved for use through EUA as a preventive treatment for those unlikely to respond to COVID-19 vaccination because of severe underlying immunity such as prior organ transplantation or active chemotherapy treatment. This intramuscular injection provides strong protection for 3 months but declines over time. Evusheld can also be given as a preventive treatment for those unable to take the COVID-19 vaccine because of allergic reactions,<sup>1</sup> but it should not be used as an alternative to immunization.

High-risk patients exposed to COVID-19 may receive prophylactic administration of mAbs. The efficacy of mAb treatments for this purpose invariably depends on the predominant circulating

<sup>1</sup>Not FDA approved for this indication.

variant. Omicron variants are resistant to all existing mAb treatments except bebtelovimab, which is not currently approved for postexposure prophylaxis.

Infection with COVID-19 generates strong but temporary protection from reinfection, but this is relatively strain-specific. Reinfection tends to be milder than initial infection. Immunization subsequent to infection, even with a single dose, generates an especially strong immune response.

### Other Mitigation Measures

Other preventive strategies should focus on isolation of patients and rigid infection control, which includes appropriate measures to provide clinical care for infected patients. Transmission of SARS-CoV-2 is believed to occur usually through respiratory droplets spread from an infectious person to others within 6 feet and through airborne transmission of small droplets over larger distances. In rare instances, an individual just passing through a room that was previously occupied by an infected individual may become infected. For the general public, the primary preventive action is physical distancing (maintaining 6 feet between people) and isolation when ill in order to minimize transmission. Other general recommendations include avoiding close contact with individuals suffering from acute respiratory infections and washing hands frequently, especially after contact with infected individuals and their environment; individuals with acute airway infections or symptoms should keep their distance from others and follow cough and hand hygiene. Avoiding indoor public gatherings is important during periods of increased transmission, especially for high-risk or immunocompromised individuals.

Studies indicate that the combination of isolation and contact tracing with physical distancing can effectively reduce disease transmission in communities. A variety of public health interventions have been implemented worldwide during the pandemic to reduce transmission. Among the more effective associated with reduced rates of transmission are the use of home isolation after infection, the restriction of mass gatherings, travel restrictions, and social distancing. Studies assert that risk of resurgence follows when these interventions are lifted. A key priority is identifying optimal protective measures that result in the least economic and societal disruption while adequately controlling transmission and infection.

Source control is an important prevention strategy and refers to use of cloth face coverings or face masks to shield an individual's mouth and nose to prevent spread of respiratory secretions when talking, sneezing, or coughing. Because of the potential for asymptomatic and presymptomatic spread, source control measures appear to be an effective prevention tool. The regular use of masks can help protect individuals from contracting COVID-19, with N-95 masks more effective than surgical masks, which in turn are more effective than cloth masks. This measure is important to consider during periods of increased transmission, especially for those at greater risk for adverse clinical outcomes.

### Patient Isolation and Quarantine

Patients diagnosed with COVID-19 should maintain strict home isolation for at least 5 days from symptom onset or positive test if asymptomatic. If symptoms are absent or improved after 5 days, increased activity with universal mask use may occur through day 10, at which time all restrictions can be lifted. No travel through a public conveyance should occur within 10 days. Patients with more severe illness or immune compromise should home-isolate for at least 10 days.

*Quarantine* is a term used for persons who are at risk of developing a contagious illness but are not yet ill, for the purpose of preventing future transmission. Close contacts to a case of COVID-19, defined as  $\geq 15$  minutes of exposure to an infectious case within 6 feet in a 24-hour period, should quarantine themselves based on vaccination status or history of recent infection.

### Infection Control in Healthcare Settings

Infection control measures are critically important in inpatient and outpatient settings to minimize transmission to patients and staff. These recommended measures currently include source control (i.e., use of masks); screening of patients for COVID-19 infection or risk; environmental control; and isolation, quarantine, and testing of healthcare staff as indicated.

Before engaging the healthcare system, patients should be pre-screened for known COVID-19 illness, symptoms of COVID-19, or recent exposure. Patients with potential COVID-19 should be quickly isolated in an area that minimizes the risk of transmission. Healthcare workers should use medically appropriate masks (i.e., N-95) and eye protection when caring for potential COVID-19 patients. The Centers for Disease Control and Prevention (CDC) continues to recommend universal mask use in healthcare settings. This is especially important for patients with possible COVID-19 infection.

Environmental cleaning and proper air filtration are important measures to mitigate transmission. Thorough cleaning of the environment and equipment should be performed between patient encounters with an appropriate disinfectant. In the inpatient setting, dedicated equipment should be used when practicable. Proper air filtration is important and should be reviewed with physical maintenance staff. Detailed guidance is available through the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) resources for healthcare facilities.

Isolation and quarantine of healthcare personnel is a critical measure to limit transmission and protect the workforce. Healthcare workers diagnosed with COVID-19 may return to work in 10 days or as early as 7 days if symptoms have improved or are absent, the patient has a negative COVID-19 test within the previous 48 hours (antigen test or nucleic acid amplification test [NAAT]), and the patient is at least 24 hours free from fever. Employees with more severe illness or immune compromise should remain isolated for at least 10 days. Employees who are contacts to a case (without appropriate PPE) and have an up-to-date vaccination status do not have to discontinue working, but they should test on day 5 to 7. Employees who are not up-to-date on vaccination should home-quarantine for 10 days (or 7 days with a negative test on day 5 to 7). The CDC has alternative recommendations for shortened durations of quarantine for circumstances when healthcare systems are operating in contingency or crisis modes.

### Clinical Manifestations

COVID-19 patients can manifest a wide variety of symptoms, with pulmonary inflammation its main pathologic manifestation. The estimated incubation period for COVID-19 is up to 14 days from exposure, with a median incubation time of 4 to 5 days. This varies depending on the infecting variant. The spectrum of illness can range from asymptomatic infection to severe pneumonia with acute respiratory distress syndrome (ARDS) and death. Patients usually report fever; dry cough; shortness of breath; gastrointestinal symptoms such as abdominal pain, diarrhea, anorexia, and vomiting; myalgias; headaches; dizziness; anosmia; dysgeusia; sore throat; fatigue; and chills. Mild pneumonia can occur, but in more severe cases tachypnea, dyspnea, and significant pneumonia can be seen, which can develop into a critical stage with respiratory failure, septic shock, and multiorgan failure. Older adult patients occasionally present with delirium or altered mental status. Adults with severe disease usually present during the second week of illness, a period that coincides with decreasing viral loads but increasing markers of inflammation, which suggests that host tissue damage is mediated by hyperinflammatory and maladaptive immune responses.

As found in many other viral infections, there appears to be a two-phase immune response in COVID-19. The first is the body's response directly to the viral infection. This is followed by a second reactive-stage infection that precipitates a cytokine release syndrome, a consequence of the host's reaction to the infection

and the resulting cytokine activation cascade, which causes autoimmune-induced damage to the lungs, vascular endothelium, gastric mucosa, and other structures. This is mediated by non-T leukocytes and is found to be associated with lymphocytopenia, increased ferritin levels, decreased platelet count, and elevated erythrocyte sedimentation rate. This cytokine storm and its extensive tissue damage and dysfunctional coagulation are thought to result from an overactive immune response mediated in part by IL-6 and other cytokine pathways.

Thrombotic aberration in COVID-19 patients is common and appears to contribute to organ failure and death. Platelet hyperactivity, which is recognized in COVID-19, also contributes to morbidity through increased platelet-platelet and platelet-leukocyte interactions. Hemostatic alterations that mimic disseminated intravascular coagulopathy associated with sepsis often present with severe COVID-19 illness, with elevated risk of thrombosis rather than bleeding.

Most children with COVID-19 present either without symptoms or with milder symptoms than in adults. Symptoms resemble routine acute chest infections, with pyrexia, dry cough, sore throat, sneezing, myalgia, and lethargy. Less commonly, wheezing, diarrhea, and vomiting have also been noted. An uncommon disorder, MIS-C has also been associated with SARS-CoV-2. MIS-C can result in severe illness in previously healthy children and adolescents. Although it is less common in children, death can result from either complications from infection or MIS-C. A similar syndrome to MIS-C can also occur in adults.

### Long COVID or Post-COVID Conditions

A substantial proportion of COVID-19 patients develop a prolonged syndrome of various symptoms that is commonly referred to as *long COVID*. This likely represents a constellation of different pathologic processes, and there is no consensus terminology currently in place. Common symptoms include fatigue, malaise, fever, cough, difficulty concentrating, muscle pain, rash, intestinal disorders, and others. Loss or change of taste and/or smell are common after infection with SARS-CoV-2 but usually resolves over several weeks, though persistent aberrations may occur. Long COVID is more common in those with more severe illness, prolonged hospitalization, need for ICU care, and unvaccinated status before COVID-19 infection. More than 1 in 10 COVID-19 patients have symptoms 1 month or more after infection. The pathophysiology for these symptoms is not defined, and there is no effective treatment identified. Precluding COVID-19 infection via vaccination and preventive safety measures is the best way to avoid long COVID. Prior vaccination is associated with a substantially lower risk of developing long COVID symptoms. Numerous medical centers are operating specialized clinics that focus on patients with this ill-defined syndrome.

