the joys of childhood

About the Editor

Russell A. Barkley, PhD, ABPP, ABCN, is Clinical Professor of Psychiatry at the Virginia Treatment Center for Children and Virginia Commonwealth University School of Medicine. Dr. Barkley has worked with children, adolescents, and families since the 1970s and is the author of numerous bestselling books for both professionals and the public, including *Taking Charge of ADHD* and *Your Defiant Child*. He has also published six assessment scales and more than 280 scientific articles and book chapters on ADHD, executive functioning, and childhood defiance, and is editor of the newsletter *The ADHD Report*. A frequent conference presenter and speaker who is widely cited in the national media, Dr. Barkley is past president of the Section on Clinical Child Psychology (the former Division 12) of the American Psychological Association (APA), and of the International Society for Research in Child and Adolescent Psychopathology. He is a recipient of awards from the American Academy of Pediatrics and the APA, among other honors. His website is *www.russellbarkley.org*.

Preface

This fourth edition constitutes a nearly complete revision and update of the third edition, comprising at least 80% or more new material, a substantial expansion of topical areas covered on attention-deficit/hyperactivity disorder (ADHD), and at least triple the number of contributors in comparison to the prior edition. While it is essentially a new textbook, like its predecessors, this edition strives to extract from the mine of available scientific literature those nuggets of clinically important information regarding the nature, assessment, diagnosis, and management of ADHD in children, adolescents, and adults. The task of doing so has increased substantially with each new edition given the increasing frequency of journal articles relating to ADHD appearing in the scientific literature, now estimated to be at least 800–1,000 per year, a rate that seems to have doubled in just the past few years owing to a vast increase in the number of international contributors outside of Western Europe and North America. More than 6,000 studies on ADHD have been published since the publication of the 2006 edition of this work. So formidable an undertaking requires the assistance of many more contributors than in prior editions, for it is clear that no single individual can be an expert in all facets of this disorder and its management.

To help me with this endeavor, I have invited back many of the principal authors of chapters from the previous edition, along with many new contributors, each expert in the topics contained in their respective chapters. All were charged with incorporating new findings and new conclusions and clinical recommendations from the available research and related publications. I am truly grateful that all agreed to join in this endeavor. In order to draw out the messages essential for clinicians within each chapter, all chapters conclude with a checklist of "Key Clinical Points," most of which I prepared to help the reader quickly summarize the major conclusions and recommendations discussed in that chapter.

From time to time, media flare-ups have centered on ADHD, sometimes challenging its very existence. Taken in its totality, this book is a complete refutation of such assertions. It continues to show, as did previous editions, that ADHD is as valid a mental disorder as we are likely to find, with massive evidence from more than 10,000 studies dating back to medical descriptions in 1775. It clearly represents a serious deficiency in one or more psychological adaptations that harm the individuals so afflicted, which is the very definition of a mental disorder.

As in previous editions, I once again thank Kitty Moore, Seymour Weingarten, and Robert Matloff at The Guilford Press for supporting this book and providing a home for this and my other books. I also wish

to thank Carolyn Graham, Jacquelyn Coggin, and Laura Specht Patchkofsky at Guilford for helping to shepherd this book through the publication process in a professional and expeditious manner. My debt to them and the rest of Guilford's superbly capable staff for having assisted me for more than 33 years of publishing is incalculable, and I express my deep appreciation to all members of the Guilford "family" here. I am also extraordinarily appreciative of my wife, Patricia, who has stood by me for more than 45 years and provided a loving home for me, our two sons, Ken and Steve, now all grown up, and now our two grandsons, to whom this edition is dedicated. All provide me with a profound sense of family and their affection, for which I am exceptionally grateful. In such a home can this type of creative work be accomplished.

PART I. THE NATURE OF ADHD

PART I

The Nature of ADHD

CHAPTER 1

History of ADHD

Russell A. Barkley

Attention-deficit/hyperactivity disorder (ADHD) continues to be the current diagnostic label for children and adults presenting with significant problems with attention, and typically with impulsiveness and excessive activity as well. Children and adults with ADHD represent a rather heterogeneous population that displays considerable variation in the degree of members' symptoms, age of onset, cross-situational pervasiveness of those symptoms, and the extent to which other disorders occur in association with ADHD. The disorder represents one of the most common reasons children with behavioral problems are referred to medical and mental health practitioners in the United States and is one of the most prevalent childhood psychiatric disorders. Currently, referrals of adults for ADHD are also increasing at a rapid pace; until the 1990s and even to date, this age group has been a markedly underrecognized and underserved segment of the ADHD population.

This chapter presents an overview of ADHD's history—a history that spans more than two centuries in the medical and scientific literature. Whereas the previous edition noted that the medical history of ADHD began with Still's description of childhood cases in 1902, we now know that a number of earlier physicians described such cases dating back to the textbook by Melchior Adam Weikard published in German in 1775 (Barkley & Peters, 2012). This extends the history of ADHD in the medical literature back another 127 years. These new additions to the history of ADHD are described below. But given that the history of ADHD as understood from 1902 through 2006 has changed little since the preceding edition of this text (Barkley, 2006), little has been needed to update those sections of this chapter. In contrast, developments since that previous edition are described at the end of this chapter.

In the history of ADHD reside the nascent concepts that serve as the foundation for the current conceptualization of the disorder as largely involving self-regulation and executive functioning, as discussed here by Eric Willcutt (Chapter 15) and myself (Chapter 16). In this history also can be seen the emergence of current notions about its treatment. Such a history remains important for any serious student of ADHD, for it shows that many contemporary themes concerning its nature arose long ago. They have recurred throughout the subsequent history of ADHD to the present as clinicians and scientists strove for a clearer, more accurate understanding of the condition, its comorbid disorders, life course, impairments, and etiologies. Readers are directed to other and earlier sources for additional discussions of the history of this disorder (Accardo &

Blondis, 2000; Goldstein & Goldstein, 1998; Kessler, 1980; Ross & Ross, 1976, 1982; Schachar, 1986; Taylor, 2011; Warnke & Riederer, 2013; Werry, 1992).

THE HISTORICAL ORIGINS OF ADHD

The Late 1700s

One can find literary references to individuals having serious problems with inattention, hyperactivity, and poor impulse control in Shakespeare, who made mention of a malady of attention in *King Henry VIII*. But as of this writing, the medical history of ADHD-like descriptions traces back nearly 240 years to 1775. This early history has been expertly detailed in several sources (Taylor, 2011; Warnke & Riederer, 2013) but should be amended by more recent discoveries in that history, as discussed below.

It now appears that the first description of disorders of attention, at least as of this writing, occurred in the medical textbook by Melchior Adam Weikard in German in 1775 (or perhaps even 1770; see Barkley & Peters, 2012). Initially published anonymously, hence the difficulty with ascertaining the year of its initial publication, the medical textbook by Weikard described adults and children who were inattentive, distractible, lacking in persistence, overactive, and impulsive, which is quite similar to today's description of ADHD. Weikard implied that the disorder could result from poor childrearing but also suggests some biological predispositions as well. For treatment, he recommended sour milk, plant extracts, horseback riding, and even seclusion for severe cases.

This textbook would be followed in short order in 1798 with much more detailed descriptions of ADHD-like symptoms in the medical textbook by the Scottish physician Alexander Crichton (see Palmer & Finger, 2001), who may well have studied with Weikard in his medical training. Crichton described two types of attention disorders. The first was a disorder of distractibility, frequent shifting of attention or inconstancy, and lack of persistence or concentration, and aligns more closely with the attention disturbance evident in ADHD. The second was a disorder of diminished power or energy of attention that seems more like the attention problem evident in current descriptions of children and adults with sluggish cognitive tempo (SCT), which is briefly discussed in Chapter 2 on ADHD symptoms and subtypes and far more detailed coverage in Chapter 17, this volume. Crichton had little to say about this second disorder of attention other than it may be associated with debility or torpor of the body that weakens attention and results in individuals who are often characterized as retiring, unsocial, and having few friendships or attachments of any kind; even those few friendships seldom were of a durable nature. He argued that the faculty of attention can become sufficiently weakened that it may leave an individual insensible to external objects or to impressions that ordinarily would awaken social feelings.

The 1800s

In 1809, John Haslam described what may have been a case of ADHD in a 10-year-old boy who was uncontrollable, impulsive, and "a creature of volition and the terror of the family" (p. 199). Three years later, the famous American physician Benjamin Rush (1812) discussed three cases involving "the total perversion of moral faculties" (p. 359), which included the inability to focus attention. In the mid-1800s, the German pediatrician Heinrich Hoffman (1865) published a book of poems about psychological conditions of children based on observations from his clinical practice. He described both a very impulsive fidgety child he called "Fidgety Phil" and a very inattentive, daydreamy child he called "Johnny Head-in-Air" (see Stewart, 1970). Two years thereafter in England, Henry Maudsley (1867) published a report about a child who was driven by impulsiveness and was also quite destructive. In 1899, the Scottish psychiatrist, Thomas Clouston discussed cases of impulsive children who had learning problems. Much later in the United States, William James (1890/1950) noted in his *Principles of Psychology* a normal variant of character that he called the "explosive will," which may resemble the difficulties experienced by those who today are described as having ADHD.

In France the concept of ADHD may have originated in 1845 in the description of children and adults with attention problems by Jean-Etienne Dominique Esquirol, who believed that the insane no longer "enjoy the faculty of fixing, and directing their attention" (p. 28). Or perhaps the French history of ADHD began in the notion of "mental instability" that appears in the French medical literature in the 1885–1895 period under the leadership of Désiré-Magloire Bourneville (1885, 1895; see Bader & Hidjikhani, in press) at the Hospital Bicêtre in Paris. He observed children and adolescents who had been labeled "abnormal" and placed in medical and educational institutions, many

of whom were characterized by attention and other behavioral problems. Charles Baker, a student of Bourneville, wrote a clinical description of hyperactive and impulsive symptoms in 4 children in his 1892 thesis, according to Bourneville (1895). Attention problems were also mentioned in one case in this work.

THE PERIOD 1900 TO 1959

Still's Description in 1902

In the earlier editions of this text, credit for authoring the first medical description of cases resembling ADHD was awarded to George Still in 1902, owing to the lack of information on the earlier works of Weikard and Crichton. While this no longer remains the case, having been ousted from this credit by the discovery of Weikard's description noted earlier, Still did provide probably the most detailed account of the symptoms of these cases and the largest sample of such cases to that time. For these reasons, his observations deserve some recognition here. In a series of three published lectures to the Royal College of Physicians in 1902, Still described 43 children in his clinical practice who had serious problems with sustained attention; he agreed with William James (1890/1950) that such attention may be an important element in the "moral control of behavior." Most were also quite overactive. Many were often aggressive, defiant, resistant to discipline, and excessively emotional or "passionate." These children showed little "inhibitory volition" over their behavior, and they also manifested "lawlessness," spitefulness, cruelty, and dishonesty. Still proposed that the immediate gratification of the self was the "keynote" quality of these children, among other attributes. Passion (or heightened emotionality) was the most commonly observed attribute and the most noteworthy. Still noted further that such children had an insensitivity to punishment, for they would be punished (even physically) yet engage in the same infraction within a matter of hours.

Still believed that these children displayed a major "defect in moral control" over their behavior; a defect that was relatively chronic in most cases. He believed that in some cases, these children had acquired the defect secondary to an acute brain disease, and it might remit on recovery from the disease. He noted a higher risk for criminal acts in later development in some, though not all, of the chronic cases. Although this defect could be associated with intellectual retardation, as it was in 23 of the cases, it could also arise in children of near-normal intelligence, as it seemed to do in the remaining 20.

To Still (1902), the moral control of behavior meant "the control of action in conformity with the idea of the good of all" (p. 1008). Moral control was thought to arise out of a cognitive or conscious comparison of the individual's volitional activity with that of the good of all—a comparison he termed "moral consciousness." For purposes that will become evident later, it is important to realize here that to make such a comparison inherently involves the capacity to understand the consequences of one's actions over time and to hold in mind forms of information about oneself and one's actions, along with information on their context. Those forms of information involve the action being proposed by the individual, the context, and the moral principle or rule against which it must be compared. This notion may link Still's views with the contemporary concepts of self-awareness, working memory, and rule-governed behavior discussed later in this text. Still did not specifically identify these inherent aspects of the comparative process, but they are clearly implied in the manner in which he used the term "conscious" in describing this process. He stipulated that this process of comparison of proposed action to a rule concerning the greater good involved the critical element of the conscious or cognitive relation of individuals to their environment, or "self-awareness." Intellect was recognized as playing a part in moral consciousness, but equally or more important was the notion of volition or will. The latter is where Still believed the impairment arose in many of those with defective moral control who suffered no intellectual delay. Volition was viewed as being primarily inhibitory in nature, that a stimulus to act must be overpowered by the stimulus of the idea of the greater good of all.

Still concluded that a defect in moral control could arise as a function of three distinct impairments: "(1) defect of cognitive relation to the environment; (2) defect of moral consciousness; and (3) defect in inhibitory volition" (p. 1011). He placed these impairments in a hierarchical relation to each other in the order shown, arguing that impairments at a lower level would affect those levels above it and ultimately the moral control of behavior. Much as researchers do today, Still noted a greater proportion of males than females (3:1) in his sample, and he observed that the disorder appeared to arise in most cases before 8 years of age (typically in early childhood). Many of Still's cases displayed a

proneness to accidental injuries—an observation corroborated by numerous subsequent studies reviewed in a later chapter. And Still saw these youngsters as posing an increased threat to the safety of other children because of their aggressive or violent behavior. Alcoholism, criminality, and affective disorders such as depression and suicide were noted to be more common among their biological relatives—an observation once again buttressed by numerous studies published in recent years. Some of the children displayed a history of significant brain damage or convulsions, whereas others did not. A few had associated tic disorders, or "microkinesia"; this was perhaps the first time tic disorders and ADHD were noted to be comorbid conditions. We now recognize that while 10–15% of children with ADHD may manifest some form of tic disorder, as many as 50–70% of children with tic disorders and Tourette syndrome may have ADHD (Simpson, Jung, & Murphy, 2011).

Although many of Still's subjects were reported to have a chaotic family life, others came from households that provided a seemingly adequate upbringing. In fact, Still believed that when poor childrearing was clearly involved, the children should be exempt from the category of lack of moral control; he reserved it instead only for children who displayed a morbid (organic) failure of moral control despite adequate training. He proposed a biological predisposition to this behavioral condition that was probably hereditary in some children but the result of pre- or postnatal injury in others. In keeping with the theorizing of James (1890/1950), Still hypothesized that the deficits in inhibitory volition, moral control, and sustained attention were causally related to each other and to the same underlying neurological deficiency. He cautiously speculated on the possibility of either a decreased threshold for inhibition of responding to stimuli or a cortical disconnection syndrome, in which intellect was dissociated from "will" in a manner that might be due to neuronal cell modification. Any biologically compromising event that could cause significant brain damage ("cell modification") and retardation could, he conjectured, in its milder forms lead only to this defective moral control.

Also in England, Alfred Tredgold (1908) described children of low intelligence having abnormal behavior and limited powers of attention, impulse control, and willpower. He extended Still's theories and observations that early brain damage might present as behavioral and learning problems in later childhood. Foreshadowing current views of treatment, both Still (1902) and Tredgold found that temporary improvements in conduct might be achieved by alterations in the environment or by medications, but they stressed the relative permanence of the defect even in these cases. They emphasized the need for special educational environments for these children. We see here the origins of many later and even current notions about children with ADHD and oppositional defiant disorder (ODD), although it would take almost 70 years to return to many of them—owing in part to the ascendance in the interim of psychoanalytic, psychodynamic, and behavioral views that overemphasized childrearing as largely causing such behavioral disorders in children. The children described by Still and Tredgold would probably now be diagnosed as having not only ADHD but also ODD or conduct disorder (CD), and most likely a learning disability as well (see Chapters 5 and 6).

Around this same time, in Spain, the physician Rodriguez-Lafora (1917) wrote about his interests in childhood mental illness and described a group of children having psychopathic constitutions, a subset of which he called the "unstables." His description of them matches closely the modern view of ADHD (Bauermeister & Barkley, 2010), including inconstancy of attention, excessive activity, and impulsive behavior, as does his observation that such children get carried away by their adventurous temperament.

The Influence of the Encephalitis Epidemic

The history of interest in ADHD in North America can be traced to the outbreak of an encephalitis epidemic in 1917–1918, when clinicians were presented with a number of children who survived this brain infection but were left with significant behavioral and cognitive sequelae (Cantwell, 1981; Kessler, 1980; Stewart, 1970). Numerous articles that reported these sequelae (Ebaugh, 1923; Strecker & Ebaugh, 1924; Stryker, 1925) included many of the characteristics we now incorporate into the concept of ADHD. Such children were described as being impulsive and having impaired attention and regulation of activity, as well as impairments in other cognitive abilities, including memory; they were often noted to be socially disruptive as well. Symptoms of what is now called ODD, as well as delinquency and CD, also arose in some cases. "Postencephalitic behavior disorder," as it was called, was clearly the result of brain damage. The large number of affected

children resulted in significant professional and educational interest in this behavioral disorder. Its severity was such that many children were recommended for care and education outside the home and away from normal educational facilities. Despite a rather pessimistic view of the prognosis of these children, some facilities reported significant success in their treatment with simple behavior modification programs and increased supervision (Bender, 1942; Bond & Appel, 1931).

The Origins of a Brain Damage Syndrome

This association of a brain disease with behavioral pathology apparently led early investigators to study other, potential causes of brain injury in children and their behavioral manifestations, including birth trauma (Shirley, 1939); other infections besides encephalitis, such as measles (Meyer & Byers, 1952); lead toxicity (Byers & Lord, 1943); epilepsy (Levin, 1938); and head injury (Blau, 1936; Werner & Strauss, 1941). All were studied in children and found to be associated with numerous cognitive and behavioral impairments, including the triad of ADHD symptoms noted earlier. Other terms introduced during this era for children displaying these behavioral characteristics were "organic driveness" (Kahn & Cohen, 1934) and "restlessness" syndrome (Childers, 1935; Levin, 1938). Many of the children seen in these samples also had mental retardation or more serious behavioral disorders than what is today called ADHD. It would take investigators several decades to attempt to parse out the separate contributions of intellectual delay, learning disabilities, or other neuropsychological deficits from those of behavioral deficits in the maladjustment of these children. Even so, scientists at this time would discover that activity level was often inversely related to intelligence in children, increasing as intelligence declined in a sample—a finding supported in many subsequent studies (Rutter, 1989). It should also be noted that a large number of children in these older studies did in fact have brain damage or signs of such damage (epilepsy, hemiplegias, etc.).

Notable during this era was also recognition of the striking similarity between hyperactivity in children and the behavioral sequelae of frontal lobe lesions in primates (Blau, 1936; Levin, 1938). Frontal lobe ablation studies of monkeys had been done more than 60 years earlier (Ferrier, 1876), and the lesions were known to result in excessive restlessness, poor ability to sustain interest in activities, aimless wandering, and excessive appetite, among other behavioral changes. Several investigators, such as Levin (1938), used these similarities to postulate that severe restlessness in children might well be the result of pathological defects in the forebrain structures, although gross evidence of such was not always apparent in many of these children. Later, investigators (e.g., Barkley, 1997a; Chelune, Ferguson, Koon, & Dickey, 1986; Lou, Henriksen, & Bruhn, 1984; Lou, Henriksen, Bruhn, Borner, & Nielsen, 1989; Mattes, 1980) would return to this notion, but with greater evidence to substantiate their claims. Milder forms of hyperactivity, in contrast, were attributed in this era to psychological causes, such as "spoiled" child-rearing practices or delinquent family environments. This idea that poor or disrupted parenting causes ADHD would also be resurrected in the 1970s, and it continues even today among many laypeople and critics of ADHD.