### Diagnosis

The diagnosis of COVID-19 is established by a suggestive clinical history including exposure history and clinical manifestations of SARS-CoV-2 infection, confirmed by detection of SARS-CoV-2 nucleic acid (via NAAT) or antigen from an upper respiratory sample (i.e., a nasopharyngeal, nasal, or oropharyngeal specimen). Numerous platforms are currently available for both diagnostic approaches. NAAT has superior sensitivity when compared with antigen testing, which is typically faster and more convenient. Home antigen tests are widely available for use, presenting the possibility of patients self-diagnosing before presentation. Lower respiratory tract specimens have a higher viral load and are recommended for intubated or mechanically ventilated patients with clinical signs and symptoms of COVID-19. If the initial viral test results are positive for SARS-CoV-2, the patient should be considered to have COVID-19 and additional testing pursued (i.e., NAAT confirmation), regardless of whether other findings are also present. Because of false-negative test result rates of SARS-CoV-2 viral testing, other data such as imaging and laboratory tests are often helpful in making a presumptive diagnosis. Many cases of COVID-19 are asymptomatic or minimally

symptomatic and will test positive by antigen or NAAT. Serologic testing is not recommended for the diagnosis of acute COVID-19. Repeat NAAT for SARS-CoV-2 is not recommended as results may remain positive in the absence of active infection.

Because pulmonary inflammation is the major pathologic manifestation of COVID-19, chest radiography should be the initial imaging study. A plain chest radiograph in COVID-19 may reveal peribronchial thickening (which is typical in viral infections), pneumonia, nonspecific findings, or even negative findings. A chest computed tomography (CT) scan is usually more helpful in providing a definitive diagnosis. Multiple studies reveal that COVID-19 pneumonia is more likely to have a peripheral distribution, ground-glass opacity (GGO), fine reticular opacity, bilateral consolidations, and vascular thickening. These studies also reveal that COVID-19 is less likely to have a central plus peripheral distribution, pleural effusion, and lymphadenopathy. However, differentiating radiographic findings of COVID-19 pneumonia, influenza virus pneumonia, and other viral pneumonias in clinical practice remains difficult.

Despite its diagnostic benefits, a chest CT is not recommended as a first-line screening test for those with suspected COVID-19 infection. As well, a chest CT should be used sparingly and reserved for hospitalized patients with clinical indications for CT. If a patient medically declines, a chest CT may be indicated to better assess pulmonary status and disease progression. In the first 2 weeks after symptom onset, there can be a rapid evolution of CT abnormalities, after which these findings recede gradually.

Laboratory testing also plays a role in the initial evaluation and diagnosis of COVID-19, especially in the workup of hospitalized patients. Multiple laboratory abnormalities are often seen in positive patients and can assist in assessing whether a patient is improving or declining. Among typical abnormal results are elevations in serum C-reactive protein, lactate dehydrogenase, ferritin, procalcitonin, creatine kinase, alanine aminotransferase, and aspartate aminotransferase. Many patients also present with a low albumin. Lymphocytopenia, which is associated with an increased risk of ICU care and acute kidney injury, is the most common hematologic abnormality seen, although leukopenia and leukocytosis are also common. A modest prolongation of prothrombin times, mild thrombocytopenia, and elevated D-dimer values often are seen and have also been associated with higher rates of ARDS and mortality. However, some of these laboratory findings are nonspecific, being common in pneumonia in general, and their clinical utility remains uncertain.

### Differential Diagnosis

In its initial stages, COVID-19 appears clinically like many other viral and bacterial respiratory illnesses, presenting with a broad range of nonspecific and varied signs and symptoms. These other illnesses not only must be considered in the differential diagnosis but also may occur simultaneously with COVID-19 infection.

Viral infections in the differential diagnosis include influenza, parainfluenza, coronavirus, adenovirus, respiratory syncytial virus, infectious mononucleosis, acute human immunodeficiency virus (HIV), human rhinovirus/enterovirus, and human metapneumovirus. Bacterial pneumonias that should be considered in the differential diagnosis include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Chlamydia pneumoniae*, and *Moraxella catarrhalis*. Atypical pneumonias in the differential include *Legionella pneumophila* and *Mycoplasma pneumoniae*. In immunocompromised hosts, *Pneumocystis jirovecii* should be considered. If patients have returned from international travel, such illnesses as dengue and malaria should be considered.

In addition to these infectious illnesses, the differential diagnosis may include noninfectious disorders such as pulmonary embolism, COPD exacerbation, asthma, pulmonary edema, vasculitis, cor pulmonale, pneumonitis, ARDS, acute coronary syndrome, congestive heart failure, valvular disease, cancer, or acute chest syndrome in sickle cell disease.

## Treatment

### Outpatient Management

The majority of COVID-19 patients have a relatively mild illness and can be managed on an outpatient basis. It is essential to identify patients at highest risk of poor outcomes and evaluate them for treatment with mAbs or oral SARS-CoV-2 antivirals. Those at highest risk include individuals with underlying immune suppression (regardless of vaccination status) and those 65 years of age and older. Numerous underlying medical conditions increase the risk of adverse outcomes. A summary of high-risk clinical conditions provided by the CDC is listed in [Table 1](#). Clinically stable patients who are at increased risk for adverse outcomes and do not require supplemental oxygen or increased oxygen should be evaluated for outpatient treatment. Current preferred therapies are oral nirmatrelvir/ritonavir (Paxlovid)<sup>1</sup> or intravenous remdesivir (Veklury). When these preferred treatments are not available, oral molnupiravir (Lagevrio)<sup>1</sup> or intravenous bebtelovimab<sup>1</sup> are recommended treatment options. Early diagnosis is key as most treatments must be provided early in the illness to be effective.

Nirmatrelvir/ritonavir (Paxlovid) is a viral protease inhibitor that has demonstrated activity against all known human coronaviruses. When used early in COVID-19 illness, this agent demonstrated an 88% decrease in death or hospitalization in the Evaluation of Protease Inhibition for COVID-19 in High Risk Patients (EPIC-HR) trial. Paxlovid is available through EUA for the treatment of COVID-19. This treatment consists of nirmatrelvir 300 mg and ritonavir 100 mg twice daily for 5 days ( $\geq 12$  years and  $\geq 40$  kg) and must be started within 5 days of symptom onset. Doses must be adjusted for renal impairment, and this drug is not recommended for those with a creatinine clearance of  $< 30$  mL/min or those with advanced liver disease. Numerous potential drug-drug interactions with this treatment necessitate a thorough review of potential interactions with current medications. There also have been some case reports of a phenomenon called *COVID-19 rebound* in which patients who completed a full course of paxlovid and recovered with subsequent negative viral testing experienced a recurrent illness 2 to 8 days later with positive test results. This rebound usually resolved without additional COVID-19 treatment over 3 days.

Remdesivir (Veklury) is a nucleotide analogue that inhibits RNA-dependent RNA polymerase. This treatment is recommended for nonhospitalized patients with mild to moderate illness from COVID-19 at increased risk for adverse outcomes. This 3-day intravenous outpatient treatment is administered as a 200 mg dose on day one followed by 100 mg on days 2 and 3. Treatment with remdesivir has demonstrated similar efficacy to nirmatrelvir/ritonavir with an 87% reduction in hospitalization or deaths. Treatment must be provided within 7 days of onset of illness and is used for individuals who are 12 years of age and older and weigh at least 40 kg. This treatment is not approved in the setting of advanced renal insufficiency (creatinine clearance  $< 30$  mL/min).

Bebtelovimab<sup>1</sup> and molnupiravir (Lagevrio)<sup>1</sup> are recommended as second-line outpatient treatment options for those unable to receive nirmatrelvir/ritonavir or remdesivir. Bebtelovimab is a recombinant human mAb with activity against SARS-CoV-2, including all currently identified Omicron variants. Molnupiravir is a ribonucleoside that produces unstable mutagenesis in the replicating SARS-CoV-2 virus. It has demonstrated lesser efficacy than first-line recommended treatments, and it should not be used in pregnancy. Conception and pregnancy should be avoided for males and females during and immediately following treatment.

Corticosteroid treatment is not generally recommended for use in the outpatient setting, but it could be considered in circumstances when hospitalization is not available for patients with

**TABLE 1** High-Risk Clinical Conditions

- Asthma
- Cancer
- Cerebrovascular disease
- Chronic kidney disease
- Chronic lung diseases limited to:
  - Interstitial lung disease
  - Pulmonary embolism
  - Pulmonary hypertension
  - Bronchiectasis
  - Chronic obstructive pulmonary disease (COPD)
- Chronic liver diseases limited to:
  - Cirrhosis
  - Non-alcoholic fatty liver disease
  - Alcoholic liver disease
  - Autoimmune hepatitis
- Cystic fibrosis
- Diabetes mellitus, type 1 and type 2
- Disabilities
  - Attention-deficit/hyperactivity disorder (ADHD)
  - Cerebral palsy
  - Congenital malformations (birth defects)
  - Limitations with self-care or activities of daily living
  - Intellectual and developmental disabilities
  - Learning disabilities
  - Spinal cord injuries
- Heart conditions (such as heart failure, coronary artery disease, or cardiomyopathies)
- Human immunodeficiency virus (HIV)
- Mental health disorders limited to:
  - Mood disorders, including depression
  - Schizophrenia spectrum disorders
- Neurologic conditions limited to dementia
- Obesity (BMI  $\geq 30$  kg/m<sup>2</sup>)
- Primary immunodeficiencies
- Pregnancy and recent pregnancy
- Physical inactivity
- Smoking, current and former
- Solid organ or hematopoietic cell transplantation
- Tuberculosis
- Use of corticosteroids or other immunosuppressive medications

Modified from Centers for Disease Control and Prevention. Underlying Medical Conditions Associated with Higher Risk for Severe COVID-19: Information for Healthcare Professionals. Updated June 15, 2022. Available at: <https://www.cdc.gov/coronavirus/2019-ncov/hcp/clinical-care/underlyingconditions.html#:~:text=Certain%20underlying%20medical%20conditions%20increased,a%20condition%20increased%20with%20age>

new oxygen requirements (i.e., overwhelmed hospital system capacity). Recommended treatment in this setting would be oral dexamethasone<sup>1</sup> 6 mg daily for the duration of oxygen requirement not to exceed 10 days.