Over the next decade, it became fashionable to consider most children hospitalized in psychiatric facilities with this symptom picture to have suffered from some type of brain damage (e.g., encephalitis or prenatal–perinatal trauma), whether or not there was evidence of such in the clinical history of the case. The concept of the "brain-injured child" was born in this era (Strauss & Lehtinen, 1947) and applied to children with these behavioral characteristics, many of whom had insufficient or no evidence of brain pathology. In fact, Strauss and Lehtinen argued that the psychological disturbances alone were de facto evidence of brain injury as the etiology. Owing in part to the absence of such evidence of brain damage, this term would later evolve into the concept of "minimal brain damage" and eventually "minimal brain dysfunction" (MBD) by the 1950s and 1960s. Even so, a few early investigators, such as Childers (1935), would raise serious questions about the notion of brain damage in these children when no historical documentation of damage existed. Substantial recommendations for educating these "brain-damaged" children were made in the earlier text by Tredgold (1908) and later in the classic text on special education by Strauss and Lehtinen (1947), which served as a forerunner to special educational services adopted much later in U.S. public schools. These recommendations included placing these children in smaller, more carefully regulated classrooms and reducing the amount of distracting stimulation in the environment. Strikingly austere classrooms were developed,

in which teachers avoided wearing jewelry or brightly colored clothing, and few pictures adorned the walls so as not to interfere unnecessarily with the education of these highly distractible students.

Although the population served by the Pennsylvania center in which Strauss, Werner, and Lehtinen worked principally contained children with mental retardation, the work of Cruickshank and his students (Dolphin & Cruickshank, 1951a, 1951b, 1951c) later extended these neuropsychological findings to children with cerebral palsy but near-normal or normal intelligence. This extension resulted in the extrapolation of the educational recommendations of Strauss to children without mental retardation who manifested behavioral or perceptual disturbances (Cruickshank & Dolphin, 1951; Strauss & Lehtinen, 1947). Echoes of these recommendations are still commonplace today in most educational plans for children with ADHD or learning disabilities, despite the utter lack of scientific support for their efficacy (Kessler, 1980; Routh, 1978; Zentall, 1985). These classrooms are historically significant because they were predecessors as well as instigators of the types of educational resources that would be incorporated into the initial Education for All Handicapped Children Act of 1975 (Public Law 94-142) mandating the special education of children with learning disabilities and behavioral disorders, and its later reauthorization, the Individuals with Disabilities Education Act of 1990 (IDEA; Public Law 101-476).

The Beginnings of Child Psychopharmacology for ADHD

Another significant series of articles on the treatment of hyperactive children appeared from 1937 to 1941. They marked the beginnings of medication therapy (particularly stimulants) for behaviorally disordered children in particular, as well as the field of child psychopharmacology in general (Bradley, 1937; Bradley & Bowen, 1940; Molitch & Eccles, 1937). Initiated originally to treat the headaches that resulted from conducting pneumoencephalograms during research studies of these disruptive youth, the administration of amphetamine resulted in a noticeable improvement in their behavioral problems and academic performance. Later studies would also confirm such a positive drug response in half or more of hyperactive hospitalized children (Laufer, Denhoff, & Solomons, 1957). As a result, by the 1970s, stimulant medications were gradually becoming the treatment of choice for the behavioral symptoms now associated with ADHD. And so they remain today (see Chapter 27).

The Emergence of a Hyperkinetic Impulse Syndrome

In the 1950s, researchers began a number of investigations into the neurological mechanisms underlying these behavioral symptoms, the most famous of which was probably that by Laufer and colleagues (1957). These writers referred to children with ADHD as having "hyperkinetic impulse disorder," and reasoned that the central nervous system (CNS) deficit occurred in the thalamic area. Here, poor filtering of stimulation occurred, allowing an excess of stimulation to reach the brain. The evidence was based on a study of the effects of the "photo-Metrozol" method, in which the drug metronidazole (Metrozol) is administered while flashes of light are presented to a child. The amount of drug required to induce a muscle jerk of the forearms, along with a spike wave pattern on the electroencephalogram (EEG), serves as the measure of interest. Laufer and colleagues found that inpatient children with hyperactivity required less Metrozol than those without hyperactivity to induce this pattern of response. This finding suggested that the hyperactive children had a lower threshold for stimulation, possibly in the thalamic area. No attempts to replicate this study have been done, and it is unlikely that such research would pass today's standards of ethical conduct in research required by institutional review boards on research with human subjects. Nevertheless, it remains a milestone in the history of the disorder for its delineation of a more specific mechanism that might give rise to hyperactivity (low cortical thresholds or overstimulation). Others at the time also conjectured that the existence of an imbalance between cortical and subcortical areas caused diminished control of subcortical areas responsible for sensory filtering that permitted excess stimulation to reach the cortex (Knobel, Wolman, & Mason, 1959).

By the end of this era, it seemed well accepted that hyperactivity was a brain damage syndrome, even when evidence of damage was lacking. The disorder was thought to be best treated through educational classrooms characterized by reduced stimulation or through residential centers. Its prognosis was considered fair to poor. The possibility that a relatively new class of medications, the stimulants, might hold promise for its treatment was beginning to be appreciated.

THE PERIOD 1960 TO 1969

The Decline of MBD and the Rise of Hyperactivity

In the late 1950s and early 1960s, critical reviews began to question the concept of a unitary syndrome of brain damage in children. They also pointed out the logical fallacy that if brain damage resulted in some of these behavioral symptoms, these symptoms could be pathognomonic of brain damage without any other corroborating evidence of CNS lesions. Chief among these critical reviews were those of Birch (1964), Herbert (1964), and Rapin (1964), who questioned the validity of applying the concept of brain damage to children who had only equivocal signs of neurological involvement, not necessarily damage. A plethora of research followed on children with MBD (see Rie & Rie, 1980, for reviews); in addition, a task force by the National Institute of Neurological Diseases and Blindness (Clements, 1966) recognized at least 99 symptoms for this disorder. The concept of MBD would die a slow death as it eventually was recognized to be vague, overinclusive, of little or no prescriptive value, and without much neurological evidence (Kirk, 1963). Its remaining value was its emphasis on neurological mechanisms over the often excessive, pedantic, and convoluted environmental mechanisms proposed at that time—particularly those etiological hypotheses stemming from psychoanalytical theory, which blamed parental and family factors entirely for these problems (Hertzig, Bortner, & Birch, 1969; Kessler, 1980; Taylor, 1983). The term "MBD" would eventually be replaced by more specific labels applying to somewhat more homogeneous cognitive, learning, and behavioral disorders, such as "dyslexia," "language disorders," "learning disabilities," and "hyperactivity." These new labels were based on children's observable and descriptive deficits rather than on some underlying, unobservable etiological mechanism in the brain.

The Hyperactivity Syndrome

As dissatisfaction with the term "MBD" was occurring, clinical investigators shifted their emphasis to the behavioral symptom thought to most characterize the disorder—that of hyperactivity. And so the concept of a hyperactivity syndrome arose, described in the classic articles by Laufer and Denhoff (1957), Chess (1960), and other reports of this era (Burks, 1960; Ounsted, 1955; Prechtl & Stemmer, 1962). Chess defined "hyperactivity" as follows: "The hyperactive child is one who carries out activities at a higher than normal rate of speed than the average child, or who is constantly in motion, or both" (p. 2379). Chess's article was historically significant for several reasons: (1) It emphasized activity as the defining feature of the disorder rather than speculation about underlying neurological causes, as other scientists of the time would also do; (2) it stressed the need to consider objective evidence of the symptom beyond the subjective reports of parents or teachers; (3) it took the blame for the child's problems away from the parents; and (4) it separated the syndrome of hyperactivity from the concept of a brain damage syndrome. Other scientists of this era would emphasize similar points (Werry & Sprague, 1970). Hyperactivity would now be recognized as a behavioral syndrome that could not only arise from organic pathology but also occur in its absence. Even so, it would continue to be viewed as the result of some biological difficulty rather than as being due solely to environmental causes.

Chess (1960) described the characteristics of 36 children diagnosed with "physiological hyperactivity" from a total of 881 children seen in a private practice. The ratio of males to females was approximately 4:1, and many children were referred prior to 6 years of age, intimating a relatively earlier age of onset than that for other childhood behavioral disorders. Educational difficulties were common in this group, particularly scholastic underachievement, and many displayed oppositional defiant behavior and poor peer relationships. Impulsive and aggressive behaviors, as well as poor attention span, were commonly associated characteristics. Chess believed that the hyperactivity could also be associated with mental retardation, organic brain damage, or serious mental illness (e.g., schizophrenia). Similar findings in later research would lead others to question the specificity and hence the utility of this symptom for the diagnosis of ADHD (Douglas, 1972). As with many of today's prescriptions, a multimodal treatment approach incorporating parent counseling, behavior modification, psychotherapy, medication, and special education was recommended. Unlike Still (1902), Chess and others writing in this era stressed the relatively benign nature of hyperactivity's symptoms and claimed that in most cases they resolved by puberty (Laufer & Denhoff, 1957; Solomons, 1965). Here, then, were the beginnings of a belief that would be widely held among clinicians well into the 1980s—that hyperactivity (ADHD) was outgrown by adolescence.

Also noteworthy in this era was the definition of hyperactivity given in the official diagnostic nomenclature at the time, the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II; American Psychiatric Association, 1968). It employed only a single sentence describing the hyperkinetic reaction of childhood disorder and, following the lead of Chess (1960), stressed the view that the disorder was developmentally benign: "The disorder is characterized by overactivity, restlessness, distractibility, and short attention span, especially in young children; the behavior usually diminishes by adolescence" (p. 50).

Europe and North America Diverge in Viewpoints

It is likely that during this period (or even earlier), the perspective on hyperactivity in North America began to diverge from that in Europe, particularly Great Britain. In North America, hyperactivity would become a behavioral syndrome recognized chiefly by greater-than-normal levels of activity; would be viewed as a relatively common disturbance of childhood; would not necessarily be associated with demonstrable brain pathology or mental retardation; and would be regarded as more of an extreme degree in the normal variation of temperament in children. In Great Britain, the earlier and narrower view of a brain damage syndrome would continue into the 1970s: Hyperactivity or hyperkinesis was seen as an extreme state of excessive activity of an almost driven quality; was viewed as highly uncommon; and was usually thought to occur in conjunction with other signs of brain damage (e.g., epilepsy, hemiplegias, or mental retardation) or a clearer history of brain insult (e.g., trauma or infection) (Taylor, 1988). The divergence in views would lead to large discrepancies between North American and European estimations of the prevalence of the disorder, their diagnostic criteria, and their preferred treatment modalities. A rapprochement between these views would not occur until well into the 1980s (Rutter, 1988, 1989; Taylor, 1986, 1988).

The Prevailing View by 1969

As Ross and Ross (1976) noted in their exhaustive and scholarly review of the era, the perspective on hyperactivity in the 1960s was that it remained a brain dysfunction syndrome, although of a milder magnitude than previously believed. The disorder was no longer ascribed to brain damage; instead, a focus on brain mechanisms prevailed. The disorder was also viewed as having a predominant and relatively homogeneous set of symptoms, chief among which was excessive activity level or hyperactivity. Its prognosis was now felt to be relatively benign because it was believed to be often outgrown by puberty. The recommended treatments now consisted of short-term treatment with stimulant medication and psychotherapy, in addition to the minimum-stimulation types of classrooms recommended in earlier years.

THE PERIOD 1970 TO 1979

Research in the 1970s took a quantum leap forward, with more than 2,000 published studies by the time the decade ended (Weiss & Hechtman, 1979). Numerous clinical and scientific textbooks (Cantwell, 1975; Safer & Allen, 1976; Trites, 1979; Wender, 1971) appeared, along with a most thorough and scholarly review of the literature by Ross and Ross (1976). Special journal issues were devoted to the topic (Barkley, 1978; Douglas, 1976), along with numerous scientific gatherings (Knights & Bakker, 1976, 1980). Clearly, hyperactivity had become a subject that attracted serious professional, scientific, and popular attention.

By the early 1970s, the defining features of hyperactivity or hyperkinesis were broadened to include what investigators previously felt to be only associated characteristics, including impulsivity, short attention span, low frustration tolerance, distractibility, and aggressiveness (Marwitt & Stenner, 1972; Safer & Allen, 1976). Others (Wender, 1971, 1973) persisted with the excessively inclusive concept of MBD, in which even more features (e.g., motor clumsiness, cognitive impairments, and parent–child conflict) were viewed as hallmarks of the syndrome, and in which hyperactivity was unnecessary for the diagnosis. As noted earlier, the diagnostic term "MBD" would fade from clinical and scientific usage by the end of this decade—the result in no small part of the scholarly tome by Rie and Rie (1980) and critical reviews by Rutter (1977, 1982). These writings emphasized the lack of evidence for such a broad syndrome. The symptoms were not well defined, did not correlate significantly among themselves, had no well-specified etiology, and displayed no common course and outcome. The heterogeneity of the disorder was overwhelming, and more than a few commentators took note of the apparent hypocrisy in defin-

ing an MBD syndrome with the statement that there was often little or no evidence of neurological abnormality (Wender, 1971). Moreover, even in cases of well-established cerebral damage, the behavioral sequelae were not uniform across cases, and hyperactivity was seen in only a minority of individuals. Hence, contrary to 25 years of theorizing to this point, hyperactivity was not a common sequela of brain damage; children with true brain damage did not display a uniform pattern of behavioral deficits; and children with hyperactivity rarely had substantiated evidence of neurological damage (Rutter, 1989).

Wender's Theory of MBD

This decade was notable for two different models of the nature of ADHD (see also Barkley, 1998): Wender's theory of MBD (outlined here) and Douglas's model of attention and impulse control in hyperactive children (discussed in a later section). At the start of the decade, Wender (1971) described the essential psychological characteristics of children with MBD as comprising six clusters of symptoms: problems in (1) motor behavior, (2) attentional and perceptual–cognitive functioning, (3) learning, (4) impulse control, (5) interpersonal relations, and (6) emotion. Many of the characteristics first reported by Still (1902) were echoed by Wender (1971) within these six domains of functioning.

1. Within the realm of motor behavior, the essential features were noted to be hyperactivity and poor motor coordination. Excessive speech, colic, and sleeping difficulties were thought to be related to the hyperactivity. Foreshadowing the later official designation of a group of children with attentional problems but without hyperactivity (American Psychiatric Association, 1980), Wender (1971) expressed the opinion that some of these children who were hypoactive and listless still demonstrated attention disturbances. Such cases might now be considered to have the predominantly inattentive type of ADHD. He argued that they should be viewed as having this syndrome because of their manifestation of many of the other difficulties thought to characterize it.

2. Short attention span and poor concentration were described as the most striking deficits in the domain of attention and perceptual–cognitive functioning. Distractibility and daydreaming were also included with these attention disturbances, as was poor organization of ideas or percepts.

3. Learning difficulties were another domain of dysfunction, with most of these children observed to be doing poorly in their academic performance. A large percentage were described as having specific difficulties with learning to read, with handwriting, and with reading comprehension and arithmetic.

4. Impulse control problems, or a decreased ability to inhibit behavior, were identified as a characteristic of most children with MBD. Within this general category, Wender (1971) included low frustration tolerance; an inability to delay gratification; antisocial behavior; lack of planning, forethought, or judgment; and poor sphincter control, leading to enuresis and encopresis. Disorderliness or lack of organization and recklessness (particularly with regard to bodily safety) were also listed within this domain of dysfunction.

5. In the area of interpersonal relations, Wender (1971) singled out the unresponsiveness of these children to social demands as the most serious. Extraversion, excessive independence, obstinence, stubbornness, negativism, disobedience, noncompliance, sassiness, and imperviousness to discipline were some of the characteristics that instantiated the problem with interpersonal relations.

6. Finally, within the domain of emotional difficulties, Wender (1971) included increased lability of mood, altered reactivity, increased anger, aggressiveness, and temper outbursts, as well as dysphoria. The dysphoria of these children involved the specific difficulties of anhedonia, depression, low self-esteem, and anxiety. A diminished sensitivity to both pain and punishment was also felt to typify this area of dysfunction in children with MBD. All these symptoms bear a striking resemblance to the case descriptions that Still (1902) had provided in lectures to support his contention that a defect in moral control and volitional inhibition could exist in children apart from intellectual delay.

Wender (1971) theorized that these six domains of dysfunction could be best accounted for by three primary deficits: (1) a decreased experience of pleasure and pain, (2) a generally high and poorly modulated level of activation, and (3) extraversion. A consequence of the first deficit was that children with MBD would prove less sensitive to both reward and punishment, making them less susceptible to social influence. The generally high and poorly modulated level of activation was thought to be an aspect of poor inhibition. Hyperactivity, of course, was the consummate demon-

stration of this high level of activation. The problems with poor sustained attention and distractibility were conjectured to be secondary aspects of high activation. Emotional overreactivity, low frustration tolerance, quickness to anger, and temper outbursts resulted from the poor modulation of activation. These three primary deficits, then, created a cascade of effects into the larger social ecology of these children, resulting in numerous interpersonal problems and academic performance difficulties.

Like Still (1902), Wender (1971) gave a prominent role to the construct of poor inhibition. He believed that it explained the activation difficulties and the attention problems stemming from them, as well as the excessive emotionality, the low frustration tolerance, and the hot-temperedness of these children. It is therefore quite puzzling why deficient inhibition was not made a primary symptom in this theory, in place of high activation and poor modulation of activation.

Unlike Still (1902), who attempted to devise a theory, however, Wender (1971) did not say much about normal developmental processes with respect to the three primary areas of deficit, and therefore did not clarify more precisely what might be going awry in them to give rise to these characteristics of MBD. The exception was his discussion of a diminished sensitivity to the reasonably well-understood processes of reinforcement and punishment. A higher-than-normal threshold for pleasure and pain, as noted earlier, was thought to create these insensitivities to behavioral consequences.

From a present-day perspective, Wender (1971) is also unclear about a number of issues. For instance, how would the three primary deficits account for the difficulties with motor coordination that occurred alongside hyperactivity in his category of motor control problems? It is doubtful that the high level of activation that was said to cause the hyperactivity would also cause these motor deficits. Nor is it clear just how the academic achievement deficits in reading, math, and handwriting could arise from the three primary deficits in the model. It is also unclear why the construct of extraversion needed to be proposed at all, if what Wender meant by it was reduced social inhibition. This model might be just as parsimoniously explained by the deficit in behavioral inhibition already posited. And the meaning of the term "activation" as used by Wender is not very clearly specified. Did it refer to excessive behavior, in which case hyperactivity would have sufficed? Or did it refer to level of CNS arousal, in which case ample subsequent evidence has not found this to be the case (Hastings & Barkley, 1978; Rosenthal & Allen, 1978)? To his credit, Wender recognized the abstract nature of the term "activation" as he employed it in this theory but retained it because he felt it could be used to incorporate both hyperactivity and hypoactivity in children. It is never made clear just how this could be the case, however. Finally, Wender failed to distinguish symptoms from their consequences (impairments). The former would be the behavioral manifestations directly associated with or stemming from the disorder itself, such as impulsiveness, inattention, distractibility, and hyperactivity. The latter would be the effects of these behaviors on the social environment, such as interpersonal conflict within the family, poor educational performance, peer rejection, and accident proneness, to name just a few.

From the advantage of hindsight and subsequent research over the decades since the formulation of this theory, it is also evident that Wender (1971) was combining the symptoms of ODD (and even CD) with those of ADHD to form a single disorder. Still (1902) did very much the same thing. This was understandable given that clinic-referred cases were the starting point for both theories, and many clinic-referred cases are comorbid for both disorders (ADHD and ODD). However, sufficient accumulated evidence has subsequently shown that ADHD and ODD are not the same disorder (August & Stewart, 1983; Hinshaw, 1987; Stewart, deBlois, & Cummings, 1980).