Fluvoxamine (Luvox),<sup>1</sup> a selective serotonin reuptake inhibitor (SSRI), has demonstrated potential utility for treating COVID-19 but is currently only recommended for use in the context of clinical trials. Other treatment options, including hydroxychloroquine,<sup>1</sup> azithromycin (Zithromax),<sup>1</sup> and ivermectin (Stromectol)<sup>1</sup> have been shown not to offer benefit for the treatment of COVID-19 in randomized-controlled trials and are not recommended.

### Inpatient Management

In addition to general supportive measures, specific therapeutic strategies are recommended to treat COVID-19 patients in the inpatient setting. For hospitalized patients not requiring supplemental oxygen, intravenous remdesivir for 5 days (200 mg on day one followed by 100 mg daily) is a recommended option and may be extended based on clinical circumstances. This treatment can be effective if started less than 10 days from symptom onset.

<sup>1</sup>Not FDA approved for this indication.

For patients with increasing oxygen requirements, the addition of oral dexamethasone,<sup>1</sup> 6 mg daily until hospital discharge or up to a maximum of 10 days, is recommended and may be used in combination with remdesivir. For those with rapidly deteriorating hypoxemia or markedly elevated inflammatory markers, the addition of immune modulators (IL-6 inhibitors tocilizumab [Actemra]<sup>1</sup> or sarilumab [Kevzara],<sup>1</sup> or Janus kinase inhibitors baricitinib [Olumiant] or tofacitinib [Xeljanz]<sup>1</sup>) should be considered as an intervention to modulate the inflammatory cascade.

In general, prophylactic doses of heparin for the prevention of venous thromboembolism should be initiated unless contraindicated. Therapeutic doses may be considered for those with elevated D-dimer levels and supplemental oxygen requirement if there is no elevated risk of bleeding.

### Critical Illness

In general, the care of patients with critical illness from COVID-19 mirrors best practices of the management of critically ill patients with other inflammatory illness with additional approaches directed at treatment SAR-CoV-2 and the subsequent inflammatory response. High-flow nasal cannula oxygen is recommended over noninvasive ventilation for those with advanced oxygen requirements not requiring mechanical ventilation. Dexamethasone<sup>1</sup> should be administered to all patients requiring mechanical ventilation or extracorporeal membrane oxygenation. If within 24 hours of ICU admission, the addition of tocilizumab<sup>1</sup> is also recommended. Prophylactic doses of heparin for the prevention of venous thromboembolism should be initiated unless contraindicated.

### Multisystem Inflammatory Syndrome in Children

MIS-C is defined as an inflammatory condition in individuals younger than 21 years of age with fever, laboratory evidence of inflammation, and clinically severe illness requiring hospitalization, with multisystem organ involvement within 4 weeks of COVID-19 infection. This is a severe illness that requires urgent intervention with management, preferably in a tertiary referral center. Treatment generally consists of IV immunoglobulin<sup>1</sup> and methylprednisolone.<sup>1</sup> Refractory cases may require additional immunomodulatory therapy. A similar syndrome in adults (MIS-A) also occurs, but treatment recommendations are less well standardized.

### Conclusions

Much remains unknown in our understanding of the transmission, infection, and management of this novel coronavirus (SARS-CoV-2). Several medical organizations, including the Infectious Diseases Society of America, the World Health Organization, and the National Institutes of Health, have developed interim guidelines that are modified as more information becomes available during this rapidly evolving pandemic. Most of these guidelines emphasize that there are few proven treatments for COVID-19, that few randomized clinical trials have been published to guide effective management, and that further randomized trials are needed. The foundation of prevention of COVID-19 is vaccination, and the most effective current therapy centers on antiviral therapy and the early use of neutralizing mAbs. Because of the broad presence of some degree of immunity in the population and possibly less pathogenic COVID-19 variants, new cases have resulted in a lower proportion of deaths and hospitalizations. It remains to be seen how SARS-CoV-2 will settle into the landscape of other respiratory viruses and whether it will develop a clear seasonality as the pandemic shifts to more of an endemic phase. This unprecedented pandemic requires therapeutic flexibility and a continuous reshaping of treatment protocols and vaccine

recommendations based on available scientific evidence for the most favorable patient outcomes.

## EBOLA VIRUS DISEASE

Method of

Uma Malhotra, MD

### CURRENT DIAGNOSIS

- Detection of viral RNA in the blood by reverse transcriptase-polymerase chain reaction (RT-PCR) beginning 3 days after the onset of symptoms.
- Repeat testing may be necessary for patients with illness duration shorter than 3 days.
- Details on specimen collection and handling can be found on the Centers for Disease Control and Prevention (CDC), and World Health Organization (WHO) websites.

<sup>1</sup>Not FDA approved for this indication.

## CURRENT THERAPY

- Intensive fluid management to correct volume losses and electrolyte abnormalities.
- Aggressive use of antiemetics, antidiarrheals, and rehydration solutions.
- Respiratory and hemodynamic support.
- Blood products for management of coagulopathy.
- Evaluate and treat any concomitant infections.
- Two monoclonal antibody therapies, REGN-EB3 (Inmazeb) and mAb114 (Ebanga), have been approved by the US Food and Drug Administration (FDA) for the treatment of adults and children with disease due to the *Zaire ebolavirus*.
- Strict infection control measures, with contact and droplet precautions, must be used.
- Personnel trained in the correct use of personal protective equipment (PPE) should care for the patients.
- The rVSV-ZEBOV Ebola vaccine (Ervebo), a replication-competent, live attenuated vaccine is now approved by the FDA for the prevention of disease caused by *Zaire ebolavirus* in adults aged  $\geq 18$  years at high risk for occupation exposure. A second two-component vaccine, Ad26.ZEBOV/MVA-BN-Filo (Zabdeno and Mvabea),<sup>5</sup> given in two doses 8 weeks apart, has been found to be safe and immunogenic when given to at-risk populations in regions where there is no active disease transmission and is expected to provide longer protection.

<sup>5</sup>Investigational drug in the United States.

*Filoviridae*, derived from the Latin word “filum,” meaning thread-like, is a family of viruses with a filamentous structure that can cause severe hemorrhagic fever and fulminant septic shock. Filoviruses have been divided into three genera: Ebola-like viruses with six species—*Zaire*, *Sudan*, *Tai Forest*, *Bundibugyo*, *Reston*, and *Bombali*; Marburg-like viruses with a single species—*Marburg*, which has caused outbreaks in Central Africa; and Cuevavirus, detected only as viral RNA in bats in Spain. Using paleoviruses (genomic fossils) found in mammals, we can extrapolate that the viruses probably diverged several thousand years ago, and that the family itself is at least tens of millions of years old.

## Epidemiology

Of the six Ebola virus species only four—*Zaire*, *Sudan*, *Tai Forest*, and *Bundibugyo*—cause disease in humans. Since its first recognition in 1976, *Zaire ebolavirus* has caused multiple outbreaks in Central Africa. It is the causative agent of the 2014 West African epidemic, with an initial estimated case fatality rate as high as 70%, although as the epidemic evolved, lower fatality rates in the range of 30% to 40% were observed. The 2014 epidemic began in Guinea, when a 2-year-old child became infected in late 2013, and *Zaire ebolavirus* subsequently spread to Liberia, Sierra Leone, Nigeria, Senegal, and Mali. The epidemic resulted in over 28,000 cases and 11,000 deaths, with more than 800 infections occurring in health care workers. Outbreaks due to the *Zaire* species continue to occur in the Democratic Republic of the Congo (DRC). *Sudan* virus has been associated with a case-fatality rate of approximately 50% in four epidemics, which occurred in Sudan and Uganda between 1970 and 2004. *Tai Forest* virus has been identified as the cause of illness in one person following exposure during a necropsy on a chimpanzee found dead in the Tai Forest. *Bundibugyo* virus, most closely related to the Ivory Coast species, emerged in Uganda in 2007, causing an outbreak with a case fatality rate of approximately 30%. *Reston* virus, discovered after an outbreak of lethal infection in macaques imported into the United States in 1989, is maintained in animal reservoirs in the Philippines. *Bombali* virus RNA has been found in African

bats. Ebola virus outbreak updates can be found on the WHO website.

## Risk Factors/Transmission

Outbreaks generally begin when an individual becomes infected through contact with the tissue or body fluids of an infected animal. The virus then spreads to others who come into contact with the infected individual's blood, skin, or other body fluids. Prior to the 2014 epidemic in West Africa, outbreaks occurred in remote regions with low population density and were controlled within short periods. However, this epidemic showed that movement of infected individuals facilitates the extensive and rapid spread of the virus.

Transmission occurs most commonly through direct contact of broken skin or mucous membranes with virus-containing body fluids from an infected person, the most infectious being blood, feces, and vomit. During the early phase of illness, the level of virus in the blood is typically quite low, but then increases rapidly to very high levels in advanced stages of the illness, when patients become highly infectious. In fact, corpses of persons who die from Ebola are highly infectious, and ritual washing of bodies at funerals has played a significant role in the spread of infection. The virus has also been detected in urine, semen, saliva, breast milk, tears, and sweat, and can persist in some of these fluids much longer than in blood. Ebola virus may also be transmitted through contact with contaminated surfaces where the virus can remain infectious from hours to days.

Transmission to health care workers may occur when appropriate PPE is not used, especially when caring for severely ill patients in advanced stages of illness. During the 2014 outbreak in West Africa, a large number of health care workers became infected. In Sierra Leone, the incidence of confirmed cases at the peak of the epidemic was about 100-fold higher in health care workers than in the general population. Several factors have contributed to the high rates of infections among health providers, including failure to recognize infection among patients and corpses, limited availability and training in the use of appropriate PPE, and inadequate management of contaminated waste and burial of corpses. Although there is no evidence of respiratory transmission, the virus is highly infectious when released in laboratory experiments as a small-particle aerosol, and therefore health care workers may be at risk if exposed to aerosols generated during procedures.

Human infection can occur through contact with infected wild animals during hunting, butchering, and preparing meat, with several episodes having occurred following contact with infected gorillas or chimpanzees. To prevent infection, food products should be properly cooked to inactivate the virus, and basic hygiene measures should be followed. Direct transmission of virus infection from bats to wild primates or humans has not been proven, although Ebola RNA sequences and antibodies have been detected in bats in Central Africa. Bats likely form a major reservoir.

## Pathophysiology

*Ebolavirus* is a negative-sense, single-stranded RNA virus resembling rhabdoviruses and paramyxoviruses in its genome organization and replication mechanisms. The tubular virions contain the nucleocapsid surrounded by an outer envelope, which is derived from the host cell membrane and studded with viral glycoprotein spikes. The virions attach to host cell receptors through the spikes and are then endocytosed into vesicles. Initially, productive infection occurs primarily in dendritic cells, monocytes, and macrophages, resulting in impaired interferon production and release of proinflammatory cytokines, which have secondary effects on innate and adaptive immune responses, inflammation, and vascular integrity. Neutrophils are activated, with resultant degranulation, and lymphocytes undergo apoptosis. The virus then spreads to regional lymph nodes, resulting in further rounds of replication, followed by dissemination to the liver, spleen, thymus, and other lymphoid tissues.

When the virus infects cells, it hijacks the cell and forces it to become a virus-producing factory, churning out new copies of the virus, which results in a loss of cellular function and eventual cell death by apoptosis. As the disease progresses, there is extensive tissue necrosis accompanied by a systemic inflammatory response induced by the release of various cytokines, chemokines, and proinflammatory mediators, as well as a severe coagulopathy triggered by the release of tissue factors. This systemic inflammatory response may contribute to gastrointestinal dysfunction, and ultimately there is a multisystem failure caused by the damage to vascular and coagulation systems.

### Clinical Manifestations and Laboratory Findings

Patients with Ebola virus disease (EVD) typically have an abrupt onset of symptoms at an average of 8 to 10 days after exposure, with a range of 2 to 21 days. The first phase of the illness is characterized by high fever, chills, headaches, myalgia, and malaise. The second phase is marked by gastrointestinal symptoms, which develop by day 3 to 5, and includes watery diarrhea, nausea, vomiting, and abdominal pain. Patients may also develop chest pain, hiccups, shortness of breath, conjunctival injection, and rash. The rash is usually diffuse erythematous, maculopapular, involving the face, neck, trunk, and arms. Respiratory symptoms such as cough are rare. Common neurologic symptoms include delirium, manifested by confusion, slowed cognition, or agitation, and less frequently, seizures.

The final phase, beginning in the second week, is marked by either progression to shock and death or gradual recovery. Fatal disease is characterized by development of multisystem failure usually as a consequence of massive fluid losses that lead to shock, loss of consciousness, and renal failure. Major bleeding, typically hemorrhage from the gastrointestinal tract, is infrequent and seen in less than 5% during the terminal phase of illness. Patients who survive begin to improve during the second week of illness, with a prolonged convalescence marked by weakness, fatigue, myalgias, headache, and memory loss. About half of the survivors are plagued by chronic debilitating joint pain and a quarter experience eye problems. Other manifestations have included hearing loss, sloughing of skin, and hair loss, which may result from necrosis of dermal structures. The virus can persist in the eye for months, leading to uveitis, cataracts, and sometimes blindness. The prevalence of uveitis, unlike other causes, continues to increase until at least two years after symptom onset, with about 33% of the patients affected by that point.

During acute illness patients typically develop leukopenia, lymphopenia, thrombocytopenia, serum transaminase elevations, and proteinuria. They may develop renal insufficiency and electrolyte disturbances as a result of the gastrointestinal losses. Severe cases develop coagulation abnormalities with prolonged prothrombin and partial thromboplastin times, and elevated fibrin degradation products, consistent with disseminated intravascular coagulation.

### Diagnosis

The approach to evaluating patients depends on whether or not appropriate signs and symptoms are evident, and if an exposure occurred within 21 days prior to the onset of symptoms. Infection control precautions must be used for all symptomatic patients with an identifiable risk for EVD. All symptomatic patients should be isolated in a single room with a private bathroom, and implementation of contact and droplet precautions. Only essential personnel who are well trained in the use of PPE should interact with the patient. Phlebotomy and laboratory testing should be limited to essential tests. Both the CDC and the WHO have provided detailed recommendations for approach to the evaluation of persons who may have been exposed to the virus.

Rapid diagnostic tests are the most commonly used tests for diagnosis. Viral RNA is generally detectable by RT-PCR in the blood 3 days after the onset of symptoms. Repeat testing may be necessary for patients with illness duration shorter than 3 days. A negative RT-PCR test greater than or equal to 72 hours after the onset of symptoms rules out EVD. Details on specimen collection and handling can be found on the CDC website. For clinicians

outside the United States, the WHO has issued guidance for the collection and shipment of specimens from patients with suspected disease.

Rapid immunoassays that detect virus antigen have also been developed. However, the tests are associated with both false positives and false negatives. Therefore they must be verified using RT-PCR test. The rapid immunoassays are mostly useful to make a provisional diagnosis in the appropriate clinical setting when RT-PCR is not readily available.

### Differential Diagnosis

Acute onset of febrile illness in a person who lives or has recently been in West or Central Africa may be caused by a variety of local infectious diseases, which must be considered in the differential diagnosis. **Malaria** may have similar findings and might occur concurrently. Examination of blood smears and rapid antigen tests are typically used to diagnose malaria. **Typhoid** is characterized by fever and abdominal pain, and diagnosed by blood cultures.

Patients with **Lassa fever** may develop a severe clinical syndrome resembling EVD and progress to fatal shock. The illness is restricted to West Africa, where it is transmitted through exposure to the aerosolized excretions of rodents, and diagnosed by RT-PCR testing and/or serology. Clinical manifestations of **Marburg virus disease** are similar to EVD, and cases have been identified in Central Africa. The diagnosis is made by RT-PCR. Patients with **influenza** may have a similar initial presentation, but respiratory signs and symptoms are prominent.

### Therapy

Good supportive care can significantly improve the chances of recovery from EVD. Mortality rates have been as low as 18% among those cared for in the US and Europe, receiving careful fluid and electrolyte management, nutritional support, and critical care. Large volumes of intravenous fluids and electrolytes are often needed to correct dehydration and electrolyte abnormalities resulting from gastrointestinal losses. Supportive care is required for complications such as shock, hypoxia, hemorrhage, and multiorgan failure. Patients may develop secondary bacterial infections, which may require concurrent management with antimicrobials. Infection prevention and control measures are critical; all bodily fluids and tissues must be considered potentially infectious. The illness is associated with high rates of pregnancy-associated hemorrhage and fetal death. The CDC and the American College of Obstetrics and Gynecology have issued recommendations for the care of pregnant women with EVD. However, there are no definitive data to recommend cesarean section versus vaginal delivery or the preferred timing for delivery. According to WHO guidelines from 2020, labor should not be induced. Additionally, procedures such as cesarean delivery, episiotomy, and vacuum extraction should only be performed for maternal indications, with the overall goal of reducing maternal morbidity and mortality.

Several monoclonal antibodies (mAbs) have been evaluated in animal studies and in clinical trials. Two products, mAb114 (ansuvimab-zykl, Ebanga) and REGN-EB3 (atoltivimab/maftivimab/odesivimab, Inmazeb) were approved for use by the FDA in 2020, and recommended for use by the WHO during the recent 2021 outbreak in the DRC. The first, mAb114, was isolated from a survivor of EVD and shown to protect 100 percent of macaques from lethal infection when administered up to five days after virus challenge. The second, REGN-EB3, contains three mAbs (atoltivimab, maftivimab, odesivimab) that target the virus surface glycoprotein, providing potent virus neutralization. In rhesus macaques, a single infusion prevented death, even when administered after the onset of illness. The antibodies showed modest reductions in overall mortality in the range 14.6%–17.8% when compared to ZMapp, a three mAb combo, that had previously shown a small reduction in mortality compared to placebo (22% versus 37%). Clinicians may contact the

CDC's Emergency Operations Center for additional information on use of experimental therapeutics for treatment of EVD.

### Long-Term Follow-up

The WHO suggests close follow-up of patients after hospital discharge for the first year. A suggested schedule is first follow-up 2 weeks after discharge, then monthly for 6 months, and then every three 3 months to complete 1 year. Survivors with ocular findings require follow-up to assess for cataracts. Semen testing should be done at follow-up visits until negative for Ebola virus RNA. If semen testing is unavailable, then WHO recommends that men practice safe sex for 12 months from onset of illness.

If patients develop fever, then they should be assessed for relapse, while also being evaluated for other causes of infection. Development of uveitis and meningitis may suggest relapse. Spinal fluid analysis should be done when meningitis is suspected, even if the blood tests are negative for Ebola virus RNA.