The Emergence of a Central Place for Attention Deficits

At this time, disenchantment developed over the exclusive focus on hyperactivity as the sine qua non of this disorder (Werry & Sprague, 1970). Significant at this historical juncture would be the article based on the presidential address of Virginia Douglas (1972) to the Canadian Psychological Association. She argued that deficits in sustained attention and impulse control were more likely than just hyperactivity to account for the difficulties seen in these children. These other symptoms were also seen as the major areas on which the stimulant medications used to treat the disorder had their impact. Douglas's article was historically significant in other ways as well. Her extensive and thorough battery of objective measures of various behavioral and cognitive domains, heretofore unused in research on ADHD, allowed her to rule in or out

various characteristics felt to be typical for these children in earlier clinical and scientific lore. For instance, Douglas found that hyperactive children did not necessarily and uniformly have more reading or other learning disabilities than other children, did not perseverate on concept-learning tasks, did not manifest auditory or right–left discrimination problems, and had no difficulties with short-term memory. Most important, she and Susan Campbell (1973) demonstrated that children with hyperactivity were not always more distractible than children without it, and that the sustained attention problems could emerge in conditions in which no significant distractions existed.

The McGill University research team headed by Douglas repeatedly demonstrated that hyperactive children had some of their greatest difficulties on tasks assessing vigilance or sustained attention, such as the continuous-performance test (CPT). These findings would be repeatedly reconfirmed over the next 30 years of research using CPTs (Corkum & Siegel, 1993; Frazier, Demareem, & Youngstrom, 2004). Variations of this test would eventually be standardized and commercially marketed for diagnosis of the disorder (Conners, 1995; Gordon, 1983; Greenberg & Waldman, 1992). Douglas (1972) remarked on the extreme degree of variability demonstrated during task performances by these children—a characteristic that would later be advanced as one of the defining features of the disorder. The McGill team (Freibergs, 1965; Freibergs & Douglas, 1969; Parry & Douglas, 1976) also found that hyperactive children could perform at normal or near-normal levels of sustained attention under conditions of continuous and immediate reinforcement, but that their performance deteriorated dramatically when partial reinforcement was introduced, particularly at schedules below 50% reinforcement. Campbell, Douglas, and Morgenstern (1971) further demonstrated substantial problems with impulse control and field dependence in the cognitive styles of hyperactive children. Like Still (1902), roughly 70 years earlier, Douglas commented on the probable association between deficits in attention–impulse control and deficiencies in moral development that were plaguing her subjects, particularly in their adolescent years. The research of the McGill team showed dramatic improvements in these attention deficiencies during stimulant medication treatment, as did the research at other laboratories at the time (Conners & Rothschild, 1968; Sprague, Barnes, & Werry, 1970).

Finally, of substantial significance were the observations of Douglas's colleague, Gabrielle Weiss, from her follow-up studies (see Weiss & Hechtman, 1986) that although the hyperactivity of these children often diminished by adolescence, their problems with poor sustained attention and impulsivity persisted. This persistence of the disabilities and the risk for greater academic and social maladjustment would be identified by other research teams from their own follow-up investigations (Mendelson, Johnson, & Stewart, 1971), and would be better substantiated by more rigorous studies in the next two decades (see Barkley, Fischer, Edelbrock, & Smallish, 1990; Barkley, Fischer, Smallish, & Fletcher, 2002; Gittelman, Mannuzza, Shenker, & Bonagura, 1985).

Douglas's Model of Attention Deficits

Douglas (1980a, 1980b, 1983; Douglas & Peters, 1979) later elaborated, refined, and further substantiated her model of hyperactivity, which culminated in the view that four major deficits could account for symptoms of ADHD: (1) the investment, organization, and maintenance of attention and effort; (2) the inhibition of impulsive responding; (3) the modulation of arousal levels to meet situational demands; and (4) an unusually strong inclination to seek immediate reinforcement. This perspective initiated or guided a substantial amount of research over the next 15 years, including my own early studies (Barkley, 1977, 1989b; Barkley & Ullman, 1975). It constituted a model as close to a scientific paradigm as the field of hyperactivity was likely to have in its history to that point. Yet over the next 10 years results that emerged were somewhat at odds with this perspective. Scientists began seriously to question both the adequacy of an attention model in accounting for the varied behavioral deficits seen in children with ADHD and the effects of stimulant medications on them (Barkley, 1981, 1984; Draeger, Prior, & Sanson, 1986; Haenlein & Caul, 1987; van der Meere & Sergeant, 1988a, 1988b). Also deserving of mention is that such a description of deficiencies constitutes a pattern and not a theory, given that it stipulates no conditional relations among its parts or how they orchestrate to create the problems seen in the disorder. That is, it makes no testable or falsifiable predictions apart from those contained in the pattern so described.

Douglas's article and the subsequent research published by her team were so influential that they were probably the major reasons the disorder was renamed attention deficit disorder (ADD) in 1980 with the publication of DSM-III (American Psychiatric Associa-

tion, 1980). In this revised official taxonomy, deficits in sustained attention and impulse control were formally recognized as being of greater significance in the diagnosis than hyperactivity. The shift to attention deficits rather than hyperactivity as the major difficulty of these children was useful, at least for a time, because of the growing evidence (1) that hyperactivity was not specific to this particular condition but could be noted in other psychiatric disorders (anxiety, mania, autism, etc.); (2) that there was no clear delineation between "normal" and "abnormal" levels of activity; (3) that activity was in fact a multidimensional construct; and (4) that the symptoms of hyperactivity were quite situational in nature in many children (Rutter, 1989). But this approach corrected the problem of definition for little more than a decade before these same concerns were also raised about the construct of attention (multidimensional, situationally variable, etc.). Yet some research would show that at least deficits in vigilance or sustained attention could be used to discriminate this disorder from other psychiatric disorders (Werry, 1988).

Other Developments of the Era

A number of other historical developments during this period deserve mention.

The Rise of Medication Therapy

The first of these developments was the rapidly increasing use of stimulant medication with school-age hyperactive children. This use was no doubt spawned by the significant increase in research showing that stimulants often had dramatic effects on these children's hyperactive and inattentive behavior. A second development was the use of much more rigorous scientific methodology in drug studies, due in large measure to the early studies by C. Keith Conners (then working with Leon Eisenberg at Harvard University), and somewhat later to the research of Robert Sprague at the University of Illinois, Virginia Douglas at McGill University, and John Werry in New Zealand. This body of literature became voluminous (see Barkley, 1977; Ross & Ross, 1976), with more than 120 studies published through 1976 and more than twice this number by 1995 (Swanson, McBurnett, Christian, & Wigal, 1995), making this treatment approach the most well-studied therapy in child psychiatry.

Despite the proven efficacy of stimulant medication, public and professional misgivings about its increasingly widespread use with children emerged. For example, one news account (Maynard, 1970) reported that in Omaha, Nebraska, as much as 5–10% of the children in grade schools were receiving behavior-modifying drugs. This estimate of drug treatment would later be shown to be grossly exaggerated, as much as 10-fold, due to a misplaced decimal point in the story. And this would certainly not be the last instance of the mass media's penchant for hyperbole, sensation, and scandal in their accounts of stimulant medication treatments for ADHD—a penchant that seems only to have increased over subsequent years. Yet the public interest that was generated by the initial reports led to a congressional review of the use of psychotropic medications for schoolchildren. At this same time, the claim was being advanced that hyperactivity was a "myth" arising from intolerant teachers and parents, and an inadequate educational system (Conrad, 1975; Schrag & Divoky, 1975).

Environment as Etiology

Almost simultaneous with this backlash against "drugging" schoolchildren for behavior problems was another significant development in that decade: a growing belief that hyperactivity was a result of environmental causes. It is not just coincidental that this development occurred at the same time that the United States was experiencing a popular interest in natural foods, health consciousness, the extension of life expectancy via environmental manipulations, psychoanalytic theory, and behaviorism. An extremely popular view was that allergic or toxic reactions to food additives, such as dyes, preservatives, and salicylates (Feingold, 1975), caused hyperactive behavior. It was claimed that more than half of all hyperactive children had developed their difficulties because of diet. Effective treatment could be had if families of these children would buy or make foods that did not contain the offending substances. This view became so widespread that organized parent groups or "Feingold associations," comprised mainly of parents advocating Feingold's diet, were established in almost every U.S. state, and legislation was introduced (although not passed) in California requiring that all school cafeteria foods be prepared without these substances. A sizable number of research investigations was undertaken (see Conners, 1980, for a review), the more rigorous of which found these substances to have little, if any, effect on children's behavior. A National Advisory Committee on Hyperkinesis and Food Addi-

tives (1980) that was convened to review this literature concluded more strongly than Conners that the available evidence clearly refuted Feingold's claims. Nevertheless, it would be more than 10 years before this notion receded in popularity, to be replaced by the equally unsupported hypothesis that refined sugar was more to blame for hyperactivity than were food additives (for reviews, see Milich, Wolraich, & Lindgren, 1986; Wolraich, Wilson, & White, 1995).

The emphasis on environmental causes, however, spread to include possible sources other than diet. Block (1977) advanced the rather vague notion that technological development and more rapid cultural change would result in an increasing societal "tempo," causing growing excitation or environmental stimulation. This excitation or stimulation would interact with a predisposition in some children toward hyperactivity, making it manifest. It was felt that this theory explained the apparently increasing incidence of hyperactivity in developed cultures. Ross and Ross (1982) provided an excellent critique of the theory and concluded that there was insufficient evidence in support of it and some that would contradict it. Little evidence suggested that hyperactivity incidence was increasing, though its identification among children may well have been. Nor was there evidence that its prevalence varied as a function of societal development. Instead, Ross and Ross proposed that cultural effects on hyperactivity have more to do with whether important institutions of enculturation are consistent or inconsistent in the demands made and standards set for child behavior and development. These cultural views were said to determine the threshold for deviance that will be tolerated in children, as well as to exaggerate a predisposition to hyperactivity in some children. Consistent cultures will have fewer children diagnosed with hyperactivity, as they minimize individual differences among children and provide clear and consistent expectations and consequences for behavior that conforms to the expected norms. Inconsistent cultures, by contrast, will have more children diagnosed with hyperactivity, as they maximize or stress individual differences and provide ambiguous expectations and consequences to children regarding appropriate conduct. This intriguing hypothesis remains unstudied. However, on these grounds, an equally compelling case could be made for the opposite effects of cultural influences: In highly consistent, highly conforming cultures, hyperactive behavior may be considerably more obvious in children as they are unable to conform to these societal expectations, whereas inconsistent and low-conforming cultures may tolerate deviant behavior to a greater degree as part of the wider range of behavioral expression they encourage.

A different environmental view—that poor childrearing generally and poor child behavior management specifically lead to hyperactivity—was advanced by schools of psychology/psychiatry at diametrically opposite poles. Both psychoanalysts (Bettelheim, 1973; Harticollis, 1968) and behaviorists (Willis & Lovaas, 1977) promulgated this view, though for very different reasons. The psychoanalysts claimed that parents lacking tolerance for negative or hyperactive temperament in their infants would react with excessively negative, demanding parental responses, giving rise to clinical levels of hyperactivity. The behaviorists stressed poor conditioning of children to stimulus control by commands and instructions that would give rise to noncompliant and hyperactive behavior. Both groups singled out mothers as especially etiologically important in this causal connection, and both could derive some support from studies that found negative mother–child interactions in the preschool years to be associated with the continuation of hyperactivity into the late childhood (Campbell, 1987) and adolescent (Barkley, Fischer, et al., 1990) years.

However, such correlational data cannot prove a cause. They do not prove that poor childrearing or negative parent–child interactions cause hyperactivity; they only show that such factors are associated with its persistence. It could just as easily be that the severity of hyperactivity elicits greater maternal negative reactions, and that this severity is related to persistence of the disorder over time. Supporting this interpretation are the studies of stimulant drug effects on the interactions of mothers and their hyperactive children, which show that mothers' negative and directive behavior is greatly reduced when stimulant medication is used to reduce the hyperactivity in their children (Barkley, 1989b; Barkley & Cunningham, 1979; Barkley, Karlsson, Pollard, & Murphy, 1985; Danforth, Barkley, & Stokes, 1991). Moreover, follow-up studies show that the degree of hyperactivity in childhood is predictive of its own persistence into later childhood and adolescence, apart from its association with maternal behavior (Barkley, Fischer, et al., 1990; Campbell & Ewing, 1990). And given the dramatic hereditary contribution to ADHD, it is also just as likely that the more negative, impulsive, emotional, and inattentive behavior of mothers with their hyperactive children stems in

part from the mothers' own ADHD—a factor that has never been taken into account in the analysis of such data or in interpreting findings in this area. Nevertheless, family context would still prove to be important in predicting the outcome of hyperactive children, even though the mechanism of its action was not yet specified (Weiss & Hechtman, 1986). Parent training in child behavior management, furthermore, would be increasingly recommended as an important therapy in its own right (Dubey & Kaufman, 1978; Pelham, 1977), despite a paucity of studies concerning its actual efficacy at the time (Barkley, 1989c).

The Passage of Public Law 94-142

Another highly significant development was the passage of Public Law 94-142 in 1975, mandating special educational services for children with physical, learning, and behavioral disabilities, in addition to those services already available for mental retardation (see Henker & Whalen, 1980, for a review of the legal precedents leading up to this law). Although many of its recommendations were foreshadowed by Section 504 of the Rehabilitation Act of 1973 (Public Law 93-112), the financial incentives for the states associated with the adoption of Public Law 94-142 probably encouraged its immediate and widespread implementation by them all. Programs for learning disabilities, behavioral–emotional disturbance, language disorders, physical handicaps, and motor disabilities, among others, were now required to be provided to all eligible children in all public schools in the United States.

The full impact of these widely available educational treatment programs for hyperactive children has not yet been completely appreciated, for several reasons. First, hyperactivity, by itself, was overlooked in the initial criteria set forth for behavioral and learning disabilities warranting eligibility for these special classes. Children with such disabilities typically also had to have another condition, such as a learning disability, language delay, or emotional disorder, to receive exceptional educational services. The effects of special educational resources on the outcome of hyperactivity are difficult to assess given this confounding of multiple disorders. It was only after the passage of IDEA in 1990 (and a subsequent 1991 memorandum) that the U.S. Department of Education and its Office of Special Education chose to reinterpret these regulations, thereby allowing children with ADHD to receive special educational services for ADHD per se under the "Other Health Impaired" category of IDEA. Second, the mandated services had been in existence for only a little more than a decade when the long-term outcome studies begun in the late 1970s began to be reported. Those studies (e.g., Barkley, Fischer, et al., 1990) suggested that over 35% of children with ADHD received some type of special educational placement. Although the availability of these services seems to have reduced the percentage of children with ADHD retained in grade for their academic problems, compared to earlier follow-up studies, the rates of school suspensions and expulsions did not decline appreciably from pre-1977 rates. A more careful analysis of the effects of Public Law 94-142, and especially of its more recent reauthorization as the IDEA, is in order before its efficacy for children with ADHD can be judged.

The Rise of Behavior Modification

This growing emphasis on educational intervention for children with behavioral and learning disorders was accompanied by a plethora of research on the use of behavior modification techniques in the management of disruptive classroom behavior, particularly as an alternative to stimulant medication (Allyon, Layman, & Kandel, 1975; O'Leary, Pelham, Rosenbaum, & Price, 1976). Supported in large part by their successful use for children with mental retardation, behavioral technologies were now being extended to myriad childhood disorders—not only as potential treatments of symptoms but also as theoretical statements of their origins. Although the studies demonstrated considerable efficacy of these techniques in the management of inattentive and hyperactive behavior, they were not found to achieve the same degree of behavioral improvement as the stimulants (Gittelman-Klein et al., 1976), and so did not replace them as a treatment of choice. Nevertheless, opinion was growing that the stimulant drugs should never be used as a sole intervention, but should be combined with parent training and behavioral interventions in the classroom to provide the most comprehensive management approach for the disorder.

Developments in Assessment

Another hallmark of this era was the widespread adoption of the parent and teacher rating scales developed by C. Keith Conners (1969) for the assessment of symptoms of hyperactivity, particularly during trials on stimulant medication. For at least 20 years, these simply constructed ratings of behavioral items would be the "gold standard" for rating children's hyperac-

tivity for both research purposes and treatment with medication. The scales would also come to be used for monitoring treatment responses during clinical trials. Large-scale normative data were collected, particularly for the teacher scale, and epidemiological studies throughout the world relied on both scales for assessing the prevalence of hyperactivity in their populations. Their use moved the practice of diagnosis and the assessment of treatment effects from that of clinical impression alone to one in which at least some structured, semi-objective, and quantitative measure of behavioral deviance was employed. These scales would later be criticized for their confounding of hyperactivity with aggression. This confounding called into question whether the findings of research that relied on the scales were the result of oppositional, defiant, and hostile (aggressive) features of the population or of their hyperactivity (Ullmann, Sleator, & Sprague, 1984). Nevertheless, the widespread adoption of these rating scales in this era marks a historical turning point toward the use of quantitative assessment methods that can be empirically tested and assist in determining developmental patterns and deviance from norms.

Also significant during this decade was the effort to study the social-ecological impact of hyperactive–inattentive behavior. This line of research set about evaluating the effects on family interactions produced by a child with hyperactivity. Originally initiated by Campbell (1973, 1975), this line of inquiry dominated my own research over the next decade (Barkley & Cunningham, 1979; Cunningham & Barkley, 1978, 1979; Danforth et al., 1991), particularly evaluations of the effects of stimulant medication on these social exchanges. These studies showed that children with hyperactivity were much less compliant and more oppositional during parent–child exchanges than children without it, and that their mothers were more directive, commanding, and negative than mothers of nonhyperactive children. These difficulties would increase substantially when the situation changed from free-play to task-oriented demands. Studies also demonstrated that stimulant medication resulted in significant improvements in child compliance and decreases in maternal control and directiveness. Simultaneously, Humphries, Kinsbourne, and Swanson (1978) reported similar effects of stimulant medication, all of which suggested that much of parents' controlling and negative behavior toward hyperactive children was the result rather than the cause of the children's poor self-control and inattention. At the same time, Carol Whalen and Barbara Henker at the University of California–Irvine demonstrated similar interaction conflicts between hyperactive children and their teachers and peers, as well as similar effects of stimulant medication on these social interactions (Whalen & Henker, 1980; Whalen, Henker, & Dotemoto, 1980). This line of research would increase substantially in the next decade, and would be expanded by Charles Cunningham and others to include studies of peer interactions and the effects of stimulants on them (Cunningham, Siegel, & Offord, 1985).

A Focus on Psychophysiology

The decade of the 1970s was also noteworthy for a marked increase in the number of research studies on the psychophysiology of hyperactivity in children. There were numerous published studies measuring galvanic skin response, heart rate acceleration and deceleration, various parameters of the EEG, electropupillography, averaged evoked responses, and other aspects of electrophysiology. Many researchers were investigating the evidence for theories of over- or underarousal of the CNS in hyperactivity—theories that grew out of the speculations in the 1950s on cortical overstimulation and the ideas of both Wender (1971) and Douglas (1972; both discussed earlier) regarding abnormal arousal in the disorder. Most of these studies were seriously methodologically flawed, difficult to interpret, and often contradictory in their findings. Two influential reviews at the time (Hastings & Barkley, 1978; Rosenthal & Allen, 1978) were highly critical of most investigations but concluded that if there was any consistency across findings, it might be that hyperactive children showed a sluggish or underreactive electrophysiological response to stimulation. These reviews laid to rest the belief in an overstimulated cerebral cortex as the cause of the symptoms in hyperactivity, but they did little to suggest a specific neurophysiological mechanism for the observed underreactivity. Further advances in the contributions of psychophysiology to understanding hyperactivity would await further refinements in instrumentation and in definition and diagnosis of the disorder, along with advances in computer-assisted analysis of electrophysiological measures.

An Emerging Interest in Adult MBD or Hyperactivity

Finally, the 1970s should be credited with the emergence of clinical and research interests in the existence of MBD or hyperactivity in adult clinical patients. Ini-

tial interest in adult MBD can be traced to the latter part of the 1960s, seemingly arising as a result of two events. The first of these was the publication of several early follow-up studies demonstrating persistence of symptoms of hyperactivity or MBD into adulthood in many cases (Mendelson et al., 1971; Menkes, Rowe, & Menkes, 1967). The second was the publication by Harticollis (1968) of the results of neuropsychological and psychiatric assessments of 15 adolescent and young adult patients (ages 15–25) seen at the Menninger Clinic. The neuropsychological performance of these patients suggested evidence of moderate brain damage. Their behavioral profile suggested many of the symptoms that Still (1902) initially identified in the children he studied, particularly impulsiveness, overactivity, concreteness, mood lability, and proneness to aggressive behavior and depression. Some of the patients appeared to have demonstrated this behavior uniformly since childhood. Using psychoanalytic theory, Harticollis speculated that this condition arose from an early and possibly congenital defect in the ego apparatus, in interaction with busy, action-oriented, successful parents.

The following year, Quitkin and Klein (1969) reported on two behavioral syndromes in adults that might be related to MBD. The authors studied 105 patients at the Hillside Hospital in Glen Oaks, New York, for behavioral signs of "organicity" (brain damage); behavioral syndromes that might be considered neurological "soft signs" of CNS impairment; and any EEG findings, psychological testing results, or aspects of clinical presentation and history that might differentiate these patients from patients with other types of adult psychopathology. From the initial group of 105 patients, the authors selected those having a childhood history that suggested CNS damage, including early hyperactive and impulsive behavior. These subjects were further sorted into three groups based on current behavioral profiles: those having socially awkward and withdrawn behavior (n = 12), those having impulsive and destructive behavior (n = 19), and a "borderline" group that did not fit neatly into these other two groups (n = 11). The results indicated that nearly twice as many of the patients in these three "organic" groups as those in the control group had EEG abnormalities and impairments on psychological testing indicating organicity. Furthermore, early history of hyperactive–impulsive–inattentive behavior was highly predictive of placement in the adult impulsive–destructive group, implying a persistent course of this behavioral pattern from childhood to adulthood. Of the 19 patients in the impulsive–destructive group, 17 had received clinical diagnoses of character disorders (primarily emotionally unstable types), as compared to only five patients in the socially awkward group (who received diagnoses of the schizoid and passive–dependent types).

The results were interpreted as being in conflict with the beliefs widely held at the time that hyperactive–impulsive behavior tends to wane in adolescence. Instead, the authors argued that some of these children continued into young adulthood with this specific behavioral syndrome. Quitkin and Klein (1969) also took issue with Harticollis's (1968) psychoanalytic hypothesis that demanding and perfectionistic childrearing by parents caused or contributed to this syndrome given that their impulsive–destructive patients did not uniformly experience such an upbringing. In keeping with Still's (1902) original belief that family environment could not account for this syndrome, these authors hypothesized "that such parents would intensify the difficulty, but are not necessary to the formation of the impulsive–destructive syndrome" (Quitkin & Klein, 1969, p. 140) and that the "illness shaping role of the psycho-social environment may have been overemphasized by other authors" (p. 141). Treatment with a well-structured set of demands and educational procedures, as well as with phenothiazine medication, was thought to be indicated.

Later in this decade, Morrison and Minkoff (1975) similarly argued that explosive personality disorder or episodic dyscontrol syndrome in adulthood might well be the adult sequel to the hyperactivity syndrome in childhood. They also suggested that antidepressant medications might be useful in their management; this echoed a suggestion made earlier by Huessy (1974) in a letter to the editor of a journal that both antidepressants and stimulants might be the most useful medications for the treatment of adults with hyperkinesis or MBD. But the first truly scientific evaluation of the efficacy of stimulants for adults with MBD must be credited to Wood, Reimherr, Wender, and Johnson (1976), who used a double-blind, placebo-controlled method to assess response to methylphenidate in 11 of 15 adults with MBD, followed by an open trial of pemoline (another stimulant) and the antidepressants imipramine and amitriptyline. The authors found that eight of the 11 individuals tested on methylphenidate had a favorable response, whereas 10 of the 15 individuals tested in the open trial showed a positive response to either the stimulants or the antidepressants. Others in the 1970s and into the 1980s would also make the case for the existence of an adult equivalent of childhood hyperki-

nesis or MBD and the efficacy of using stimulants and antidepressants for its management (Gomez, Janowsky, Zetin, Huey, & Clopton, 1981; Mann & Greenspan, 1976; Packer, 1978; Pontius, 1973; Rybak, 1977; Shelley & Riester, 1972). Yet not until the 1990s would both the lay public and the professional field of adult psychiatry seriously begin to recognize the adult equivalent of childhood ADHD on a more widespread basis and to recommend stimulant or antidepressant treatment in these cases (Spencer et al., 1995; Wender, 1995) and even then the view was not without its critics (Shaffer, 1994).

The work of Pontius (1973) in this decade is historically notable for her proposition that many cases of MBD in adults demonstrating hyperactive and impulsive behavior may arise from frontal lobe and caudate dysfunction. Such dysfunction would lead to "an inability to construct plans of action ahead of the act, to sketch out a goal of action, to keep it in mind for some time (as an overriding idea) and to follow it through in actions under the constructive guidance of such planning" (p. 286). Moreover, if adult MBD arises from dysfunction in this frontal–caudate network, it should also be associated with an inability "to re-program an ongoing activity and to shift within *principles* of action whenever necessary" (p. 286, original emphasis). Pontius went on to show that, indeed, adults with MBD demonstrated deficits indicative of dysfunction in this brain network. Such observations would prove quite prophetic over 20 years later, when research demonstrated reduced size in the prefrontal–caudate network in children with ADHD (Castellanos et al., 1996; Filipek et al., 1997), and when ADHD theorists argued that the neuropsychological deficits associated with it involved the executive functions, such as planning; and the control of behavior by mentally represented information, rule-governed behavior, and response fluency and flexibility; among other deficits (Barkley, 1997a, 1997c).

The Prevailing View by 1979

The 1970s closed with the prevailing view that hyperactivity was not the only or most important behavioral deficit seen in hyperactive children, and that poor attention span and impulse control were equally (if not more) important in explaining their problems. Brain damage was relegated to an extremely minor role as a cause of the disorder, at least in the realm of childhood hyperactivity or MBD; however, other brain mechanisms, such as under-arousal or under-reactivity, brain neurotransmitter deficiencies (Wender, 1971), or neurological immaturity (Kinsbourne, 1977), were viewed as promising. Greater speculation about potential environmental causes or irritants emerged, particularly diet and childrearing. Thus, the most frequently recommended therapies for hyperactivity were not only stimulant medication but also widely available special education programs, classroom behavior modification, dietary management, and parent training in child management skills. A greater appreciation for the effects of hyperactive children on their immediate social ecology, and for the impact of stimulant medication in altering these social conflicts, was beginning to emerge.

However, the sizable discrepancy between North American and European views of the disorder remained: North American professionals continued to recognize the disorder as more common, in need of medication, and more likely to be an attention deficit, while those in Europe continued to view it as uncommon, defined by severe overactivity, and associated with brain damage. Those children in North America diagnosed as having hyperactivity or attention deficits would in Europe likely be diagnosed as having CD and be treated with psychotherapy, family therapy, and parent training in child management. Medication would be disparaged and little used. Nevertheless, the view that attention deficits were as important in the disorder as hyperactivity was beginning to make its way into European taxonomies (e.g., the *International Classification of Diseases*, ninth revision [ICD-9]; World Health Organization, 1978). Finally, in the 1970s there was some recognition that there were adult equivalents of childhood hyperactivity or MBD, that they might be indicative of frontal–caudate dysfunction, and that these cases responded to the same medication treatments suggested earlier for childhood ADHD (the stimulants and antidepressants).

THE PERIOD 1980 TO 1989

The exponential increase in research on hyperactivity characteristic of the 1970s continued unabated into the 1980s, making hyperactivity the most well-studied childhood psychiatric disorder in existence. More books were written, conferences convened, and scientific articles presented during this decade than in any previous historical period. This decade would become known for its emphasis on attempts to develop more specific diagnostic criteria; the differential conceptualization and diagnosis of hyperactivity versus other

psychiatric disorders; and, later in the decade, critical attacks on the notion that an inability to sustain attention was the core behavioral deficit in ADHD.

The Creation of an ADD Syndrome

Marking the beginning of this decade was the publication of DSM-III (American Psychiatric Association, 1980) and its radical reconceptualization (from that in DSM-II) of the hyperkinetic reaction of childhood diagnosis to that of ADD (with or without hyperactivity). The new diagnostic criteria were noteworthy for not only their greater emphasis on inattention and impulsivity as defining features of the disorder but also their creation of much more specific symptom lists, an explicit numerical cutoff score for symptoms, specific guidelines for age of onset and duration of symptoms, and the requirement of exclusion of other childhood psychiatric conditions as better explanations of the presenting symptoms. This was also a radical departure from the ICD-9 criteria set forth by the World Health Organization (1978) in its own taxonomy of child psychiatric disorders, which continued to emphasize pervasive hyperactivity as a hallmark of this disorder.

Even more controversial was the creation of subtypes of ADD, based on the presence or absence of hyperactivity (+ H/– H), in the DSM-III criteria. Little, if any, empirical research on this issue existed at the time these subtypes were formulated. Their creation in the official nomenclature of psychiatric disorders would, by the end of the 1980s, initiate numerous research studies into their existence, validity, and utility, along with a search for other potentially useful ways of subtyping ADD (situational pervasiveness, presence of aggression, stimulant drug response, etc.). Although the findings were at times conflicting, the trend in these studies was that children with ADD – H differed from those with ADD + H in some important domains of current adjustment. Those with ADD – H were characterized as more prone to daydreaming, hypoactive, lethargic, and disabled in academic achievement, but as substantially less aggressive and less rejected by their peers (Barkley, Grodzinsky, & DuPaul, 1992; Carlson, 1986; Goodyear & Hynd, 1992; Lahey & Carlson, 1992). Unfortunately, this research came too late to be considered in the subsequent revision of DSM-III.

In that revision (DSM-III-R; American Psychiatric Association, 1987), only the diagnostic criteria for ADD + H (now renamed ADHD; see "ADD Becomes ADHD," below) were stipulated. ADD – H was no longer officially recognized as a subtype of ADD, but was relegated to a minimally defined category, undifferentiated ADD. This reorganization was associated with an admonition that far more research on the utility of this subtyping approach was necessary before its place in this taxonomy could be identified. Despite the controversy that arose over the demotion of ADD – H in this fashion, it was actually a prudent gesture on the part of the committee asked to formulate these criteria. At the time, the committee (on which I served) had little available research to guide its deliberations in this matter. There was simply no indication whether ADD – H had a similar or qualitatively different type of attention deficit, which would make it a separate childhood psychiatric disorder in its own right. Rather than continue merely to conjecture about the nature of the subtype and how it should be diagnosed, the committee essentially placed the concept in abeyance until more research was available to its successor committee to guide its definition. Notable in the construction of DSM-III-R was its emphasis on the empirical validation of its diagnostic criteria through a field trial, which guided the selection of items for the symptom list and the recommended cutoff score on that list (Spitzer, Davies, & Barkley, 1990).

The Development of Research Diagnostic Criteria

At the same time that the DSM-III criteria for ADD + H and ADD – H were gaining recognition, others attempted to specify research diagnostic criteria (Barkley, 1982; Loney, 1983). My own efforts in this endeavor were motivated by the rather idiosyncratic and highly variable approach to diagnosis being used in clinical practice up to that time, the vague or often unspecified criteria used in published research studies, and the lack of specificity in current theoretical writings on the disorder up to 1980. There was also the more pragmatic consideration that, as a young scientist attempting to select hyperactive children for research studies, I had no operational or consensus-based criteria available for doing so. Therefore, I set forth a more operational definition of hyperactivity, or ADD + H. This definition not only required the usual parent and/or teacher complaints of inattention, impulsivity, and overactivity, but it also stipulated that these symptoms had to (1) be deviant for the child's mental age, as measured by well-standardized child behavior rating scales; (2) be relatively pervasive within the jurisdiction of the major

caregivers in the child's life (parent/home and teacher/school); (3) have developed by 6 years of age; and (4) have lasted at least 12 months (Barkley, 1982).

Concurrently, Loney (1983) and her colleagues had been engaged in a series of historically important studies that would differentiate the symptoms of hyperactivity or ADD + H from those of aggression or conduct problems (Loney, Langhorne, & Paternite, 1978; Loney & Milich, 1982). Following an empirical/statistical approach to developing research diagnostic criteria, Loney demonstrated that a relatively short list of symptoms of hyperactivity could be empirically separated from a similarly short list of aggression symptoms. Empirically derived cutoff scores on these symptom ratings by teachers could create these two semi-independent constructs. These constructs would prove highly useful in accounting for much of the heterogeneity and disagreement across studies. Among other things, it would become well established that many of the negative outcomes of hyperactivity in adolescence and young adulthood were actually due to the presence and degree of aggression coexisting with the hyperactivity. Purely hyperactive children would be shown to display substantial cognitive problems with attention and overactivity, whereas purely aggressive children would not. Previous findings of greater family psychopathology in hyperactive children would also be shown to be primarily a function of the degree of coexisting aggression or CD in the children (August & Stewart, 1983; Lahey et al., 1988). Furthermore, hyperactivity would be found to be associated with signs of developmental and neurological delay or immaturity, whereas aggression was more likely to be associated with environmental disadvantage and family dysfunction (Hinshaw, 1987; Milich & Loney, 1979; Paternite & Loney, 1980; Rutter, 1989; Werry, 1988; Weiss & Hechtman, 1986). The need for future studies to specify clearly the makeup of their samples along these two dimensions was now obvious. And the raging debate as to whether hyperactivity was separate from or merely synonymous with conduct problems would be settled by the important research discovery of the semi-independence of these two behavioral dimensions and their differing correlates (Ross & Ross, 1982). These findings would also lead to the demise of the commonplace use of the Conners's 10-item Hyperactivity Index to select children as hyperactive. It would now be shown that many of these items actually assessed aggression rather than hyperactivity, resulting in samples of children with mixed disorders (Ullmann et al., 1984).

The laudable drive toward greater clarity, specificity, and operational defining of diagnostic criteria would continue throughout this decade. Pressure would now be exerted from experts within the field (Quay, 1988b; Rutter, 1983, 1989; Werry, 1988) to demonstrate that the symptoms of ADHD could distinguish it from other childhood psychiatric disorders—a crucial test for the validity of a diagnostic entity—rather than continuing simply to demonstrate differences from nondisordered populations. The challenge would not be easily met. Eric Taylor (1986) and colleagues in Great Britain made notable advances in further refining the criteria and their measurement along more empirical lines. Taylor's (1989) statistical approach to studying clusters of behavioral disorders resulted in the recommendation that a syndrome of hyperactivity could be valid and distinct from other disorders, particularly conduct problems. This distinction required that the symptoms of hyperactivity and inattention be excessive and handicapping to the children; occur in two of three broadly defined settings (e.g., home, school, and clinic); be objectively measured rather than subjectively rated by parents and teachers; develop before age 6; last at least 6 months; and exclude children with autism, psychosis, anxiety, or affective/mood disorders (depression, mania, etc.).

Efforts to develop research diagnostic criteria for ADHD eventually led to an international symposium on the subject (Sergeant, 1988) and a general consensus that subjects selected for research on ADHD should at least meet the following criteria: (1) reports of problems with activity and attention by adults in at least two of three independent settings (home, school, clinic); (2) endorsement of at least three of four difficulties with activity and three of four with attention; (3) onset before 7 years of age; (4) duration of 2 years; (5) significantly elevated scores on parent–teacher ratings of these ADHD symptoms; and (6) exclusion of autism and psychosis. These proposed criteria were quite similar to others developed earlier in the decade (Barkley, 1982) but provided for greater specificity of symptoms of overactivity and inattention, and a longer duration of symptoms.

Subtyping of ADD

Also important in this era was the attempt to identify useful approaches to subtyping other than those just based on the degree of hyperactivity (+ H/– H) or aggression associated with ADD. A significant though underappreciated line of research by Roscoe Dykman

and Peggy Ackerman at the University of Arkansas distinguished between ADD with and ADD without learning disabilities, particularly reading impairments. Their research (Ackerman, Dykman, & Oglesby, 1983; Dykman, Ackerman, & Holcomb, 1985) and that of others (e.g., McGee, Williams, Moffit, & Anderson, 1989) showed that some of the cognitive deficits (verbal memory, intelligence, etc.) formerly attributed to ADHD were actually more a function of the presence and degree of language/reading difficulties than of ADHD. And although some studies showed that ADHD with reading disabilities is not a distinct subtype of ADHD (Halperin, Gittelman, Klein, & Rudel, 1984), the differential contributions of reading disorders to the cognitive test performance of children with ADHD required that subsequent researchers carefully select subjects with pure ADHD not associated with reading disability. If they did not, then they at least should identify the degree to which reading disorders exist in the sample and partial out the effects of these disorders on the cognitive test results.

Others in this era attempted to distinguish between "pervasive" and "situational" hyperactivity; the former was determined by the presence of hyperactivity at home and school, and the latter referred to hyperactivity in only one of these settings (Schachar, Rutter, & Smith, 1981). It would be shown that children with pervasive hyperactivity were likely to have more severe behavioral symptoms, greater aggression and peer relationship problems, and poor academic achievement. DSM-III-R (American Psychiatric Association, 1987) incorporated this concept into an index of severity of ADHD (see the last portion of Table 2.1). British scientists even viewed pervasiveness as an essential criterion for the diagnosis of a distinct syndrome of hyperactivity (as noted earlier). However, research appearing at the end of the decade (Costello, Loeber, & Stouthamer-Loeber, 1991) demonstrated that such group differences were more likely to be the results of differences in the source of the information used to classify the children (parents vs. teachers) than of actual behavioral differences between the situational and pervasive subgroups. This did not mean that symptom pervasiveness might not be a useful means of subtyping or diagnosing ADHD, but that more objective means of establishing it were needed than just comparing parent and teacher ratings on a questionnaire.

A different and relatively understudied approach to subtyping was created by the presence or absence of significant anxiety or affective disturbance. Several studies demonstrated that children with both ADHD and significant problems with anxiety or affective disturbance were likely to show poor or adverse responses to stimulant medication (Taylor, 1983; Voelker, Lachar, & Gdowski, 1983) and would perhaps respond better to antidepressant medications (Pliszka, 1987). The utility of this latter subtyping approach would be investigated and supported further in the next decade (DuPaul, Barkley, & McMurray, 1994; Tannock, 2000).

ADD Becomes ADHD

Later in the 1980s, in an effort to improve further the criteria for defining this disorder, the DSM was revised (DSM-III-R; American Psychiatric Association, 1987) as noted earlier, resulting in the renaming of the disorder to ADHD. The revisions were significant in several respects. First, a single list of symptoms and a single cutoff score replaced the three separate lists (inattention, impulsivity, and hyperactivity) and cutoff score in DSM-III. Second, the item list was now based more on empirically derived dimensions of child behavior from behavior rating scales, and the items and cutoff score underwent a large field trial to determine their sensitivity, specificity, and power to distinguish ADHD from other psychiatric disorders and from the absence of disorder (Spitzer et al., 1990). Third, the need was stressed that one had to establish the symptoms as developmentally inappropriate for the child's mental age. Fourth, the coexistence of mood disorders with ADHD no longer excluded the diagnosis of ADHD. And, more controversially, the subtype of ADD – H was removed as a subtype and relegated to a vaguely defined category, undifferentiated ADD, which was in need of greater research on its merits. ADHD was now classified with two other behavioral disorders (ODD and CD) in a supraordinate family or category known as the "disruptive behavior disorders," in view of their substantial overlap or comorbidity in clinic-referred populations of children.