### Prevention

Two vaccines have shown promise in the prevention of EVD. The recombinant vesicular stomatitis virus-Zaire Ebola vaccine (rVSV-ZEBOV) has been found to have an efficacy of 97.5% when given as part of a ring vaccination strategy, where contacts of infected people are vaccinated, as are any subsequent contacts of those people. In November 2019, the WHO specified that the vaccine met standards for implementation in the prevention of EVD. The greatest role for the vaccine may be in disease prevention when given promptly post-exposure. The FDA approved rVSV-ZEBOV (Ervebo) in December, 2019. In the US, the vaccine is recommended for pre-exposure prophylaxis in adults at risk for occupation exposure to the *Zaire* virus species.

A second vaccine, Ad26.ZEBOV/MVA-BN-Filo (Zabdeno and Mvabea)<sup>5</sup>, was introduced in the DRC in November 2019 in response to the ongoing Ebola epidemic. Given in two doses, Zabdeno and Mvabea 8 weeks apart, this prime-boost vaccine has been found to be safe and immunogenic. In contrast to the rVSV-ZEBOV vaccine, which is being employed in a ring vaccination strategy for health care workers in the outbreak area, the Ad26.ZEBOV/MVA-BN-Filo vaccine will be given to at-risk populations in regions where there is no active disease transmission and is expected to provide longer protection.

Recommendations for travelers to an area affected by an Ebola outbreak or those residing in such an area are as follows:

- Practice careful hand hygiene and avoid contact with an infected person's blood or body fluids, including personal items that may have come in contact with blood and body fluids.
- Avoid unprotected contact with the body of a deceased person who was infected with EVD.
- Avoid contact with bats and nonhuman primates, including blood, bodily fluids, and tissues from these animals.
- Monitor health for 21 days after return from an Ebola endemic region, and seek medical care immediately if any symptoms develop.

Health care workers at risk for exposure to Ebola must wear PPE and notify appropriate health officials at their institutions if they have unprotected contact with the blood or bodily fluids of a person infected with EVD. Finally institutions must have proper infection control and sterilization measures in place for handling of biohazardous materials. Clinicians may contact the CDC for additional information on use of experimental therapeutics and vaccines for prophylaxis following a high-risk occupational exposure to Ebola virus.

### Monitoring

Local authorities may have specific regulations for management of asymptomatic individuals with Ebola virus exposure. This includes self-monitoring versus direct observation by a health official, and the need for quarantine. In general, asymptomatic

persons who have had an exposure should be monitored for 21 days after the last known exposure, and should immediately report the development of fever or other clinical manifestations suggestive of EVD to the health authorities.

## FOODBORNE ILLNESSES

Method of

Anita Devi K. Ravindran, MD; and Viswanathan K. Neelakantan, MD

### CURRENT DIAGNOSIS

- Infective foodborne illnesses are innumerable and are caused by various microorganisms. Some microorganisms are established agents, several others are emerging pathogens, and the pathogenicity of the remainder is still under speculation.
- Classification of these illnesses is best done according to their incubation periods, the symptoms they produce, or both.
- Nausea and vomiting predominate in illnesses with short incubation periods caused by preformed toxins, whereas diarrhea predominates in those with long incubation periods caused by toxins produced in the intestine.
- Undercooked charcuterie, meat, poultry, and seafood account for a majority of foodborne illness, but dairy products, salads, pastries, fruits, and vegetables can also cause illness.
- Contaminated water acts as a vehicle in almost all instances.

### CURRENT THERAPY

- The majority of infective foodborne illnesses with symptoms confined to the gastrointestinal tract, although apparently alarming, are self-limiting and need only supportive measures including replacement of water and electrolytes.
- Antimicrobial agents are indicated only in certain patients, including those with systemic illnesses, extremes of age, immunocompromised and malnourished states, and severe life-threatening illness.
- Antitoxin is useful in botulism poisoning.
- Vaccines are available against *Vibrio cholerae*, *Salmonella typhi*, hepatitis A virus, and rotavirus, but their effectiveness and cost-effectiveness are debatable.

The Centers for Disease Control and Prevention (CDC) estimates that each year roughly one in six Americans (about 48 million people) gets sick from foodborne illnesses; 128,000 are hospitalized, and 3000 die. These figures are higher in developing nations, and many cases are not brought to light because they occur in

<sup>5</sup>Investigational drug in the United States.

remote villages. The 2011 estimates provide the most accurate picture of infective foodborne illnesses, of which bacteria, viruses, and parasites account for the majority. Processing of ready-to-eat foods increases the risk of acquiring foodborne illness because of increased food handling, leading to introduction and growth of pathogens. Increased international travel and migration have also resulted in a greater risk because travelers are at high risk for developing foodborne gastroenteritis caused by pathogens to which they have not been exposed at home.

### Classification of Foodborne Illnesses

Agents causing foodborne diseases may be classified in several ways. The most common scheme is a taxonomic combined with a classification based on mode of action (Tables 1 to 3).

### Bacteria

#### *Aeromonas* Species

Species of *Aeromonas* are ubiquitous and autochthonous in aquatic environments, more so after the tsunami that followed the Indonesian earthquake in December 2004. These aeromonads

share many biochemical characteristics with members of the Enterobacteriaceae. The mesophilic species *Aeromonas caviae*, *Aeromonas hydrophila*, and *Aeromonas veronii* are principally associated with gastroenteritis; *A. caviae* particularly infects children younger than 3 years.

Transmission is documented as occurring from a contaminated piped water source, as seen in community-based outbreaks, especially among children. The probability of occurrence of *Aeromonas* infection increased significantly when the mean seasonal temperature exceeded 14°C (57°F), and this was exacerbated where the mean free chlorine concentration fell below 0.1 mg/L.

*Aeromonas* species are potential food-poisoning agents. *A. hydrophila* is psychrotrophic and has been associated with spoilage of refrigerated animal products including chicken, beef, pork, lamb, fish, oysters, crab, and milk.

The incubation period for *Aeromonas*-associated traveler's diarrhea is 1 to 2 days. It usually causes a sporadic illness. Usually a mild to moderate but self-limiting diarrhea occurs, but it can be severe enough in children to require hospitalization.

**TABLE 1** Classification of Foodborne Illnesses

SIGNS AND SYMPTOMS OR MECHANISM	PATHOGENS
<b>Based on Symptoms and Duration of Onset</b>	
Nausea and vomiting within 6 h	<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i>
Abdominal cramps and diarrhea within 8–16 h	<i>Clostridium perfringens</i> , <i>Bacillus cereus</i>
Fever, abdominal cramps, and diarrhea within 16–48 h	<i>Salmonella</i> , <i>Shigella</i> , <i>Vibrio parahaemolyticus</i> , enteroinvasive <i>Escherichia coli</i> , <i>Campylobacter jejuni</i>
Abdominal cramps and watery diarrhea within 16–72 h	Enterotoxigenic <i>E. coli</i> , <i>Vibrio cholerae</i> O1, O139 Bengal, <i>Vibrio parahaemolyticus</i> , NAG (nonagglutinable) vibrios, <i>Norovirus</i>
Fever and abdominal cramps within 16–48 h	<i>Yersinia enterocolitica</i>
Bloody diarrhea without fever within 72–120 h	Enterohemorrhagic <i>E. coli</i> O157:H7
Nausea, vomiting, diarrhea, and paralysis within 18–36 h	<i>Clostridium botulinum</i>
<b>Based on Pathogenesis</b>	
Food intoxications resulting from the ingestion of preformed bacterial toxins	<i>Staphylococcus aureus</i> , <i>Bacillus cereus</i> , <i>Clostridium botulinum</i> , <i>Clostridium perfringens</i>
Food intoxications caused by noninvasive bacteria that secrete toxins while adhering to the intestinal wall	Enterotoxigenic <i>E. coli</i> , <i>Vibrio cholerae</i> , <i>Campylobacter jejuni</i>
Food intoxications that follow an intracellular invasion of intestinal epithelial cells	<i>Shigella</i> , <i>Salmonella</i>
Diseases caused by bacteria that enter the bloodstream via the intestinal tract	<i>Salmonella typhi</i> , <i>Listeria monocytogenes</i>
<b>Based on Toxin Production</b>	
The organisms responsible produce two major types of toxins, or they may be invasive, with no toxin production.	
Secretory toxins are enterotoxins produced by microbes that colonize the intestines in large numbers by attaching to the mucosal epithelial cells without invasion of mucosa, and, hence, there is no fever or other systemic symptoms as a result of lack of inflammatory response. Massive quantities of fluid and electrolytes are lost into the large bowel as its reabsorbing capacity is exceeded by the hypersecretion of isotonic fluid produced by the enterotoxins.	<i>Vibrio cholerae</i> , enterotoxigenic <i>E. coli</i> , <i>Shigella dysenteriae</i> , <i>Salmonella typhimurium</i>
Cytotoxins are those that destroy the epithelial cells of the mucosa.	<i>Shigella dysenteriae</i> elaborating Shiga toxin, causing destructive colitis, enterohemorrhagic <i>E. coli</i> , producing a similar toxin causing hemorrhagic colitis and hemolytic uremic syndrome (HUS), and <i>Vibrio parahaemolyticus</i> <i>Clostridium perfringens</i> , which produces a secretory enterotoxin, also has a cytotoxic action.
Secretory toxins, cytotoxins, and/or neurotoxins that are preformed are ingested directly in food.	<i>Bacillus cereus</i> , <i>Staphylococcus aureus</i> , <i>Clostridium botulinum</i>
Certain invasive microbes produce systemic symptoms such as fever, headache, and myalgia, in addition to gastrointestinal symptoms.	Salmonellosis typhoid fever, shigellosis, and brucellosis