ADHD as a Motivation Deficit Disorder

One of the more interesting conceptual developments only began to emerge in the latter half of the decade. This was the nascent and almost heretical view that ADHD was not actually a disorder of attention. Doubt about the central importance of attention to the disorder crept in late in the 1970s, as some researchers more fully plumbed the depths of the attention construct

with objective measures, while others took note of the striking situational variability of the symptoms (Douglas & Peters, 1979; Rosenthal & Allen, 1978; Routh, 1978; Sroufe, 1975). As more rigorous and technical studies of attention in children with ADHD appeared in the 1980s, an increasing number failed to find evidence of problems with attention under some experimental conditions, while observing them under others (for reviews, see Douglas, 1983, 1988; also see Barkley, 1984; Draeger et al., 1986; Sergeant, 1988; Sergeant & van der Meere, 1989; van der Meere & Sergeant, 1988a, 1988b). Moreover, if attention was conceptualized as involving the perception, filtering, and processing of information, no substantial evidence could be found in these studies for any such deficits. These findings, coupled with the realization that both instructional and motivational factors in an experiment played a strong role in determining the presence and degree of ADHD symptoms, led some investigators to hypothesize that deficits in motivation might be a better model for explaining the symptoms seen in ADHD (Glow & Glow, 1979; Rosenthal & Allen, 1978; Sroufe, 1975). Following this line of reasoning, others pursued a behavioral or functional analysis of these symptoms, resulting in hypothesized deficits in the stimulus control over behavior, particularly by rules and instructions. I argued that such deficits arose from neurological factors (Barkley, 1988a), whereas others argued that they arose from poor training of the child by parents (Willis & Lovaas, 1977).

I initially raised the possibility that rule-governed behavior might account for many of the deficits in ADHD but later amended this view to include the strong probability that response to behavioral consequences might also be impaired and could conceivably account for the problems with following rules (Barkley, 1981, 1984, 1990). Others independently advanced the notion that a deficit in responding to behavioral consequences, not attention, might be the difficulty in ADHD (Benninger, 1989; Haenlein & Caul, 1987; Quay, 1988a; Sagvolden, Wultz, Moser, Moser, & Morkrid, 1989; Sergeant, 1988; van der Meere & Sergeant, 1988a). That is, ADHD might arise out of an insensitivity to consequences (reinforcement, punishment, or both). This insensitivity was viewed as being neurological in origin. Yet this idea was not new, having been advanced some 10–20 years earlier by investigators in Australia (Glow & Glow, 1979), by those studying children with conduct problems (see Patterson, 1982, for a review), and by Wender (1971) in his classic text on MBD (discussed earlier). What was original in these more recent ideas is the greater specificity of their hypotheses and increasing evidence supporting them. Others continued to argue against the merits of a Skinnerian or functional analysis of the deficits in ADHD (Douglas, 1989), and for the continued explanatory value of cognitive models of attention in accounting for the deficits in ADHD.

The appeal of the motivational model came from several different sources: (1) its greater explanatory value in accounting for the more recent research findings on situational variability in attention in ADHD; (2) its consistency with neuroanatomical studies suggesting decreased activation of brain reward centers and their cortical–limbic regulating circuits (Lou et al., 1984, 1989); (3) its consistency with studies of the functions of dopamine pathways in regulating locomotor behavior and incentive or operant learning (Benninger, 1989); and (4) its greater prescriptive power in suggesting potential treatments for the ADHD symptoms. Whether or not ADHD would be labeled a motivational deficit, there was little doubt that these new theories based on the construct of motivation required altering the way in which this disorder was to be conceptualized. From here on, any attempts at theory construction would need to incorporate some components and processes dealing with motivation or effort.

Other Developments of the Era

The Increasing Importance of Social Ecology

The 1980s also witnessed considerably greater research into the social-ecological impact of ADHD symptoms on the children, their parents (Barkley, 1989b; Barkley, Karlsson, & Pollard, 1985; Mash & Johnston, 1982), teachers (Whalen, Henker, & Dotemoto, 1980, 1981), siblings (Mash & Johnston, 1983), and peers (Cunningham et al., 1985; Henker & Whalen, 1980). These investigations further explored the effects of stimulant medications on these social systems; they buttressed the conclusion that children with ADHD elicit significant negative, controlling, and hostile or rejecting interactions from others, which can be greatly reduced by stimulant medication. From these studies emerged the view that the disabilities associated with ADHD do not rest solely in a child, but in the interface between the child's capabilities and the environmental demands made within the social-ecological context in which that child must perform (Whalen & Henker, 1980). Changing the attitudes, behaviors, and expecta-

tions of caregivers, as well as the demands they make on children with ADHD in their care, should result in changes in the degree to which such children are disabled by their behavioral deficits.

Theoretical Advances

During this decade, Herbert Quay adopted the neuropsychological model of anxiety by Jeffrey Gray (1982, 1987, 1994) to explain the origin of the poor inhibition evident in ADHD (Quay, 1988a, 1988b, 1997). Gray identified both a behavioral inhibition system (BIS) and a behavioral activation system (BAS) as being critical to understanding emotion. He also stipulated mechanisms for basic nonspecific arousal and for the appraisal of incoming information that must be critical elements of any attempt to model the emotional functions of the brain. According to this theory, signals of reward serve to increase activity in the BAS, thus giving rise to approach behavior and the maintenance of such behavior. Active avoidance and escape from aversive consequences (negative reinforcement) likewise activate this system. Signals of impending punishment (particularly conditioned punishment), as well as frustrative nonreward (an absence of previously predictable reward), increase activity in the BIS. Another system is the fight–flight system, which reacts to unconditioned punitive stimuli.

Quay's use of this model for ADHD indicated that the impulsiveness characterizing the disorder could arise from diminished activity in the brain's BIS. This model predicted that those with ADHD should prove less sensitive to such signals, particularly in passive avoidance paradigms (Quay, 1988b). The theory also specifies predictions that can be used to test and even falsify the model as it applies to ADHD. For instance, Quay (1988a, 1988b) predicted that there should be greater resistance to extinction following periods of continuous reinforcement in those with ADHD, but less resistance when training conditions involve partial reward. They should also demonstrate a decreased ability to inhibit behavior in passive avoidance paradigms in which avoidance of the punishment is achieved through the inhibition of responding. And those with ADHD should also demonstrate diminished inhibition to signals of pain and novelty, as well as to conditioned signals of punishment. Finally, Quay predicted increased rates of responding by those with ADHD under fixed-interval or fixed-ratio schedules of consequences. Some of these predictions were supported by subsequent research; others either remain to be investigated more fully and rigorously, or have not been completely supported by the available evidence (see Milich, Hartung, Martin, & Haigler, 1994; Quay, 1997). Nevertheless, the theory remains a viable one for explaining the origin of the inhibitory deficits in ADHD and continues to deserve further research.

Further Developments in Nature, Etiology, and Course

Another noteworthy development in this decade was the greater sophistication of research designs in the attempt to explore the unique features of ADHD relative to other psychiatric conditions, rather than just in comparison to the absence of disorder. As Rutter (1983, 1989) noted repeatedly, the true test of the validity of a syndrome of ADHD is the ability to differentiate its features from other psychiatric disorders of children, such as mood or anxiety disorders, learning disorders, and particularly CD. Those studies that undertook such comparisons indicated that situational hyperactivity was not consistent in discriminating among psychiatric populations, but that difficulties with attention and pervasive (home and school) hyperactivity were more reliable in doing so and were often associated with patterns of neuropsychological immaturity (Firestone & Martin, 1979; Gittelman, 1988; McGee, Williams, & Silva, 1984a, 1984b; Rutter, 1989; Taylor, 1988; Werry, 1988).

The emerging interest in comparing children with ADD + H to those with ADD – H furthered this line of inquiry by demonstrating relatively unique features of each group in contrast to each other (see Chapters 2 and 17) and to groups of children with learning disabilities and no disability (Barkley, DuPaul, & McMurray, 1990, 1991). Further strengthening the position of ADHD as a psychiatric syndrome is evidence from family aggregation studies that relatives of children with ADHD have a different pattern of psychiatric disturbance than that of children with CD or mixed ADHD and CD (Biederman, Munir, & Knee, 1987; Lahey et al., 1988). Children with pure ADHD were more likely to have relatives with ADHD, academic achievement problems, and dysthymia, whereas those children with CD had a greater prevalence of relatives with CD, antisocial behavior, substance abuse, depression, and marital dysfunction. This finding led to speculation that ADHD has a different etiology than CD. The former was said to arise out of a biologically based disorder of

temperament or a neuropsychological delay; the latter, from inconsistent, coercive, and the dysfunctional childrearing and management frequently associated with parental psychiatric impairment (Hinshaw, 1987; Loeber, 1990; Patterson, 1982, 1986).

Equally elegant research examined potential etiologies of ADHD. Several studies on cerebral blood flow revealed patterns of underactivity in the prefrontal areas of the CNS and their rich connections to the limbic system via the striatum (Lou et al., 1984, 1989). Other studies (Hunt, Cohen, Anderson, & Minderaa, 1988; Rapoport & Zametkin, 1988; Shaywitz, Shaywitz, Cohen, & Young, 1983; Shekim, Glaser, Horwitz, Javaid, & Dylund, 1988; Zametkin & Rapoport, 1986) of brain neurotransmitters provided further evidence that deficiencies in dopamine, norepinephrine, or both, may be involved in explaining these patterns of brain underactivity—patterns arising in precisely those brain areas in which dopamine and norepinephrine are most involved. Drawing these lines of evidence together even further is the fact that these brain areas are critically involved in response inhibition, motivational learning, and response to reinforcement. More rigorous published studies on the hereditary transmission of ADHD (Goodman & Stevenson, 1989) indicated a strong heritability for ADHD symptoms.

Follow-up studies appearing in this decade were also more methodologically sophisticated, and hence more revealing of not only widespread maladjustment in children with ADHD as they reached adolescence and adulthood but also potential mechanisms involved in the differential courses shown within this population (Barkley, Fischer, et al., 1990, 1991; Fischer, Barkley, Edelbrock, & Smallish, 1990; Gittelman et al., 1985; Lambert, 1988; Weiss & Hechtman, 1993). These findings are discussed in Chapter 9. Again, neuropsychological delays, the presence and pervasiveness of early aggression, and mother–child conflict were associated with a different, and more negative, outcome in later childhood and adolescence than was ADHD alone (Campbell, 1987; Paternite & Loney, 1980).

There was also a movement during this decade away from the strict reliance on clinic-referred samples of children with ADHD toward the use of community-derived samples. This change was prompted by the widely acknowledged bias that occurs among clinic-referred samples of children with ADHD as a result of the process of referral itself. It is well known that children who are referred are often more (though not always the most) impaired, have more numerous comorbid conditions, are likely to have associated family difficulties, and are skewed toward those socioeconomic classes that value the utilization of mental health care resources. Such biases can create findings that are not representative of the nature of the disorder in its natural state. For instance, it has been shown that the ratio of boys to girls within clinic-referred samples of children with ADHD may range from 5:1 to 9:1, and that girls with ADHD within these samples are as likely to be as aggressive or oppositional as boys (see Chapter 2). By contrast, in samples of children with ADHD derived from community- or school-based samples, the ratio of boys to girls is only 2.5:1, and girls with ADHD are considerably less likely than boys to be aggressive. For these and other reasons, a greater emphasis on studying epidemiological samples of children, and the rates and nature of ADHD within them (Offord et al., 1987), arose toward the latter half of the 1980s.

Developments in Assessment

The 1980s also witnessed some advances in the tools of assessment, in addition to those for treatment. The Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983, 1986) emerged as a more comprehensive, more rigorously developed and better-normed alternative to the Conners Rating Scales (Barkley, 1988c). It would become widely adopted in research on child psychopathology in general, not just in ADHD, by the end of the decade. Other rating scales more specific to ADHD were also developed, such as the ADD – H Comprehensive Teacher's Rating Scale (ACTeRS; Ullmann et al., 1984), the Home and School Situations Questionnaires (Barkley & Edelbrock, 1987; DuPaul & Barkley, 1992), the Child Attention Profile (see Barkley, 1988c), and the ADHD Rating Scale (DuPaul, 1991).

Gordon (1983) developed, normed, and commercially marketed a small, portable, computerized device that administered two tests believed to be sensitive to the deficits in ADHD. One was a CPT measuring vigilance and impulsivity, and the other was a direct reinforcement of low rates (DRL) test assessing impulse control. This device became the first commercially available objective means of assessment for children with ADHD. Although the DRL test showed some promise in early research (Gordon, 1979), it was subsequently shown to be insensitive to stimulant medication effects (Barkley, Fischer, Newby, & Breen, 1988) and was eventually deemphasized as useful in the diagnosis in ADHD. The

CPT, by contrast, showed satisfactory discrimination of children with ADHD from nondisabled groups and was sensitive to medication effects (Barkley et al., 1988; Gordon & Mettelman, 1988). Although cautionary statements indicated that more research evidence was needed to evaluate the utility of the instrument (Milich, Pelham, & Hinshaw, 1985), and that its false-negative rate (misses of children with legitimate ADHD) might be greater than that desired in a diagnostic tool, the device and others like it (Conners, 1995; Greenberg & Waldman, 1992) found a wide clinical following by the next decade.

Greater emphasis was also given to developing direct behavioral observation measures of ADHD symptoms that could be taken in the classroom or clinic, and that would be more objective and useful adjuncts to the parent and teacher rating scales in the diagnostic process. Abikoff, Gittelman-Klein, and Klein (1977) and O'Leary (1981) developed classroom observation codes with some promise for discriminating between children with ADHD and those with other or no disabilities (Gittelman, 1988). Roberts (1979), drawing on the earlier work of Routh and Schroeder (1976) and Kalverboer (1988), refined a laboratory playroom observation procedure that discriminated not only between children with ADHD and nondisabled children, but also between children with aggression or mixed aggression and ADHD. This coding system had excellent 2-year stability coefficients. Somewhat later, I streamlined the system (Barkley, 1988b) for more convenient clinical or classroom use and found it to be sensitive to stimulant medication effects (Barkley et al., 1988), to differentiate between children with ADD + H and ADD – H (Barkley, DuPaul, et al., 1991), and to correlate well with parent and teacher ratings of ADHD symptoms (Barkley, 1991). Nevertheless, problems with developing normative data and the practical implementation of such a procedure in busy clinic practices remained hindrances to its widespread adoption.

Developments in Treatment

Developments also continued in the realm of treatments for ADHD. Comparisons of single versus combined treatments were more common during the decade (Barkley, 1989a), as was the use of more sophisticated experimental designs (Hinshaw, Henker, & Whalen, 1984; Pelham, Schnedler, Bologna, & Contreras, 1980) and mixed interventions (Satterfield, Satterfield, & Cantwell, 1981). Several of these historical developments in treatment require mention. The first was the emergence of a new approach to the treatment of ADHD: cognitive-behavioral therapy, or CBT (Camp, 1980; Douglas, 1980a; Kendall & Braswell, 1985; Meichenbaum, 1988). Founded on the work of Russian neuropsychologists (Vygotsky and Luria), North American developmental and cognitive psychologists (Flavell, Beach, & Chinsky, 1966), and early cognitive-behavioral theories (Meichenbaum, 1977), the CBT approach stressed the need to develop self-directed speech in impulsive children to guide their definition of and attention to immediate problem situations, to generate solutions to these problems, and to guide their behavior as the solutions were performed. Self-evaluation, self-correction, and self-directed use of consequences were also viewed as important (Douglas, 1980a, 1980b). Although the first reports of the efficacy of this approach appeared in the late 1960s and the 1970s (Bornstein & Quevillon, 1976; Meichenbaum & Goodman, 1971), it was not until the 1980s that the initial claims of success with nonclinical populations of impulsive children were more fully tested in clinical populations of children with ADHD. The initial results were disappointing (Abikoff, 1987; Gittelman & Abikoff, 1989). Generally, they indicated some degree of improvement in impulsiveness on cognitive laboratory tasks; however, the improvement was insufficient to be detected in teacher or parent ratings of school and home ADHD behaviors, and CBT was certainly not as effective as stimulant medication (Brown, Wynne, & Medenis, 1985). Many continued to see some promise in these techniques (Barkley, 1981, 1989b; Meichenbaum, 1988; Whalen, Henker, & Hinshaw, 1985), particularly when they were implemented in natural environments by important caregivers (parents and teachers); others ended the decade with a challenge to those who persisted in their support of the CBT approach to provide further evidence for its efficacy (Gittelman & Abikoff, 1989). Such evidence would not be forthcoming. Later, even the conceptual basis for the treatment came under attack as being inconsistent with Vygotsky's theory of the internalization of language (Diaz & Berk, 1995).

A second development in treatment was the publication of a specific parent training format for families of children with ADHD and oppositional behavior. A specific set of steps for training parents of children with ADHD in child behavior management skills was developed (Barkley, 1981) and refined (Barkley, 1997b). The approach was founded on a substantial research literature (Barkley, 1997b; Forehand & McMahon,

1981; Patterson, 1982) demonstrating the efficacy of differential attention and time-out procedures for treating oppositional behavior in children—a behavior frequently associated with ADHD. These two procedures were coupled with additional components based on a theoretical formulation of ADHD as a developmental disorder that is typically chronic and associated with decreased rule-governed behavior and an insensitivity to certain consequences, particularly mild or social reinforcement. These components included counseling parents to conceptualize ADHD as a developmentally disabling condition; implementing more powerful home token economies to reinforce behavior, rather than relying on attention alone; using shaping techniques to develop nondisruptive, independent play; and training parents in cognitive-behavioral skills to teach their children during daily management encounters, particularly in managing disruptive behavior in public places (see Chapter 21). Because of the demonstrated impact of parental and family dysfunction on the severity of children's ADHD symptoms, on the children's risk for developing ODD and CD, and on the parents' responsiveness to treatments for the children, clinicians began to pay closer attention to intervention in family systems rather than just in child management skills. Noteworthy among these attempts were the modifications to the previously described parent training program by Charles Cunningham at McMaster University Medical Center (Cunningham, 1990, 2006). Arthur Robin at Wayne State University and the Children's Hospital of Michigan, and Sharon Foster at West Virginia University (Robin & Foster, 1989) also emphasized the need for work on family systems, as well as on problem-solving and communication skills in treating the parent–adolescent conflicts so common in families of teenagers with ADHD (see Chapter 22 for a discussion of this approach).

A similar increase in more sophisticated approaches to the classroom management of children with ADHD occurred in this era (Barkley, Copeland, & Sivage, 1980; Pelham et al., 1980; Pfiffner & O'Leary, 1987; Whalen & Henker, 1980). These developments were based on earlier promising studies in the 1970s of contingency management methods in hyperactive children (Allyon et al., 1975; see Chapter 24 for the details of such an approach). Although these methods may not produce the degree of behavioral change seen with the stimulant medications (Gittelman et al., 1980), they provide a more socially desirable intervention that can be a useful alternative when children have mild ADHD and cannot take stimulants or when their parents decline the prescription. More often, these methods serve as an adjunct to medication therapy to further enhance academic achievement.

The fourth area of treatment development was in social skills training for children with ADHD (see Chapter 23). Hinshaw and colleagues (1984) developed a program for training children with ADHD in anger control techniques. This program demonstrated some initial short-term effectiveness in assisting these children to deal with this common deficit in their social skills and emotional control (Barkley et al., 2000). Related approaches to social skills training for children with ADHD also showed initially promising results (Pfiffner & McBurnett, 1997), but subsequent research did not bear out this promise and suggested that some children with ADHD may even become more aggressive after participation in such group training formats (see Chapter 23).

Finally, medication treatments for children with ADHD expanded to include the use of the tricyclic antidepressants, particularly for those children with characteristics that contraindicated use of a stimulant medication (e.g., Tourette syndrome or other tic disorders) or for those with anxiety/depression (Pliszka, 1987). The work of Joseph Biederman and his colleagues at Massachusetts General Hospital (Biederman, Baldessarini, Wright, Knee, & Harmatz, 1989; Biederman, Gastfriend, & Jellinek, 1986) on the safety and efficacy of tricyclic antidepressants encouraged the rapid adoption of these drugs by many practitioners (see Ryan, 1990), particularly when the stimulants, such as methylphenidate (Ritalin), were receiving such negative publicity in the popular media (see the next section). There simultaneously appeared initially positive research reports on the use of the antihypertensive drug clonidine in the treatment of children with ADHD, particularly those with very high levels of hyperactive–impulsive behavior and aggression (Hunt, Caper, & O'Connell, 1990; Hunt, Minderaa, & Cohen, 1985; see Chapter 27).