**TABLE 2** Common Organisms Implicated in Infective Foodborne Illness

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<b>Upper Gastrointestinal Tract Symptoms (Nausea, Vomiting) Occur First or Predominate</b>				
<i>Staphylococcus aureus</i> (preformed toxin)	1–6 h	Sudden onset of severe nausea and vomiting Abdominal cramps, diarrhea, and fever may be present	24–48 h	Unrefrigerated or improperly refrigerated meat, potato and egg salads, cream pastries
<i>Bacillus cereus</i> (preformed toxin)	1–6 h	Sudden onset of severe nausea and vomiting Diarrhea may be present	24 h	Improperly refrigerated cooked or fried rice, meat
<b>Lower Gastrointestinal Tract Symptoms (Abdominal Cramps, Diarrhea) Occur First or Predominate</b>				
<i>Bacillus cereus</i> (diarrheal toxin)	10–16 h	Abdominal cramps, watery diarrhea, nausea	24–48 h	Meat, stew, gravy, vanilla sauce
<i>Clostridium perfringens</i> (toxin)	8–16 h	Watery diarrhea, nausea, abdominal cramps; fever is rare	24–48 h	Meat, poultry, gravy, dried or precooked foods, time- and/or temperature-abused food
<i>Vibrio cholerae</i>	2 h to 5 d	Rice-water purging diarrhea leading to dehydration, shock, acidosis, renal failure, abdominal pain Cholera sicca is a severe form; patient dies before diarrhea is manifest; ileus and abdominal bloating result	2–7 d	Sewage-contaminated water Seafood: fish, shellfish, crabs, oysters, clams Contaminated rice, millet gruel, vegetables
<i>Vibrio parahaemolyticus</i>	12–24 h	Watery diarrhea, abdominal cramps, nausea, vomiting Neurologic symptoms can occur, as with <i>Clostridium botulinum</i> and <i>Trichinella spiralis</i>	2–5 d	Raw or undercooked seafood
<i>Shigella</i>	1–4 d	Abdominal cramps, fever, diarrhea Stool might contain blood and mucus	4–7 d	Food or water contaminated with fecal matter Ready-to-eat food touched by infected food worker
<i>Salmonella</i> (not typhi)	1–3 d	Diarrhea, fever, abdominal cramps, vomiting	4–7 d	Contaminated eggs, unpasteurized milk or juice, cheese, contaminated raw fruits and vegetables
Enterotoxigenic <i>Escherichia coli</i>	1–3 d	Watery diarrhea, abdominal cramps, some vomiting	3–7 d (or longer)	Food or water contaminated with human feces
Shiga toxin–producing <i>E. coli</i> , including <i>E. coli</i> O157:H7	2–6 d	Severe diarrhea that is often bloody; abdominal pain and vomiting Usually little or no fever	5–10 d	Undercooked beef, especially hamburger, unpasteurized milk and juice, raw fruit and vegetables (e.g., sprouts), salami (rarely), contaminated water
<i>Campylobacter jejuni</i>	2–5 d	Diarrhea, cramps, fever, vomiting Diarrhea may be bloody	2–10 d	Raw and undercooked poultry, unpasteurized milk, contaminated milk
<i>Vibrio vulnificus</i>	1–7 d	Vomiting, diarrhea, abdominal pain Fever, bleeding within the skin, ulcers requiring surgical removal Can be fatal to people with liver disease or weakened immune systems	2–8 d	Undercooked or raw seafood, especially oysters
<i>Yersinia enterocolitica</i>	3–7 d	Appendicitis-like symptoms: diarrhea, vomiting, fever, abdominal pain	Can remit and relapse over weeks to 1 mo	Drinking water, food contaminated with human fecal matter
<i>Cyclospora</i>	7–10 d	Diarrhea (usually watery), loss of appetite, weight loss, stomach cramps, nausea, vomiting, fatigue	Can remit and relapse over weeks to 1 mo	Fresh herbs and produce (e.g., raspberries, basil, lettuce)
<i>Giardia lamblia</i> (beaver fever)	7–10 d	Diarrhea (acute or chronic), stomach cramps, flatulence, weight loss, malabsorption, developmental delay	Days to weeks	Drinking water, food contaminated with human fecal matter

**TABLE 2** Common Organisms Implicated in Infective Foodborne Illness—cont'd

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Entamoeba histolytica</i>	1–4 wk	Intestinal: diarrhea, fever, abdominal pain, dysentery, colitis, bowel perforation, ameboma Extraintestinal amebiasis: liver abscess with anchovy-sauce pus, spread to viscera, lungs, and brain	Days to weeks	Drinking water Food contaminated with human fecal matter
<b>Both Upper and Lower Gastrointestinal Tract Symptoms</b>				
Rotavirus	18–36 h	Acute onset of fever and vomiting followed 12–24 h later by frequent watery stools	3–7 d	Contaminated drinking water, food, fomites
Norovirus and other caliciviruses	12–48 h	Nausea, vomiting, cramping, diarrhea, fever, myalgia, some headache Diarrhea is more prevalent in adults; vomiting is more prevalent in children	12–60 h	Food (including shellfish) or water contaminated with human fecal matter Ready-to-eat food touched by an infected food worker
<b>Generalized Symptoms</b>				
<i>Listeria monocytogenes</i>	9–48 h or GI symptoms; 2–6 wk for invasive disease	Fever, muscle aches, nausea or diarrhea Pregnant women can have mild flulike illness, and infection can lead to premature delivery or stillbirth Elderly and immunocompromised patients can have bacteremia or meningitis	Variable	Fresh soft cheese, unpasteurized milk, ready-to-eat deli meat, hot dogs
<i>Balantidium coli</i>	4–5 d	Mostly asymptomatic Chronic diarrhea, occasional dysentery, nausea, foul breath, colitis, abdominal pain, weight loss, deep intestinal ulcerations, possible perforation of the intestine, pneumonia-like illness	Variable	Water contaminated with pig feces
<i>Salmonella typhi</i>	8–14 d	Fever, anorexia, lethargy, malaise, headache, rose spots, constipation or diarrhea, hepatosplenomegaly	4–6 wk	Contaminated water; contaminated food, mainly via food handlers; shellfish from polluted water
<i>Ascaris lumbricoides</i>	4–16 d	Nausea, abdominal pain, intestinal obstruction, malnutrition, Loeffler's syndrome (cough, pneumonitis, eosinophilia), biliary colic, colangitis, pancreatitis, appendicitis	Variable (chronic)	Soil-contaminated raw food, food handlers, water
<i>Trichinella spiralis</i>	1–2 wk	Asymptomatic or chronic diarrhea, abdominal pain Allergy leading to rash, periorbital edema, vasculitis, intramural thrombi Weakness of jaw, biceps, diaphragm, intercostals Eosinophilia, subconjunctival, splinter hemorrhages Muscle penetration: myalgia, orbital pain, diplopia Chronic phase: neurologic symptoms	Variable Acute phase: 1–3 wk	Raw or undercooked meat of pig, horse, wild boar, bush pig, warthog, bear
Infective cysticerci of <i>Taenia solium</i> (pork tape worm)	2 months on average	Seizures, vasculitis, focal neurologic deficits, intracranial hypertension, hydrocephalus, mental changes, encephalitis and Brun's syndrome (intermittent obstruction of cerebral aqueduct), myositis, vasculitis	Highly variable	Undercooked charcuterie (pork), contaminated raw vegetables, salads, water
Hepatitis A	15–50 d	Diarrhea, dark urine, jaundice, flulike symptoms, fever, headache, nausea, aversion to food, vomiting, abdominal pain; distaste for cigarettes	Variable: 2 wk to 3 mo	Food (including shellfish) or water contaminated with human fecal matter Inadequately cooked clams, oysters, mussels, cockles Contaminated lettuce, slush beverages, frozen strawberries and salad items Ready-to-eat foods touched by an infected food worker

*Continued*

**TABLE 2** Common Organisms Implicated in Infective Foodborne Illness—cont'd

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Brucella</i> species	1–8 wk	Flulike illness; undulating fever, malaise, arthralgia, anorexia, hepatosplenomegaly, pleurisy, nausea, vomiting, diarrhea, new onset of increased desire to sleep after lunch	Variable	Unpasteurized dairy products, undercooked meat, bone marrow Contact with laboratory cultures and tissue samples Accidental injection of live brucellosis vaccine
Hepatitis E	3–8 wk	Prodrome: anorexia, nausea, vomiting, arthralgia, myalgia, weight loss, dehydration, abdominal pain Icteric phase: jaundice, pruritus, light-colored stool Urticaria, diarrhea, malaise	Variable (several weeks)	Fecally contaminated drinking water and food Raw and undercooked shellfish incriminated in sporadic outbreaks Possibly zoonotic spread
Microsporidium: <i>Encephalitozoon</i> , <i>Pleistophora</i> , <i>Nosema</i> , <i>Vittaforma</i> , <i>Trachipleistophora</i> , <i>Brachiola</i> , <i>Microsporidium</i> , <i>Enterocytozoon</i>	Unknown	Watery or bloody or unspecified diarrhea, abdominal discomfort, cramps, flatulence, weight loss, loss of appetite, wasting syndrome, subfebrile temperatures Extraintestinal: pneumonitis, myositis, keratoconjunctivitis, seizures, nephritis, cholangiopathy	Variable; self-limiting (1–2 wk) in immunocompetent patients	Contaminated water, food, or inhalation

Abbreviation: GI=gastrointestinal.

**TABLE 3** Rare and Emerging Infections

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Bacillus subtilis</i>	10 min to 14 h (average, 2.5 h)	Vomiting, diarrhea, abdominal cramps, nausea, headache, flushing, sweating	1.5–8 h	Sausage rolls, meat pasties, turkey stuffing, chicken stuffing, pizza, whole-grain bread, steak pie, pork sandwiches
Cyanobacteria: <i>Microcystic aeuroginosa</i> , <i>Anabaena circinalis</i> , <i>Anabaena flosaquae</i> , <i>Aphanizomenon flosaquae</i> , <i>Cylindrospermopsis racibarskii</i>	3–6 h	Diarrhea, vomiting, allergic reactions, breathing difficulty, dizziness, tingling and numbness, liver and kidney toxicity	8–16 h	Drinking water from untreated surface sources, inhaling aerosols from jet-skis and boats, consuming dietary supplements contaminated by microcystin
<i>Anisakis</i>	Few hours to days	Gastric: abdominal pain, nausea, vomiting Allergic: urticaria, anaphylaxis Intestinal: ileus, perforation, peritonitis, stenosis	2 wk	Raw, lightly pickled, or salted marine fish: Mackerel, squid, horse mackerel, salmon, bonito Squid, cuttlefish Sushi, sashimi
Astrovirus	1–4 d	Watery diarrhea (especially in children), vomiting, fever, anorexia, abdominal pain	3–4 d	Sewage-polluted water and food
<i>Pleisomonas shigelloides</i>	5 d	Diarrhea with blood and mucus, abdominal pain, headache, nausea, chills, fever, vomiting	1–7 d	Contaminated water used for drinking or rinsing foods to be eaten raw Contaminated raw shellfish, salted fish, crabs, oysters
<i>Cyclospora</i>	7 d	Frequent watery diarrhea, weight loss, abdominal pain, bloating, flatulence, vomiting, nausea, low-grade fever, fatigue, malabsorption, cholecystitis	1–4 wk Relapse is common	Fecally contaminated fresh raspberries, snow peas, mesclun

**TABLE 3** Rare and Emerging Infections—cont'd

ETIOLOGIC AGENT	USUAL INCUBATION PERIOD	SYMPTOMS	DURATION OF SYMPTOMS	COMMON VEHICLES
<i>Iosopora belli</i>	8–11 d	Diarrhea, steatorrhea, headache, fever, malaise, abdominal pain, vomiting, dehydration, weight loss Mesenteric lymph node, liver, spleen involvement	Variable; runs a chronic course in immunocompromised patients	Contaminated food and water
<i>Edwardisella tarda</i>	Not defined	Nausea, vomiting, diarrhea, dysentery, colitis, wound infections, septicemia	Variable: 1–2 wk or longer	Fecal contamination of food, water, raw fish
<i>Citrobacter</i> species	Not defined	Diarrhea, hemolytic uremic syndrome, thrombocytopenic purpura		Meat and milk Parsley (in green butter) from organic gardens using pig manure
Arizona	Not defined	Diarrhea		Cream pie, chocolate eclairs, custard, eggs, chicken, turkey
<i>Achromobacter xylosoxidans</i>	Not defined	Abdominal pain, diarrhea, headache, vomiting		Raw milk, spoiled canned food, contaminated well water

*Aeromonas* gastroenteritis can occur as a nondescript enteritis, as a more-severe form accompanied by bloody stools, as the etiologic agent of a subacute or chronic intestinal syndrome, as an extremely rare cause of cholera-like disease, or in association with episodic traveler's diarrhea. By far the most common presentation of *Aeromonas* gastroenteritis is watery enteritis. The most serious complication resulting from *Aeromonas* gastroenteritis is hemolytic uremic syndrome.

#### Pathogenesis

Mesophilic *Aeromonas* spp. can express a range of virulence factors, including attachment mechanisms and production of a number of toxins. Toxins include aerolysin (a pore-forming cytolysin that attaches to cell membrane, leading to leakage of cytoplasmic contents) and a cytotoxic enterotoxin with activity similar to that of cholera toxin. Strains of *A. hydrophila* produce lectins and adhesins, which enable adherence to epithelial surfaces and gut mucosa.

#### Laboratory Diagnosis

Samples are best transported using Cary-Blair medium. *Aeromonas* forms a bull's-eye-like colony on the selective medium cefsulodin irgasan novobiocin (CIN) agar owing to fermentation of D-mannitol. Ampicillin blood agar has an advantage over CIN agar in that hemolytic colonies can readily be tested for oxidase. *Aeromonas* species produce hemolysis on sheep blood agar.

#### Treatment

In *Aeromonas* infections, ciprofloxacin (Cipro)<sup>1</sup> 500 mg PO or 400 mg IV twice daily is the antimicrobial treatment of choice. Piperacillin-tazobactam (Zosyn)<sup>1</sup> 4.5 g IV three times daily or ceftazidime (Fortaz)<sup>1</sup> 2 g IV daily may be added in severe infections. The organism is also susceptible to aminoglycosides and carbapenems. Resistance is now becoming a problem because *Aeromonas* can produce  $\beta$ -lactamases and carbapenemases. Therefore it is preferable to initiate therapy with a fluoroquinolone when the organism is isolated.

#### *Bacillus cereus*

*Bacillus cereus* is found abundantly in the environment and vegetation. It is known to produce two forms of food poisoning,

emetic and diarrheal. The emetic (short-incubation) type of illness is associated with contaminated fried rice that is not refrigerated. The organism is present in uncooked rice, and the spores survive boiling. The illness is usually self-limiting, with recovery in a day. It is mediated by a heat-stable, preformed enterotoxin resembling that of *Staphylococcus aureus*. The first major outbreak of *Bacillus cereus* food poisoning was in 1971 in England. The diarrheal (long-incubation) type of illness is produced by a heat-labile diarrheal enterotoxin formed in the intestine, which activates adenylate cyclase, causing intestinal fluid secretion, similar to *Escherichia coli* LT toxin and the toxin of *Clostridium perfringens*.

#### Pathogenesis

During the slow cooling of cooked rice, spores germinate and vegetative bacteria multiply; then they sporulate again. Sporulation is also associated with toxin production. The toxin is heat stable and can easily withstand the temperatures used to cook fried rice.

#### Laboratory Diagnosis

The disease is diagnosed by the isolation of *B. cereus* from the incriminated food (emetic type) or from stool and food (diarrheal type). Isolation from stools alone is not sufficient because gastrointestinal colonization with *B. cereus* occurs in many persons.

#### Treatment

*B. cereus* food poisoning may be symptomatically managed with replacement of fluids and electrolytes. Antimicrobials have no role in treatment. *B. cereus* is also known to produce a variety of ocular and systemic infections such as meningitis, osteomyelitis, pneumonia, and endocarditis. These are usually not foodborne, and it is in this situation that vancomycin (Vancocin)<sup>1</sup> becomes the drug of choice, with clindamycin (Cleocin)<sup>1</sup> and carbapenems being the alternative drugs, both being used along with aminoglycosides for synergistic action.

#### *Campylobacter jejuni*

*Campylobacter jejuni* are harbored in the reproductive and alimentary tracts of some animals. Other than gastrointestinal symptoms, the patient has malaise and headache. The organism may be shed in the patient's stool for up to 2 months. Bacteremia is observed in a small minority of cases. The disease is usually self-limiting. Guillain-Barré syndrome and Reiter's syndrome are recognized sequelae.

<sup>1</sup>Not FDA approved for this indication.

### Pathogenesis

As few as 500 organisms can cause enteritis. The organism is invasive but generally less so than *Shigella*. *Campylobacter* produces adenylate cyclase-activating toxins resembling *E. coli* LT and cholera toxin.

### Laboratory Diagnosis

The feces may be inoculated in enrichment medium or on selective media such as Campy-BAP or Skirrow's medium.

### Treatment

Indications for antibiotic therapy in *C. jejuni* infections are prolonged fever, severe diarrhea, dysentery, and persistent symptoms for more than a week. Therapy of *Campylobacter* infection with ciprofloxacin (Cipro 500 mg orally twice daily for 7 days) early in the course of the illness shortens its duration. Unfortunately, this has led to the emergence of fluoroquinolone-resistant *Campylobacter* infections. Erythromycin eradicates carriage of susceptible *C. jejuni* and might shorten the duration of illness if given early in the disease. Erythromycin (Ery-Tab)<sup>1</sup> 250 mg PO four times daily is the drug of choice in *Campylobacter* enteritis. Azithromycin (Zithromax)<sup>1</sup> is also useful and has the advantage of shorter duration of therapy.

Gentamicin (Garamycin), carbapenems, amoxicillin-clavulanate (Augmentin),<sup>1</sup> and chloramphenicol<sup>1</sup> are useful in systemic infections. The usual duration of treatment is 2 weeks. The therapy is prolonged in immunocompromised persons and in patients with endovascular infections.

### *Clostridium botulinum*

*Clostridium botulinum* is widely distributed in soil, in sediments of lakes and ponds, and in decaying vegetation. *C. botulinum* elaborates the most potent toxin known in humans. When the toxin is ingested, paralysis occurs, often requiring prolonged artificial ventilation. Common signs and symptoms include vomiting, thirst, dry mouth, constipation, ocular palsies, dysphagia, dysarthria, bulbar paralysis, and death due to respiratory paralysis. Coma or delirium occurs in some. Infants present with lethargy, poor feeding, loss of head control, and sometimes sudden infant death syndrome (SIDS).