Developments in Public Awareness

Several noteworthy developments also occurred in the public forum during this decade. Chief and most constructive among these was the blossoming of numerous parent support associations for families with ADHD. Although less than a handful of these existed in the early 1980s, within 9 years there would be well over

100 such associations throughout the United States alone. By the end of the decade, these would begin to organize into national networks and political action organizations known respectively as CHADD (originally Children with ADD, now Children and Adults with ADHD) and the Attention Deficit Disorder Association (ADDA). With this greater public/parent activism, initiatives were taken to have state and federal laws reevaluated and, it was hoped, changed to include ADHD as an educational disability in need of special educational services in public schools.

When it was passed in 1975, Public Law 94-142 included the concept of MBD under the category of learning disabilities that would be eligible for special educational services. But it did not include hyperactivity, ADD, or ADHD in its description of learning or behavioral disorders eligible for mandated special services in public school. This oversight would lead many public schools to deny access for children with ADD or ADHD to such services, and would cause much parental and teacher exasperation in trying to get educational recognition and assistance for this clearly academically disabling disorder. Other parents would initiate lawsuits against private schools for learning-disabled students for educational malpractice in failing to provide special services for children with ADHD (Skinner, 1988). By the early 1990s, these lobbying efforts would be partially successful in getting the U.S. Department of Education to reinterpret Public Law 94-142—and its 1990 reauthorization as IDEA—to include children with ADHD under the category of "Other Health Impaired" because of their difficulties in alertness and attention. Upon this reinterpretation, children with ADHD could now be considered eligible for special educational services, provided that the ADHD resulted in significant impairment in academic performance. Such efforts to obtain special educational resources for children and adolescents with ADHD stemmed from their tremendous risk for academic underachievement, failure, retention, suspension, and expulsion, not to mention negative social and occupational outcomes (Barkley, Fischer, et al., 1990, 1991; Cantwell & Satterfield, 1978; Weiss & Hechtman, 1986).

The Church of Scientology Campaign

Yet with this increased public activism also came a tremendously destructive trend in the United States, primarily fueled by the Church of Scientology and its Citizens Commission on Human Rights (CCHR). This campaign capitalized on the mass media's general tendency to publish alarming or sensational anecdotes uncritically, as well as the public's gullibility for such anecdotes. Drawing on evidence of an increase in stimulant medication use with schoolchildren, as well as the extant public concern over drug abuse, CCHR members effectively linked these events together to play on the public's general concern about using behavior-modifying drugs with children. In a campaign reminiscent of the gross overstatement seen in the earlier "Reefer Madness" campaign by the U.S. government against marijuana, members of CCHR selectively focused on the rare cases of adverse reactions to stimulants and greatly exaggerated both their number and degree to persuade the public that these reactions were commonplace. They also argued that massive overprescribing was posing a serious threat to schoolchildren, though actual evidence of such overprescribing was never presented. By picketing scientific and public conferences on ADHD, actively distributing leaflets to parents and students in many North American cities, seeking out appearances on many national television talk shows, and placing numerous letters to newspapers decrying the evils of Ritalin and the myth of ADHD (Bass, 1988; CCHR, 1987; Cowart, 1988; Dockx, 1988), CCHR members and others took this propaganda directly to the public. Ritalin, they claimed, was a dangerous and addictive drug often used by intolerant educators and parents and by money-hungry psychiatrists as a chemical straitjacket to subdue normally exuberant children (Clark, 1988; CCHR, 1987; Dockx, 1988). Dramatic, exaggerated, or unfounded claims were made that Ritalin use could frequently result in violence or murder, suicide, Tourette syndrome, permanent brain damage or emotional disturbance, seizures, high blood pressure, confusion, agitation, and depression (CCHR, 1987; Clark, 1988; Dockx, 1988; Laccetti, 1988; "Ritalin Linked," 1988; Toufexis, 1989; Williams, 1988). They also claimed that the increasing production and prescription of Ritalin were leading to increased abuse of such drugs by the general public (Associated Press, 1988; Cowart, 1988; "Rise in Ritalin Use," 1987). Great controversy was said to exist among the scientific and professional practice communities relative to this disorder and the use of medication. No evidence presented in these articles, however, demonstrated a rise in Ritalin abuse or linked it with the increased prescribing of the medication. Moreover, close inspection of professional journals and conferences revealed that no major or widespread controversy

ever existed within the professional or scientific fields over the nature of the disorder or the effectiveness of stimulant medication. Yet lawsuits were threatened, initiated, or assisted by the CCHR against practitioners for medical negligence and malpractice, and against schools for complicity in "pressuring" parents to have their children placed on these medicines (Bass, 1988; Cowart, 1988; Henig, 1988; Twyman, 1988; see also the 1988 segment on ABC's *Nightline*). A major lawsuit ($125 million) was also filed by the CCHR against the American Psychiatric Association for fraud in developing the criteria for ADHD (Henig, 1988; "Psychiatrist Sued," 1987), though the suit would later be dismissed.

So effective was this national campaign by the CCHR, so widespread were newspaper and television stories on adverse Ritalin reactions, and so easily could public sentiment be misled about a disorder and its treatment by a fringe political–religious group and overzealous, scandal-mongering journalists that within 1 year the public attitude toward Ritalin was dramatically altered. Ritalin was seen as a dangerous and overprescribed drug, and the public believed that there was tremendous professional controversy over its use. The minor benefits to come out of this distorted reporting were that some practitioners would become more rigorous in their assessments and more cautious in prescribing medication. Schools also became highly sensitized to the percentage of their enrollment receiving stimulant medication, and in some cases encouraged exploration of alternative behavioral means of managing children.

Yet even the few modestly positive effects of this campaign were greatly outweighed by the damaging effects on parents and children. Many parents were scared into unilaterally discontinuing the medication for their children without consulting their treating physicians. Others rigidly refused to consider the treatment, if recommended, as one part of their child's treatment plan or were harassed into such refusal by well-meaning relatives misled by the distorted church propaganda and media reports. Some adolescents with ADHD began refusing the treatment, even if it had been beneficial to them, after being alarmed by these stories. Some physicians stopped prescribing the medications altogether out of concern for the threats of litigation, thereby depriving many children in their care of the clear benefits of this treatment approach. Most frustrating to watch was the unnecessary anguish created for parents whose children were already on the medication or who were contemplating its use. The psychological damage done to those children whose lives could have been improved by this treatment was incalculable. The meager, poorly organized, and sporadically disseminated response of the mental health professions was primarily defensive in nature (Weiner, 1988) and (as usual) too little, too late to change the tide of public opinion. It would take years even to partially reverse this regression in public opinion toward ADHD and its treatment by medication, and the chilling effect all this had on physicians' prescribing of the medication. Public suspicion and concern over medication use for ADHD remains even today.

The Prevailing View at the End of the 1980s

This decade closed with the professional view of ADHD as a developmentally disabling condition with a generally chronic nature, a strong biological or hereditary predisposition, and a significant negative impact on academic and social outcomes for many children. However, its severity, comorbidity, and outcome were viewed as significantly affected by environmental (particularly familial) factors. Growing doubts about the central role of attention deficits in the disorder arose late in the decade, while increasing interest focused on possible motivational factors or reinforcement mechanisms as the core difficulty in ADHD. Effective treatment was now viewed as requiring multiple methods and professional disciplines working in concert over longer time intervals, with periodic reintervention as required, to improve the long-term prognosis for ADHD. The view that environmental causes were involved in the genesis of the disorder was weakened by increasing evidence for the heritability of the condition and its neuroanatomical localization. Even so, evidence that familial–environmental factors were associated with outcome was further strengthened. Developments in treatment would expand the focus of interventions to parental disturbances and family dysfunction, as well as to the children's anger control and social skills. A potentially effective role for the use of tricyclic antidepressants and antihypertensive medications was also demonstrated, expanding the armamentarium of symptomatic interventions for helping children with ADHD.

Despite these tremendous developments in the scientific and professional fields, the general public became overly sensitized to and excessively alarmed by the increasing use of stimulant medication as a treatment for this disorder. Fortunately, the explosive growth of parent support–political action associations

for ADHD arose almost simultaneously with this public controversy over Ritalin and held the promise of partially counteracting its effects and making the education of children with ADHD a national political priority at the start of the 1990s. These associations also offered the best hope that the general public could be provided with a more accurate depiction of ADHD and its treatment. Perhaps now the public could be made to understand that hyperactive, disruptive child behaviors could arise out of a biologically based disability that could be diminished or amplified by the social environment, rather than being entirely due to bad parenting and diet, as the simplistic yet pervasive societal view maintained.

THE PERIOD 1990 TO 1999

During the 1990s, a number of noteworthy developments occurred in the history of ADHD, chief among them being the increase in research on the neurological and genetic basis of the disorder and on ADHD as it occurs in clinic-referred adults.

Neuroimaging Research

Researchers had long suspected that ADHD was associated in some way with abnormalities or developmental delays in brain functioning. Supporting such an interpretation in the 1990s were numerous neuropsychological studies showing deficits in performance by children with ADHD on tests that were presumed to assess frontal lobe or executive functions (for reviews, see Barkley, 1997a; Barkley et al., 1992; Goodyear & Hynd, 1992). Moreover, psychophysiological research in earlier decades had suggested brain underactivity, particularly in functioning related to the frontal lobes (Hastings & Barkley, 1978; Klorman, 1992). Thus, there was good reason to suspect that delayed or disturbed functioning in the brain, and particularly the frontal lobes, might be involved in this disorder.

In 1990, Alan Zametkin and his colleagues at the National Institute of Mental Health (NIMH) published a landmark study. They evaluated brain metabolic activity in 25 adults with ADHD who had both a childhood history of the disorder and children with the disorder. The authors used positron emission tomography (PET), an exceptionally sensitive technique for detecting states of brain activity and its localization within the cerebral hemispheres. The results of this study indicated significantly reduced brain metabolic activity in adults with ADHD relative to a control group, primarily in frontal and striatal regions. Such results were certainly consistent in many, though not all, respects with the earlier demonstrations of reduced cerebral blood flow in the frontal and striatal regions in children with ADHD (Lou et al., 1984, 1989). Significant in the Zametkin and colleagues (1990) study, however, was its use of a much better defined sample of patients with ADHD and its focus on adults with ADHD. Although later attempts by this research team to replicate their original results with teenagers were consistent with these initial results for girls with ADHD, no differences were found in boys with ADHD (see Ernst, 1996, for a review). Sample sizes in these studies were quite small, however, almost ensuring some difficulties with the reliable demonstration of the original findings. Despite these difficulties, the original report stands out as one of the clearest demonstrations to date of reduced brain activity, particularly in the frontal regions, in ADHD.

At the same time as the NIMH research using PET scans appeared, other researchers were employing magnetic resonance imaging (MRI) to evaluate brain structures in children with ADHD. Hynd, Semrud-Clikeman, Lorys, Novey, and Eliopulos (1990) were the first to use this method, and they focused on total brain volume, as well as specific regions in the anterior and posterior brain sections. Children with ADHD were found to have abnormally smaller anterior cortical regions, especially on the right side, and they lacked the normal right–left frontal asymmetry. In subsequent research that focused on the size of the corpus callosum, this team found that both the anterior and posterior portions were smaller in children with ADHD (Hynd et al., 1991); however, in a later study, only the posterior region was found to be significantly smaller (Semrud-Clikeman et al., 1994). Additional studies were reported by Hynd and colleagues (1993), who found a smaller left caudate region in children with ADHD, and Giedd and colleagues (1994), who found smaller anterior regions of the corpus callosum (rostrum and rostral body).

More recently, two research teams published MRI studies with considerably larger samples of children with ADHD (Castellanos et al., 1994, 1996; Filipek et al., 1997). These studies documented significantly smaller right prefrontal lobe and striatal regions in these children. Castellanos and colleagues (1996) also found smaller right-sided regions of structures in the basal ganglia, such as the striatum, as well as the right

cerebellum. Filipek and colleagues (1997) observed the left striatal region to be smaller than the right. Despite some inconsistencies across these studies, most have implicated the prefrontal–striatal network as being smaller in children with ADHD, with the right prefrontal region being smaller than the left. Such studies have placed on a considerably firmer foundation the view that ADHD does indeed involve impairments in the development of the brain, particularly in the prefrontal–striatal regions, and that these impairments are likely to have originated in embryological development (Castellanos et al., 1996). Advances in neuroimaging technology continue to provide exciting and revealing new developments in the search for the structural differences in the brain that underlie this disorder (see Chapter 14). For instance, the advent of functional MRI (fMRI), with its greater sensitivity for localization of activity, has already resulted in a number of newly initiated investigations into possible impairments in these brain regions in children and adults with ADHD.

Genetic Research

Since the 1970s, studies have indicated that the parents of children with hyperactivity, ADD, or ADHD seem to have a greater frequency of psychiatric disorders, including ADHD. Cantwell (1975) and Morrison and Stewart (1973) both reported higher rates of hyperactivity in the biological parents of hyperactive children than in adoptive parents of such children. Yet both studies were retrospective, and both failed to study the biological parents of the adopted hyperactive children as a comparison group (Pauls, 1991). In the 1990s, a number of studies, particularly those by Biederman and colleagues, clarified and strengthened this evidence of the familial nature of ADHD. Between 10 and 35% of the immediate family members of children with ADHD were found to have the disorder; the risk to siblings of these children was approximately 32% (Biederman, Faraone, & Lapey, 1992; Biederman, Keenan, & Faraone, 1990; Pauls, 1991; Welner, Welner, Stewart, Palkes, & Wish, 1977). Even more striking, research has shown that if a parent has ADHD, the risk to the offspring is 57% (Biederman et al., 1995). Thus, family aggregation studies reveal that ADHD clusters among biological relatives of children or adults with the disorder, strongly implying a hereditary basis to this condition.

At the same time that these studies were appearing, several studies of twins were focusing on the heritability of the dimensions of behavior underlying ADHD (i.e., hyperactive–impulsive and inattentive) behavior, or on the clinical diagnosis of ADHD itself. Large-scale twin studies on this issue have quite consistently found a high heritability for ADHD symptoms or for the clinical diagnosis, with minimal or no contribution made by the shared environment (Edelbrock, Rende, Plomin, & Thompson, 1995; Levy & Hay, 1992). For instance, Gilger, Pennington, and DeFries (1992) found that if one twin was diagnosed with ADHD, the concordance for the disorder was 81% in monozygotic twins and 29% in dizygotic twins. Stevenson (1994) summarized the status of twin studies on symptoms of ADHD by stating that the average heritability is .80 for symptoms of this disorder (range .50–.98). More recent large-scale twin studies are remarkably consistent with this conclusion, demonstrating that the majority of variance (70–90%) in the trait of hyperactivity–impulsivity is due to genetic factors (averaging approximately 80%), and that such a genetic contribution may increase as scores for this trait become more extreme, although this latter point is debatable (Faraone, 1996; Gjone, Stevenson, & Sundet, 1996; Gjone, Stevenson, Sundet, & Eilertsen, 1996; Rhee, Waldman, Hay, & Levy, 1999; Silberg et al., 1996; Thapar, Hervas, & McGuffin, 1995; van den Oord, Verhulst, & Boomsma, 1996). Thus, twin studies added substantially more evidence to that already found in family aggregation studies supporting a strong genetic basis to ADHD and its behavioral symptoms. More recent twin studies have further buttressed the strong genetic contribution to ADHD (see Chapter 14). Equally important is the consistent evidence in such research that whatever environmental contributions may be made to ADHD symptoms fall more within the realm of unique (nonshared) environmental effects than within that of common or shared effects.

Also in this decade, a few researchers began using molecular genetic techniques to analyze DNA taken from children with ADHD and their family members to identify genes that may be associated with the disorder. The initial focus of this research was on the dopamine type 2 gene, given findings of its increased association with alcoholism, Tourette syndrome, and ADHD (Blum, Cull, Braverman, & Comings, 1996; Comings et al., 1991), but others failed to replicate this finding (Gelernter et al., 1991; Kelsoe et al., 1989). More recently, the dopamine transporter gene was implicated in ADHD (Cook et al., 1995; Cook, Stein, & Leventhal, 1997). Another gene related to dopamine,

the *D4RD* (repeater gene) was found to be overrepresented in the seven-repetition form of the gene in children with ADHD (LaHoste et al., 1996). The latter finding has been replicated in a number of additional studies and indicates that the presence of this allele increases the risk for ADHD by 1.5. Clearly, research into the molecular genetics involved in the transmission of ADHD across generations continues to be an exciting and fruitful area of research endeavor. Such research offers promise for the eventual development of not only genetic tests for ADHD and subtyping of ADHD into potentially more homogeneous and useful genotypes but also more specific pharmacological agents for treating ADHD.

ADHD in Adults

Although articles dealing with the adult equivalents of childhood hyperactivity or MBD date back to the late 1960s and 1970s (discussed earlier), they did not initiate widespread acceptance of these adult equivalents in the field of adult psychiatry and clinical psychology. It was not until the 1990s that the professional fields and the general public recognized ADHD in adults as a legitimate disorder. This was due in large part to a best-selling book by Edward Hallowell and John Ratey (1994), *Driven to Distraction*, which brought the disorder to the public's attention. More serious and more rigorous scientific research was also conducted on adults with ADHD across this decade. In addition, the greater clinical professional community began to consider the disorder a legitimate clinical condition worthy of differential diagnosis and treatment (Goldstein, 1997; Nadeau, 1995; Wender, 1995).

This broadening acceptance of ADHD in adults continues to the present time and is likely to increase further in the decades ahead. It seems to have been strengthened in some part throughout the 1990s by the repeated publication of follow-up studies that documented the persistence of the disorder into adolescence in up to 70% of cases, and into adulthood in up to as many as 66% of childhood cases (Barkley, Fischer, et al., 1990, 2002; Mannuzza, Gittelman-Klein, Bessler, Malloy, & LaPadula, 1993; Weiss & Hechtman, 1993). And it can be attributed as well to published studies on clinically referred adults diagnosed with the disorder (Biederman et al., 1993; Murphy & Barkley, 1996; Shekim, Asarnow, Hess, Zaucha, & Wheeler, 1990; Spencer, Biederman, Wilens, & Faraone, 1994). But it is probably in part a result of pressure from the general public, which was made more cognizant of this disorder in adults through various media, including the publication of other best-selling, popular books on the subject (Kelly & Ramundo, 1992; Murphy & LeVert, 1994; Weiss, 1992); numerous media accounts of the condition in adults; the efforts of large-scale parent support groups discussed earlier (e.g., CHADD) to promote greater public awareness of this issue; and the advent of Internet chat rooms, Web pages, and bulletin boards devoted to this topic (Gordon, 1997). Adults who obtain such information and seek out evaluation and treatment for their condition are simply not satisfied any longer with outdated opinions of some adult mental health specialists that the disorder does not exist in adults and is commonly outgrown by adolescence, a belief that was widespread in the 1960s.

Also notable in the 1990s was the publication of more rigorous studies demonstrating the efficacy of stimulants (Spencer et al., 1995) and antidepressants (Wilens et al., 1996) in the management of adult ADHD. Such studies confirmed the initial clinical speculations in the 1970s, as well as the conclusions from earlier, smaller studies by Paul Wender and his colleagues in the 1970s and 1980s (described earlier), that such medications were efficacious for this disorder in adults (Wender, Reimherr, & Wood, 1981; Wender, Reimherr, Wood, & Ward, 1985). Thus, the adult form of ADHD was found not only to share many patterns of symptoms and comorbid disorders with the childhood form, but also to respond just as well to the same medications that proved so useful in the management of childhood ADHD (see Chapter 35).

Other Developments of the Era

The 1990s were marked by other significant developments in the field of ADHD. In 1994, new diagnostic criteria for the disorder set forth in DSM-IV (American Psychiatric Association, 1994) included several improvements over those in the earlier DSM-III-R. But suffice it to say here that they reintroduced criteria for the diagnosis of a purely inattentive form of ADHD, similar to ADD – H in DSM-III. The diagnostic criteria also now require evidence of symptoms' pervasiveness across settings, as well as the demonstration of impairment in a major domain of life functioning (home, school, work). Based on a much larger field trial than any of their predecessors, DSM-IV contained the most empirically based criteria for ADHD in the history of this disorder (see Chapter 2).