The incriminated foods are corn syrup, home-canned or bottled meat, fruits, fish, vegetables, herb-infused oils, and cheese sauce. Infant botulism is associated with consumption of honey; honey should not be given to infants younger than 1 year.

### Pathogenesis

Not all strains of *C. botulinum* produce botulinum toxin. Toxicogenic types of the organism, designated A, B, C1, D, E, F, and G, produce immunologically distinct forms of botulinum toxin. Lysogenic phages encode toxin C and D serotypes.

Foodborne botulism is not an infection but an intoxication because it results from the ingestion of foods that contain the preformed clostridial toxin. If contaminated food has been insufficiently heated or canned improperly, the spores can germinate and produce botulinum toxin. The toxin is released only after cell lysis and death. The toxin resists digestion and is absorbed by the upper gastrointestinal tract and enters the blood. The toxin blocks release of acetylcholine by binding to receptors at synapses and neuromuscular junctions and causes flaccid paralysis.

### Laboratory Diagnosis

Spoilage of food or swelling of cans or presence of bubbles inside the can indicate growth of *C. botulinum*. Food is homogenized in broth and inoculated in Robertson cooked meat medium and blood agar or egg-yolk agar, which is incubated anaerobically for 3 to 5 days at 37°C. The toxin can be demonstrated by

injecting the extract of food or culture into mice or guinea pigs intraperitoneally.

### Treatment

Hospitalization in an intensive care unit with immediate administration of botulinum antitoxin is vital in the management of botulism. The antitoxin neutralizes only toxin molecules unbound to nerve endings and does not reverse the paralysis. It should be given within 24 hours after the diagnosis is made. Penicillin is the antimicrobial of choice. Intubation and mechanical ventilation are needed for respiratory failure. If swallowing difficulty persists, intravenous fluids or alimentation should be given through a nasogastric tube.

### *Clostridium perfringens*

*C. perfringens* is heat resistant and elaborates two toxins that can induce specific pathology in the human intestinal tract. It is the third leading cause of foodborne illnesses in United States, after norovirus and *B. cereus*. It is present abundantly in the environment, vegetation, sewage, and animal feces.

Human diseases caused by this organism are the more common *C. perfringens* type A food poisoning and the less common, but more serious, *C. perfringens* type C food poisoning producing necrotic enteritis. Necrotic enteritis is characterized by vomiting, severe abdominal pain, and bloody diarrhea. The incubation period is 2 to 5 days. Progression to necrosis of the jejunum and death occur.

### Pathogenesis

Spores in food can survive cooking and then germinate when the food is improperly stored. When these vegetative cells form endospores in the intestine, they release enterotoxins. Food poisoning is mainly caused by type A strains, which produce alpha and theta toxins. The toxins result in excessive fluid accumulation in the intestinal lumen.

### Laboratory Diagnosis

Because the bacterium is present normally in intestines, isolation from feces might not be sufficient to implicate it as the cause of the illness. Similarly, isolation from food, except in large numbers (>10<sup>9</sup>/g), might not be significant. The homogenized food is diluted and plated on selective medium, as well as Robertson cooked meat medium, and subjected to anaerobic incubation. The isolated bacteria must be shown to produce enterotoxin.

### Treatment

Food poisoning due to *Clostridium perfringens* is managed conservatively with hydration and replacement of electrolytes. *C. perfringens* is susceptible to benzylpenicillin (penicillin G), which may be useful in managing severe infections (1 mU IV every 4 hours). Vancomycin,<sup>1</sup> clindamycin,<sup>1</sup> cefoxitin (Mefoxin), and metronidazole (Flagyl) are alternatives. *C. perfringens* type C toxoid vaccine<sup>2</sup> (two doses, 4 months apart) is preventive in pigbel.

### *Cronobacter sakazakii*

*Cronobacter sakazakii* causes neonatal meningitis or necrotizing enterocolitis and bacteremia, which results in an alarming mortality rate. Surviving patients sometimes develop ventriculitis and cerebral abscess. *C. sakazakii* has been isolated from infant formulas.

*Enterobacter* species are generally resistant to the cephalosporins, except cefepime (Maxipime),<sup>1</sup> but are responsive to carbenicillin (Geocillin),<sup>1</sup> piperacillin (Pipracil),<sup>1</sup> ticarcillin (Ticar),<sup>1</sup> amikacin (Amikin),<sup>1</sup> and tigecycline (Tygacil).<sup>1</sup>

### Enterohemorrhagic *Escherichia coli*

Many serogroups of *E. coli*, including O4, O26, O45, O91, O111, O145, and O157, are pathogenic, but the most common pathogenic serotype is O157:H7. Cattle are the main sources of infection; most cases are associated with the consumption of undercooked beef burgers and similar foods from restaurants and delicatessens. The latest outbreak of *E. coli* O157:H7 during the fall of 2019 and 2020 was linked to leafy greens (romaine salad greens).

#### Pathogenesis

Enterohemorrhagic *E. coli* (EHEC) strains can produce one or more types of cytotoxins, which are collectively referred to as Shiga-like toxins because they are antigenically and functionally similar to Shiga toxin produced by *Shigella dysenteriae*. (Shiga-like toxins were previously known as verotoxins.) The toxins provoke cell secretion and kill colonic epithelial cells, causing hemorrhagic colitis and hemolytic-uremic syndrome (HUS), leading occasionally to disseminated intravascular coagulation (DIC). A fibrin layer forms in the glomerular capillary bed, and acute renal failure occurs due to DIC. These are most likely to occur in children, elderly patients, and pregnant women. The young recover fully, but at times dialysis is warranted.

#### Laboratory Diagnosis

Laboratory diagnosis is performed by culturing the feces on McConkey's agar or sorbitol McConkey's agar. Strains can then be identified by serotyping using specific antisera. Shiga-like toxins can be detected by enzyme-linked immunosorbent assay (ELISA), and genes coding for them can be detected by DNA hybridization techniques.

#### Treatment

Hydration with electrolyte replacement is the mainstay of treatment in *E. coli* O157:H7 infection, and patients should be monitored closely and constantly for the development of HUS, which requires management in an intensive care setting with blood transfusion and dialysis. Although dysentery is self-limiting, the use of rifaximin (Xifaxan), a nonabsorbable agent, is recommended in those who are increasingly susceptible to infections. In the absence of dysentery, early institution of drugs like ciprofloxacin (Cipro) or azithromycin (Zithromax),<sup>1</sup> especially in traveler's diarrhea, decreases the duration of illness.

### Enterotoxigenic *Escherichia Coli*

Enterotoxigenic *E. coli* (ETEC) is now ubiquitous in nature. Wild animals and cattle act as reservoirs of the organism. *E. coli* is carried normally in the intestine of humans and animals. Some specific serotypes harbor plasmids that code for toxin production. This bacterium is responsible for a majority of traveler's diarrhea. The disease is self-limiting and resolves in a few days.

#### Pathogenesis

The bacteria colonize the gastrointestinal tract by means of fimbriae, attaching to specific receptors on enterocytes of the proximal small intestine. Enterotoxins produced by ETEC include the LT (heat-labile) toxin and the ST (heat-stable) toxins. LTs are similar to cholera toxin in structure and mode of action, consisting of A and B subunits. The B (binding) subunit of LTs binds to specific ganglioside receptors (GM1) on the epithelial cells of the small intestine and facilitates the entry of the A (activating) subunit, which activates adenylate cyclase. Stimulation of adenylate cyclase causes an increased production of cyclic adenosine monophosphate (cAMP), which leads to hypersecretion of water and electrolytes into the lumen and inhibition of sodium reabsorption.

#### Laboratory Diagnosis

The sample of feces is cultured on McConkey's agar. The ETEC stains are indistinguishable from the resident *E. coli* by biochemical tests. These strains are differentiated from nontoxicogenic *E. coli*

present in the bowel by a variety of in vitro immunochemical, tissue culture, or DNA hybridization tests designed to detect either the toxins or the genes that encode for these toxins. With the availability of a gene probe method, foods can be analyzed directly for the presence of ETEC in about 3 days. LTs can be detected by ligated rabbit ileal loop test and by observing morphologic changes in Chinese hamster ovary cells and Y1 adrenal cells. ELISA, immunodiffusion, and coagglutination are also used in diagnosis.

### *Listeria monocytogenes*

*Listeria monocytogenes* is quite hardy and resists the deleterious effects of freezing, drying, and heat remarkably well for a bacterium that does not form spores. It is capable of growing at 3°C and multiplies in refrigerated foods. The latest implicated food in a February 2021 outbreak is queso fresco cheese.

#### Pathogenesis

*L. monocytogenes* invades the gastrointestinal epithelium. Once the bacterium enters the host's monocytes, macrophages, or neutrophils, it is bloodborne and can grow. Its presence in phagocytes also permits access to the brain and transplacental migration to the fetus in pregnant women. Granulomatous infantile meningitis is a feature of listeriosis. The pathogenesis of *L. monocytogenes* centers on its ability to survive and multiply in phagocytic host cells.

#### Laboratory Diagnosis

The diagnosis of listeriosis is most commonly made by isolation of *L. monocytogenes* from a normally sterile site. β-Hemolytic colonies, which test negative for catalase, hydrolyze hippurate, and have a positive cAMP reaction, form on blood agar. Serologic testing is not useful in diagnosing acute invasive disease, but it can be useful in detecting asymptomatic disease and gastroenteritis in an outbreak or in other epidemiologic investigations. Stool testing is not commercially available.

#### Treatment