A further development during this decade was the NIMH multisite study of ADHD that focused on various combinations of long-term treatments (Arnold et al., 1997; MTA Cooperative Group, 1999; see Chapter 28). This study (the Multimodal Treatment Study of ADHD [MTA]) determined what combinations of treatments were most effective for what subgroups of ADHD, based on those treatment strategies with the greatest empirical support in the prior treatment literature. Another long-term treatment study reported findings of great significance to the field: The Swedish government commissioned the longest treatment study of stimulant medication ever undertaken, the results of which indicated that amphetamine treatment remained effective for the entire 15 months of the investigation (see Gillberg et al., 1997). More sobering was the report that an intensive, yearlong treatment program using primarily CBT strategies produced no substantial treatment effects either at posttreatment or at follow-up (Braswell et al., 1997). Similarly, a yearlong, intensive early intervention program for hyperactive–aggressive children found no significant impact of parent training either at posttreatment or at 2-year follow-up (Barkley et al., 2000; Barkley, Fischer, et al., 2002); the school-based portion of this multimethod program produced some immediate treatment gains, but by 2-year follow-up, these had dissipated (Shelton et al., 2000). Finally, a multisite study of stimulant medication with and without intensive behavioral and psychosocial interventions revealed that the psychosocial interventions added little or nothing to treatment outcome beyond that achieved by stimulant medication alone (Abikoff & Hechtman, 1995). Its final results, not reported until 2004 (see Chapter 28), were in keeping with the findings of the MTA that the combined treatments were generally no substantially better than medication treatment alone. Although these studies do not entirely undermine earlier studies on the effectiveness of behavioral interventions for children with ADHD, they do suggest that some of those interventions produce minimal or no improvement when used on a large-scale basis; that the extent of improvement is difficult to detect when adjunctive stimulant medication is also used; and that treatment effects may not be maintained over time following treatment termination.

The 1990s also witnessed the emergence of trends that would be developed further over the next decade. These trends included a renewed interest in theory development related to ADHD (Barkley, 1997a, 1997c; Quay, 1988a, 1997; Sergeant & van der Meere, 1994), as well as an expanding recognition and treatment of the disorder in countries outside the United States and Canada (Fonseca et al., 1995; Shalev, Hartman, Stavsky, & Sergeant, 1995; Toone & van der Linden, 1997; Vermeersch & Fombonne, 1995). A new stimulant combination, Adderall, which appeared on the market in this decade, showed promise as being as effective for ADHD as the other stimulants (Swanson et al., 1998), and at least three new nonstimulant medications and an additional stimulant were in development or in Phase II clinical trials by several pharmaceutical companies during this decade. There also appeared to be an increasing interest in the use of peers as treatment agents in several new behavioral intervention programs for academic performance and peer conflict in school settings (DuPaul & Henningson, 1993; see Chapters 23 and 24).

The Prevailing View at the End of the 1990s

It seems clear that during the 1990s there was a shift back to viewing ADHD as far more influenced by neurological and genetic factors than by social or environmental ones. Clearly, the interaction of these sources of influence is generally well accepted by professionals at this time, but greater emphasis is now being placed on the former than on the latter in understanding the potential causation of the disorder. Moreover, evidence began accruing that the influence of the environment on the symptoms of the disorder fall chiefly in the realm of unique or nonshared factors rather than among the more frequently considered but now weakly supported common or shared family factors.

Over this decade, there was also a discernible shift toward the recognition that a deficit in behavioral inhibition may be the characteristic that most clearly distinguishes ADHD from other mental and developmental disorders (Barkley, 1997a; Nigg, 2001; Pennington & Ozonoff, 1996; Schachar, Tannock, & Logan, 1993), and that this deficit is associated with a significant disruption in the development of typical self-regulation. It is also noteworthy that the subtype of ADHD comprising chiefly inattention without hyperactive–impulsive behavior may possibly be a qualitatively distinct disorder from the subtype with hyperactive–impulsive behavior or the subtype with combined behavior (Barkley et al., 1992; Goodyear & Hynd, 1992; Lahey & Carlson, 1992). The issue of comorbidity became increasingly important in subgrouping children with ADHD, leading to greater understanding of the way disorders

that coexist with ADHD may influence family functioning, academic success, developmental course and outcome, and even treatment response. In contrast to the attitudes apparent in the middle of the 20th century, the view of ADHD at the close of the century was a less developmentally benign one, owing in large part to multiple follow-up studies that documented the pervasiveness of difficulties with adaptive functioning in the adult lives of many (though by no means all) persons clinically diagnosed with ADHD in childhood.

There is little doubt that the use of pharmacology in the management of the disorder continued its dramatic rise in popularity, owing in no small part to repeated demonstration of the efficacy of stimulants in the treatment of the disorder; the greater recognition of subtypes of ADHD, as well as girls and adults with ADHD; and the rather sobering results of multimethod intensive psychosocial intervention programs. Even so, combinations of medication with psychosocial and educational treatment programs remained the norm in recommendations for the management of the disorder across the 1990s, much as they were in the 1980s.

Across this decade, the expansion, solidification, and increased political activity and power of the patient and family support organizations, such as CHADD, were indeed a marvel to behold. They clearly led to far wider public recognition of the disorder, as well as to controversies over its existence, definition, and treatment with stimulant medications; still, the general trend toward greater public acceptance of ADHD as a developmental disability remained a largely optimistic one. Moreover, such political activity resulted in increased eligibility of those with ADHD for entitlements, under the IDEA, and legal protections, under the Americans with Disabilities Act of 1990 (Public Law 101-336).

THE NEW CENTURY: 2000 TO THE PRESENT

A number of developments arising in this period are covered in detail throughout the remaining chapters in this volume, so they receive only brief topical mention here because of their importance to the history of the disorder. For instance, the recently published DSM-5 diagnostic manual contains a few important adjustments to criteria for the clinical diagnosis of ADHD (American Psychiatric Association, 2013), as discussed in the next chapter. Those adjustments, and others that were recommended but not included, have spawned recent controversy that is also addressed in that chapter.

Trends from the 1990s have certainly continued into the 21st century, with far more published research on heredity, molecular genetics, and neuroimaging, along with some initial efforts to link these fields together. The result has been an explosion in the size of the ADHD literature, which has nearly doubled in 2013 alone, along with the publication of numerous meta-analyses of various segments of it, as referenced in various chapters in this volume. Not only has the hereditary basis of ADHD become firmly established by hundreds of recent studies, but numerous candidate genes for the disorder are also being identified, and new chromosomal regions deserving of greater investigation via scans of the entire human genome that involve hundreds, and soon thousands, of affected families. This area of research has revealed that not only are genes involved in the regulation of dopamine and norepinephrine networks in the brain involved in ADHD but also other, far evolutionary older genes involved in brain cell growth, endpoint termination, and neuronal sprouting may also be implicated (see Chapter 14).

Although no entirely new theories of ADHD have been proposed, existing theories have been expanded and clarified (Barkley, 2012b). There have also been tremendous advances in establishing the underlying neurological nature and mechanisms involved in ADHD in the field of neuroimaging, along with findings from developmental (longitudinal) neuroimaging studies documenting the delayed brain growth and altered growth trajectories associated with the disorder (see Chapter 14). There continues to be abundant research on the neuropsychology of ADHD and potential endophenotypes for use in genetic and neuroimaging investigations, discussed in several chapters in this volume.

Research efforts at subtyping ADHD have also increased since 2000 (see Chapters 2 and 17; also see Milich, Balentine, & Lynam, 2001). This research seems to suggest that the prior DSM-IV subtyping approach to ADHD has not proven useful, and that the disorder is likely to be a single condition varying in severity within the population while having two highly intercorrelated yet partially distinct symptom dimensions. Yet other research is leading to the possibility that perhaps a new attention disorder has been unearthed (Barkley, 2012a, 2012b, 2013). Known as SCT, this subset may have accounted for approximately 30–50% of those children previously placed in the DSM-IV predominantly inattentive type of ADHD, what clinicians began calling ADD. It is characterized

by a cognitive sluggishness and social passivity, in sharp contrast to the distractible, impulsive, overactive, and emotional difficulties so characteristic of the combined type of the disorder. Because of its derogatory and potentially offensive name, and the implication that the underlying cognitive dysfunction is known, I have suggested that the term SCT be renamed "concentration deficit disorder" (CDD; Barkley, 2014).

Although ADHD is a single and dimensional disorder in the human population, advances in molecular genetics may offer the possibility of genetically subtyping samples of individuals with ADHD into those who do and do not possess a particular candidate allele, so as to study over time the impact of the allele on the psychological and social phenotype of the disorder, and its developmental course and risk for future impairments. Such longitudinal studies are now under way.

Further work has also examined those disorders likely to be comorbid with ADHD in both children (see Angold, Costello, & Erkanli, 1999) and adults (Barkley, Murphy, & Fischer, 2008), and the impact they may have on risk for impairments, life course, and even treatment response in ADHD. It now appears, for instance, that the overlap of ADHD with the learning disorders (reading, spelling, math) may stem from both separate, distinct etiologies that arise together in particular cases and some small shared genetic contribution to both disorders, in contrast to the earlier, more simplistic view that one type of disorder may be causing the other. For now, existing evidence suggests that although the two sets of disorders are genetically linked to each other to a small extent, they also have a greater proportion of unshared etiologies. ADHD, however, may be a direct contributor to a progressive increase in problems with reading (and even story and video) comprehension, perhaps through its detrimental effects on working memory. The case for major depressive disorder gives us fairly substantial evidence that ADHD may create a genetic susceptibility to this disorder, albeit one that may require exposure to stress, social disruption, or traumatic events to become fully manifest. And the link of ADHD to ODD and CD, as well as later substance use and antisocial activity, continues to be supported by ongoing research.

The domain of treatment has seen several advances, not the least of which has been the continued reporting of results from the MTA (see Chapter 28), although there is controversy about how initial and especially follow-up results should be interpreted. No one doubts that this monumental study indicated that medication treatment is superior to psychosocial treatment or community care as usual in the initial results. Continuing disagreement appears to concern whether the combination of medication and psychosocial components resulted in important benefits that were not as evident in the medication-only condition. Although many professionals continue to adhere to the view that many cases require combined therapy and that it offers advantages for especially comorbid cases, some certainly concede the point that some cases may do sufficiently well on medications and require little additional psychosocial care.

Another advance in treatment was the development of sustained-release delivery systems for the previously extant stimulant medications (see Chapter 27). These new delivery systems are chemical engineering marvels (sustained-release pellets, osmotic pumps, skin patches, prodrugs, etc.); within the few years of their initial introduction to the marketplace, these extended-release formulations have become the standard of care for medication management, at least in the United States. Such delivery systems allow single doses of medication to manage ADHD symptoms effectively for periods of 8–12 hours. This has eliminated the need for school dosing and its numerous associated problems, not the least of which is stigmatization of children who required midday doses.

This decade also saw U.S. Food and Drug Administration (FDA) approval of two new nonstimulants for treating ADHD. The first of these new medications was the norepinephrine reuptake inhibitor, atomoxetine (Strattera). First approved for use in the United States in January 2003 by the FDA, atomoxetine was the first drug approved for management of ADHD in adults, along with use in children and teens. Over the next several years, the drug received approval for use in numerous other countries and is now prescribed for more than 4 million individuals worldwide. Attractive to many is the fact that this medication has no abuse potential and is therefore not a scheduled drug in the United States, which makes it far easier to prescribe than stimulants, which are Schedule II medications. As one of the most studied medications ever submitted for FDA approval for a neuroscience indication, atomoxetine has become the second-choice medication behind stimulants for management of ADHD in many professional association guidelines for ADHD management.

The second nonstimulant approved by the FDA in the United States was guanfacine XR (Intuniv) in

2009. For more on this medication, see Chapter 27. Guanfacine is an alpha$_2$ agonist that was originally used in the treatment of hypertension. A similar drug, clonidine, had been investigated for use in ADHD over the past 30 years with some success and was even used clinically off-label by some physicians in efforts to better manage the impulsive, hyperactive, and emotionally excitable aspects of ADHD apart from any benefits relative to attention. Some even combined clonidine with stimulants in an attempt to gain greater coverage of ADHD or some symptoms of comorbid disorders associated with anger or other emotion dysregulation. But its significant risks for cardiotoxicity limited its adoption on a more widespread basis, along with its lack of FDA approval for the management of ADHD. In contrast, guanfacine has been shown to present less risk for adverse cardiotoxic events. By reformulating the medication into an extended-release delivery system, guanfacine XR can be taken just once daily, providing treatment coverage of ADHD symptoms across much of the waking day. Like atomoxetine, guanfacine XR does not appear to improve ADHD symptoms as much as the stimulants, but both nonstimulants appear to benefit approximately 75% of individuals taking either medication. They may also be first-choice drugs when ADHD co-occurs with certain other psychiatric disorders or health conditions that might preclude the use of stimulants, or when stimulants may arguably produce some exacerbation, such as anxiety or tic disorders.

Few new psychosocial treatments for ADHD have been identified in nearly a decade since publication of the previous edition of this volume. Research continues to show that various formats of behavioral parent training can help parents manage children and teens with ADHD (see Chapters 21 and 22, this volume), as can training teachers in various behavior management strategies (see Chapter 24). But exciting developments in the alteration or combination of existing treatments may make them more effective for managing various impairments in ADHD. For instance, new CBTs for adults that focus on the executive function deficits that are so impairing in ADHD have been developed and evaluated in randomized trials with considerable success (see Chapter 32). A new variation in social skills training, known as Friendship Coaching, developed by Mikami and colleagues (Chapter 23, this volume) may offer a successful intervention for the social problems of children with ADHD. Prior studies have suggested that social skills training, at least as traditionally delivered in clinics by professionals, has not been especially effective. Mikami's approach uses parents as therapists (friendship coaches) to deliver the appropriate methods throughout the natural stream of social interactions with children in the natural social ecology. Initial promise was evident in the development of cognitive rehabilitation training programs relying on computer software game technology, such as those for working memory training. Yet subsequent efforts to replicate these initially promising findings have shown more limited, if any, positive effects (see Chapter 26). And controversy continues to surround the issue of the effectiveness of EEG biofeedback training (neurofeedback) developed more than 20 years ago (as discussed briefly in Chapter 11), with less rigorous studies showing clinical benefits, while more rigorous ones are less beneficial, if at all.

The international recognition of ADHD has grown sharply since 2000, owing in part to the emergence and expansion of parent support groups in many countries; the dramatic increase in research articles on ADHD in journals, especially from developing or non-Western countries; and the emergence of foreign professional societies dedicated to ADHD, such as Eunythydis in Europe and the World Federation for ADHD, both of which hold annual meetings that comprise numerous presentations on topics related to ADHD. Certainly, educational and advertising efforts by the pharmaceutical industry associated with the increasing number of countries approving the use of these medications has also contributed to greater international recognition of the disorder. But substantial credit must also be given to the increasing access people have to the Internet and the increasing amount of information on ADHD existing there. The Internet allows anyone with a computer, iPad, or smartphone to have nearly instantaneous access to websites such as those sponsored by CHADD (*www.chadd.org*) and ADDA (*www.add.org*) in the United States, the Center for ADD Awareness of Canada (*www.caddac.ca*) and its partner, the Canadian ADHD Resource Alliance (*www.caddra.ca*), among others. It also permits access to numerous videos on YouTube and similar forums.

There was a time when each country had its own view of mental disorders, their causes, and their management. Hence, the United States might view ADHD one way, Sweden in another, and Italy, France, Germany, or Spain might each view it in a different way. Such walls between different countries' understand-

ings of ADHD have now figuratively come crashing down, with the democratizing spread of information via the Internet and the scientific (and nonscientific!) information it can bring to any user. This means that there is no longer an Italian view of ADHD or a U.S. view, but an international view, founded on the most recent scientific advances as they become available on the Internet. Professionals, for instance, who may still practice a psychoanalytic view of childhood disorders as arising from early upbringing, can no longer count on this view going unchallenged by parents of children or adults with ADHD in their practices. These patients and families can readily discover on the Internet that such views have no scientific credibility; that long-term, analytically focused psychotherapy is not effective for ADHD; and that medications and more empirically based psychosocial accommodations are the cutting edge treatments. If they cannot obtain them in their country, they can quickly locate a neighboring one that is better informed and where such therapies may be accessible. We should expect to see more such developments on the international scene in the coming years. But as a consequence, we also continue to expect the same sort of media sensationalism and misrepresentation, baseless social criticism, and even Scientology's propaganda efforts periodically to erupt alongside this expanding international recognition of ADHD as a legitimate mental health and public health disorder.

ADHD has undoubtedly become a valid disorder and frequent topic of scientific study, widely accepted throughout the mental health and medical professions as a legitimate neurodevelopmental disability. At this time, it is unmistakably one of the most well-studied childhood disorders. That it is also the object of healthy, sustained research initiatives into its adult counterparts has led to far greater acceptance of adult ADHD than what occurred two decades earlier for the childhood version of the disorder. Further discoveries concerning the nature, causes, and developmental course of ADHD promise tremendous advances in our insight into not only this disorder but also the very nature and development of human self-regulation more generally, and its rather substantial neurological, genetic, and unique environmental underpinnings. Along with these advances will undoubtedly come new treatments and their combinations. These, let us hope, will greatly limit the impairments experienced by many who suffer from ADHD across their lifespan.

KEY CLINICAL POINTS

- ✓ ADHD has a long and exceptionally rich history of clinical and scientific publications, more than 10,000 since the initial descriptions of clinical patients by Weikard in 1775.
- ✓ Early conceptualizations of ADHD focused on inattention, impulsive behavior, and excessive activity, as well as defective moral control of behavior. Proponents of these views recognized that ADHD-like behavior could arise from brain injuries yet might also develop from flawed social environments. Later views emphasized ADHD's association with brain damage, particularly to the frontal lobes, followed by an emphasis on brain dysfunction, then hyperactivity. Current views of the etiologies of ADHD now emphasize its neurodevelopmental nature and the prominent roles played by genetic, as well as nongenetic, neurological factors.
- ✓ Advances in developing diagnostic criteria have resulted in more precise specification of symptoms, along with two symptom lists; an emphasis on childhood or early-adolescent onset of the disorder in most cases; and a requirement for both cross-setting pervasiveness of symptoms and evidence of impairment in one or more major life activities.
- ✓ More recent theories of ADHD have viewed deficits in self-regulation as central to the disorder, while also suggesting that deficits in executive functioning and biologically based motivational difficulties that undergird self-regulation are likely to account for most or all of the symptoms associated with the disorder.
- ✓ Efforts at subtyping ADHD, such as in the DSM-IV, did not prove successful. But a subset of inattentive children manifesting SCT or CDD, along with social passivity and other distinguishing clinical features, may yet come to be recognized as a second attention disorder that is distinct from yet partially overlaps ADHD.
- ✓ Research using neuroimaging techniques has served to isolate particular brain regions (especially the frontal–striatal–cerebellar network, and possibly other regions) as underlying the disorder, and particularly as involved in the difficulties with inhibition and executive functioning.
- ✓ Increasing research on heredity and genetics has clearly shown a striking hereditary basis to ADHD, along with the identification of numerous candidate

genes or chromosomal locations that hold some promise in explaining the disorder.

- ✓ Research into the neuropsychology of ADHD has also increased substantially in the past decade; it supports the view that ADHD is not only an inhibitory disorder but also one associated with deficits in the major executive functions that underlie self-regulation.
- ✓ Further research, especially on prenatal neurological hazards and postnatal injuries and environmental toxins, suggests that some cases of ADHD may arise from brain injury rather than, or in interaction with, genetic mechanisms.
- ✓ Numerous longitudinal studies now support the conclusion that ADHD is a relatively chronic disorder affecting many domains of major life activities from childhood through adolescence and into adulthood.
- ✓ Within the past decade, new medications and new delivery systems for older medications have been developed that both broaden the range of treatment options for managing the heterogeneity of clinical cases and sustain medication effects for longer periods across the day (with less need for in-school dosing).
- ✓ Advances in psychosocial treatment research have revealed specific subsets of individuals with ADHD who may be more or less likely to benefit from these empirically proven interventions. They have also revealed the limitations of these approaches for generalization and maintenance of treatment effects if they are not specifically programmed into the treatment protocol.
- ✓ ADHD is now recognized as a universal disorder, with an ever-growing international acceptance of both its existence and its status as a chronic disabling condition, for which combinations of medications and psychosocial treatments and accommodations may offer the most effective approach to management.

CHAPTER 2

Primary Symptoms, Diagnostic Criteria, Subtyping, and Prevalence of ADHD

Walter Roberts, Richard Milich, and Russell A. Barkley

Attention-deficit/hyperactivity disorder (ADHD) is a common and well-recognized behavior disorder that affects millions of children, adolescents, and adults. A tremendous amount of research has been published on the primary characteristics and symptomatology of children and adults with ADHD. In this chapter, we briefly summarize this research to provide a concise overview of what is known about ADHD as a clinical construct. It is not our goal to review this sizable body of research critically. Instead, we have attempted to summarize information related to the phenomenology of ADHD that can help clinicians by providing the essence of what is known in this field of research to facilitate the diagnosis, assessment, and treatment of children and adults with ADHD.

The chapter begins with a discussion of the current diagnostic criteria for ADHD because these criteria define the clinical construct of ADHD. For this reason, it is important to understand the rationale behind *Diagnostic and Statistical Manual of Mental Disorders* (DSM) criteria, as well as some of the limitations of this system. We then review findings on the primary symptoms of this condition (i.e., inattention, hyperactivity–impulsivity) as they occur in children and adults, as well as sluggish cognitive tempo, a "secondary" symptom cluster that may be either a core component of at least some forms of ADHD or an entirely separate disorder that often overlaps with ADHD. What follows is a discussion of how these primary symptoms can change as a function of situational variables. We conclude the chapter with a discussion of the prevalence of ADHD.

DIAGNOSTIC CRITERIA FOR ADHD

Given the nature of our current classification system of psychopathology, it is necessary to begin our discussion of the nature of ADHD by reviewing the diagnostic criteria of the disorder. Simply put, these criteria define what is and is not ADHD. The current official diagnostic criteria for ADHD are described in the fifth edition of the DSM (DSM-5; American Psychiatric Association, 2013), which is used primarily in the United States. These criteria are similar to those in DSM-IV (American Psychiatric Association, 1994), although there are small changes that we describe throughout this chapter. Table 2.1 presents the DSM-5 criteria. DSM criteria are similar, although not identical, to

TABLE 2.1. DSM-5 Diagnostic Criteria for ADHD

A. Either (1) or (2):

(1) **Inattention:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

Note: For older adolescents and adults (age 17 and older), at least five symptoms are required. The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand task instructions.

(a) often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate)

(b) often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading)

(c) often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction)

(d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked)

(e) often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines)

(f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers)

(g) often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones)

(h) is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts)

(i) is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning to class, paying bills, keeping appointments)

(2) **Hyperactivity and impulsivity:** Six (or more) of the following symptoms have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:

Note: For older adolescents and adults (age 17 and older), at least five symptoms are required. The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand task instructions.

Hyperactivity

(a) often fidgets with hands or feet or squirms in seat

(b) often leaves seat situations where remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place)

(c) often runs about or climbs excessively in situations in which it is inappropriate (**Note:** In adolescents or adults, may be limited to subjective feelings of restlessness)

(d) often unable to play or engage in leisure activities quietly

(e) is often "on the go," acting as if "driven by a motor" (e.g., is unable or uncomfortable being still for extended time, as in restaurants, meetings, etc.; may be experienced by others as being restless or difficult to keep up with)

(f) often talks excessively

Impulsivity

(g) often blurts out answers before questions have been completed (e.g., completes people's sentences; cannot wait for turn in conversation)

(h) often has difficulty awaiting turn (e.g., while waiting in line)

(i) often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing)

(continued)

TABLE 2.1. *(continued)*

B. Several hyperactive–impulsive or inattentive symptoms that caused impairment were present prior to age 12 years.

C. Several impairments from the symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).

D. There is clear evidence that the symptoms interfere with, or reduce, the quality of social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or a personality disorder).

Specify whether:

314.01 (F90.2) combined presentation: If both Criteria A1 (inattention) and A2 (hyperactivity-impulsivity) are met for the past 6 months.

314.00 (F90.0) predominantly inattentive presentation: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity–impulsivity) is not met for the past 6 months.

314.01 (F90.1) Predominantly hyperactive–impulsive presentation: If Criterion A2 (hyperactivity–impulsivity) is met but Criterion A1 (inattention) is not met for the past 6 months.

Specify if:

In partial remission: When full criteria were met in the past, fewer than the full criteria have been met for the past 6 months, and the symptoms still result in impairment in social, academic, or occupational functioning.

Specify current severity:

Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, and symptoms result in no more than minor impairment in social or occupational functioning.

Moderate: Symptoms or functional impairment between "mild" and "severe" are present.

Severe: Many symptoms in excess of those required to make the diagnosis, or severe symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social occupational functioning.

the definition of the disorder in the 10th edition of the *International Classification of Diseases* (ICD-10; World Health Organization, 2008), which is used mainly in Europe.

DSM-5 criteria stipulate that people must have had their symptoms of ADHD for at least 6 months, and that these symptoms must occur to a degree that is developmentally deviant. The symptoms producing impairment must have developed by 12 years of age. In DSM-5, the number of symptoms required to meet criteria changes according to the individual's age. For children age 16 or younger, six or more of the nine items from at least one cluster of symptoms must be endorsed as developmentally inappropriate. For adolescents and adults age 17 or older, five or more symptoms from at least one of the symptom clusters must be endorsed. These symptoms must interfere with the individual's functioning in two or more settings. The presentation of ADHD to be diagnosed depends on whether criteria are met for inattention, hyperactivity–impulsivity, or both: the predominantly inattentive presentation (ADHD-PI), the predominantly hyperactive–impulsive presentation (ADHD-PHI), or the combined presentation (ADHD-C). Severity specifiers can be used to further specify a person's diagnosis (i.e., mild, moderate, or severe) based on his or her symptom profile and degree of functional impairment. For example, a child who shows six symptoms in both clusters and experiences minimal functional impairment in few settings might be diagnosed with ADHD-C mild, whereas a child with eight inattentive symptoms and two hyperactive–impulsive symptoms who shows considerable impairment across most settings might be diagnosed with ADHD-PI severe.

Critical Review of the DSM Criteria

Empirical Basis and Validity

Perhaps the strongest aspect of the current DSM criteria set for ADHD is its empirical basis. DSM-5 criteria, which are largely similar to their predecessors from DSM-IV, are some of the most rigorous and empirically derived criteria ever available in the history of ADHD. They were derived from a process in which (1) a committee of some of the leading experts in the field met to discuss its development; (2) a literature review of ADHD symptoms was conducted; (3) a survey of rating scales assessing the behavioral dimensions related to ADHD, along with their factor structure and psychometric properties, was undertaken; and (4) a field trial of the subsequently developed item pool was conducted with 380 children from 10 different sites in North America (Applegate et al., 1997; Lahey et al., 1994).

The pool of items from which the criteria were taken was derived primarily from factor analyses of items from parent and teacher rating scales in which the items already showed high intercorrelations with each other and the underlying dimension, as well as validity in distinguishing children with ADHD from other groups of children (Lahey et al., 1994; Spitzer, Davies, & Barkley, 1990). DSM-5 clusters these items underneath two symptom categories (i.e., inattention and hyperactivity–impulsivity); the factor structure of these items is supported by a multitude of factor analyses of behavioral ratings of over 60,000 children displaying these two symptom dimensions (Willcutt et al., 2012).

The cutoff points for the number of symptoms necessary for a diagnosis (six) were determined in a field trial (Lahey et al., 1994) as having the greatest interrater reliability and discrimination of children with ADHD from those without ADHD.[1] Thus, unlike previous iterations of the DSM, selection of the criteria put forth in the DSM-IV had an empirical basis. Other research has supported the stability of ADHD diagnoses over time (Willcutt et al., 2012), with the caveat that diagnoses are likely to shift between subtypes during subsequent assessments (Lahey, Pelham, Loney, Lee, & Willcutt, 2005). That is one reason why DSM-5 no longer allows for three subtypes and instead specifies three "presentations"; it is to emphasize that cases at certain times may have more of one symptom dimension than the other, without conveying the notion that they are distinct types. ADHD diagnoses predict future functional impairment, even when researchers control for confounding factors such as socioeconomic status, intelligence, and comorbid psychopathology (Lahey & Willcutt, 2010).

Situational Pervasiveness

The requirement that symptoms of ADHD should be present in two or more situations was introduced in DSM-IV and formalized as a diagnostic requirement in DSM-5. Given that ADHD appears to result from neurological dysfunction, it is expected that children with the disorder should show symptoms, and to a lesser extent, impairment, in more than one domain of functioning (e.g., at school and at home). If a person has symptoms only in a single setting, then it is likely that environmental influences in that setting rather than ADHD are eliciting the problematic behavior. As such, this requirement has important implications for correctly diagnosing and treating ADHD, but, unfortunately, the specifics of this criterion are not well developed in DSM-5.

An immediate problem with establishing impairment across settings is that information on each setting is often provided by a different informant(s) (e.g., parents, teachers), so ratings on each setting are typically confounded by the source. The degree of agreement between parents and teachers is modest for most dimensions of behavior; it often ranges between .30 and .50, depending on the behavioral dimension being rated (Achenbach, McConaughy, & Howell, 1987; Mitsis, McKay, Schulz, Newcorn, & Halperin, 2000). This relatively modest correlation between parent and teacher reports of behavior sets a low ceiling for the level of agreement that can be expected between two informants.

Possible causes of such disagreement between sources are numerous and difficult to establish on a case-by-case basis. Discrepancies may in part reflect real differences in the child's behavior in these different settings, probably as a function of true differences in situational demands. School, after all, is quite different from the home environment in its expectations, tasks, social context, and general demands for public self-regulation, and, as we describe later, these situational differences can have profound effects on the behavior of children with ADHD. The differences may also reflect the degree of historical knowledge the rater possesses concerning that child; at the beginning of the school year, teachers have far less information about a particular child they are asked to describe than will be the case later in the year. But the disagreements may

also reflect differences in the attitudes, experiences, and judgments of different people. Although it is likely that teachers have a larger "normative group" against which to compare a single child's behavior, parents likely have more behavioral observations of their child on which they can base their ratings. Indeed, parent and teacher ratings of symptoms predict unique components of functional impairment, suggesting that each source of information provides some valid information about the child's symptoms (Hart, Lahey, Loeber, & Hanson, 1994). As such, clinicians should interpret these assessment sources as providing information on the child *in that particular context* and nothing more, rather than as evidence as to whether or not the child really has the disorder. When agreement across parent, teacher, and clinician is a requirement for diagnosis, it severely reduces diagnosis (particularly for the ADHD-PI and ADHD-PHI presentations) within the childhood population (Mitsis et al., 2000).

In summary, the requirement that children show ADHD symptoms across settings ensures that those with behavioral problems secondary to specific environmental factors are not diagnosed with ADHD. However, there are problems with interrater agreement and situational variability in children's symptoms that can make establishing impairment across settings challenging. Clinicians do well to remember that no source of information is entirely infallible. There is also no empirical basis for requiring that reports from multiple informants be used to support a diagnosis of ADHD. Until more research is done to address this issue, even evidence for *a history* of symptoms across settings should probably be sufficient to satisfy this criterion, rather than the current implicit requirement of agreement between parents and teachers on the number and severity of symptoms—a requirement not actually stated in DSM-5.

Conceptual Considerations

The case has been made both in theoretical and empirical writings that ADHD is probably a disorder of executive functioning (EF; Barkley, 1997, 2012d). Reviews of psychometric tests of EF have typically concluded that only a minority of individuals with ADHD are impaired on these tests; thus, ADHD is not principally a disorder of EF (Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). EF deficits are therefore seen in only a subset of these patients, so other conceptualizations of the disorder must be considered. But as Barkley has argued (2011b, 2012d; Barkley & Fischer, 2011; Barkley & Murphy, 2011), this assumes that the premise of the assertion is correct, which is that psychometric tests of EF are the "gold standard" for assessing EF. This premise is highly questionable, especially since there is no relationship between EF tests and EF rating scales (Toplak, West, & Stanovich, 2013) or other measures of adaptive functioning, nor are those tests very adept at predicting impairment in major life activities with which EF ought to be involved (see Barkley, 2012d, for review and discussion). In contrast, studies using rating scales of EF indicate that the vast majority of children and adults with ADHD are so impaired, and that such scales are better at predicting impairment in major life activities (Barkley, 2011b, 2012a).

More to the point of this discussion, research has shown that rating scales of DSM symptoms are so highly correlated with EF rating scales that they approach or meet standards of colinearity (synonymity) (Barkley, 2011b, 2012a). If that continues to be the case, then it may well be that the current conceptualization of the two DSM symptom lists for ADHD should be broadened to include metacognition or EF as representing the conceptualization of the inattention dimension and behavioral disinhibition or self-restraint as representing the hyperactive–impulsive dimension. At the very least, future DSM editions may need to broaden these conceptualizations in the associated text with the criteria even if the names for the symptom dimensions remain unchanged.

Developmental Considerations

Developmental issues continue to pose significant problems for DSM ADHD criteria. The original DSM-IV field trials tested the use of ADHD criteria on children between ages 4 and 16. It is unclear at this time whether the current symptom set is appropriate for use outside of individuals in this age range. This concern arises from the finding that some symptoms, particularly those in the hyperactive–impulsive cluster, decline in frequency as people age (Hinshaw, Owens, Sami, & Fargeon, 2006; Larsson, Lichtenstein, & Larsson, 2006). This is problematic because applying symptoms that change in frequency across development may result in changing sensitivity and specificity across age groups. Given the age-dependent decline in hyperactive–impulsive symptoms, young preschool-age children (ages 2–3) may be inappropriately diagnosed as having ADHD (false positives), while a smaller than

expected percentage of adults would meet the criteria (false negatives).

This problem has been partially addressed in DSM-5. Instead of requiring six symptoms in either cluster for all age groups, older adolescents and adults are required to endorse five or more symptoms in at least one cluster to receive a diagnosis. Although this is a step in the right direction toward addressing the age-related reduction in hyperactivity–impulsivity symptoms, more could have been done. First, it is questionable whether a cutoff score of five items is most appropriate for adults. For instance, Murphy and Barkley (1996) initially found that endorsing four items placed older adults at the upper end of the distribution (i.e., > 93rd percentile). Furthermore, those adults who endorsed four or more symptoms continued to show functional impairment, which suggests that their symptoms continued to interfere with their functioning. These findings were later supported by analyses of both large samples of clinic-referred and community adults and children with ADHD followed to young adulthood (Barkley, Murphy, & Fischer, 2008). Subsequently, this cutoff was replicated using a large population sample representative of U.S. adults (Barkley, 2011a). Thus, the currently prescribed five-item cutoff for adults should probably be four symptoms on either list because the use of five items may continue to underidentify impaired adults. Others have also found this threshold to be valid for diagnosing adults with ADHD (see Barkley et al., 2008, for discussion). What this makes plain is that without some age-related adjustments to the thresholds, individuals can outgrow the DSM criteria without outgrowing their disorder, which is seen as developmentally deviant and impairing.

Second, DSM-5 does not adjust the required number of symptoms for preschool children. Unfortunately, there is little research on diagnostic thresholds in preschoolers, and none was done in support of DSM-5. For this reason it is difficult and potentially problematic to diagnose young children using DSM-5 criteria. As discussed earlier, preschool children show higher rates of hyperactive–impulsive symptoms than do school-age children. This may reflect normal developmental patterns rather than higher rates of ADHD in this age group. Indeed, it is in this age group that children are likely to be diagnosed with ADHD-PHI subtype—or "presentation" in DSM-5 terminology—a subtype of the disorder that often remits before adolescence (Willcutt et al., 2012). This may reflect typical developmental patterns rather than true ADHD in young children.

In addition to the necessity of age-dependent changes in the optimal cutoff score, one also must consider that the items themselves become more or less valid as a function of age. The items used to construct DSM-IV symptom lists were initially based entirely on research on children (Spitzer et al., 1990). To address the more egregious examples of this problem, DSM-5 now includes parenthetical clarifications of many symptoms to advise clinicians on how the symptoms might be expressed in teens or adults. This is because it is likely that a set of items developed specifically for children is not ideal for measuring the same construct in adolescents or adults. Problematic with this approach to adjusting item content is that the parenthetical clarifications were not themselves tested in any research projects as such to determine whether they in fact are clarifications of that item (are collinear with it) or actually may represent an additional symptom. These clarifications also have not been tested for their accuracy in discriminating teens or adults with ADHD, so while the intent here was commendable, the inclusion of these untested clarifications may pose problems for both reliability and validity of the item pool for diagnosis.

In a large-scale research project intended to identify the best items for the diagnosis of adult ADHD, Barkley and colleagues (2008) tested 99 new symptoms of ADHD, most of which were derived from either chart reviews of several hundred adults diagnosed with the disorder or rating scales and theories of executive functioning. Eight were from the symptom list for oppositional defiant disorder (ODD). These items were evaluated using both large samples of clinic-referred adults diagnosed with ADHD (via DSM-IV), adults seen at the same clinic but not meeting criteria for the disorder, and a community sample of adults. They were also evaluated in a study of children with ADHD who were followed to adulthood. Following the identification of the best item set from these 99 symptoms for discriminating between adults with ADHD and control groups, the resulting small set of items was then also tested against the DSM-IV 18-item set. The result was that of the nine items identified as being the most accurate at discriminating adults with ADHD, only three items were from DSM-IV and none were from the hyperactive–impulsive symptom list. These items, shown in Table 2.2, are listed in descending order of discriminative accuracy. The final two items on this list, taken from DSM-IV, were retained but contributed just 1% more accuracy to the group discriminations. Further analyses showed that a cutoff of 4 of the

TABLE 2.2. A List of Proposed Diagnostic Criteria for ADHD in Adults

Has **six** (or more) of the following nine symptoms or four or more of the first seven symptoms that have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

1. Often easily distracted by extraneous stimuli.
2. Often make decisions impulsively.
3. Often has difficulty stopping activities or behavior when they should do so.
4. Often starts a project or task without reading or listening to directions carefully.
5. Often shows poor follow through on promises or commitments they may make to others.
6. Often has trouble doing things in their proper order or sequence.
7. Often more likely to drive a motor vehicle much faster than others (excessive speeding). (If person has no driving history, substitute: "Often has difficulty engaging in leisure activities or doing fun things quietly.")
8. Often has difficulty sustaining attention in tasks or leisure activities.
9. Often has difficulty organizing tasks and activities.

Note. Copyright 2008 by Russell A. Barkley, PhD. Reprinted by permission.

first seven items or six of the entire list of nine items would be useful for making a diagnosis of adult ADHD, and better at doing so than the DSM-IV. Other studies have also shown this reduced item set to be useful in identifying adult ADHD (Vergara-Moraques et al., 2011). Using this same original item set, Biederman and colleagues (Biederman et al., 2008) found that just eight items were as useful at identifying functional impairment in adults with ADHD as the entire item set, some of which overlap with those in Table 2.2. Later, Fedele, Hartung, Canu, and Wilkowski (2010) studied this same item pool for its utility in predicting impairment in ADHD in a large sample of college students and found that 17 items were sufficient to account for such impairment accurately. Note that Barkley and colleagues (2008) developed their items from those that best discriminated between adults with ADHD and non-ADHD groups; that is a different undertaking than identifying items best at predicting functional impairment, as these latter two studies attempted to do. So it is not surprising that the resulting reduced item sets found in these studies are not identical. All of this is to say that better items than those in DSM-5 exist as symptoms for diagnosing adults with ADHD, whether for discriminating them from other conditions or for predicting impairment. Although this information was shared with the DSM-5 committee developing the criteria for ADHD, no new items were eventually included in the final DSM-5 for use with adults.

Another issue raised from an inspection of the two clusters or dimensions of items suggests that the items for inattention may have a wider developmental applicability across the school-age ranges of childhood and possibly into adolescence and young adulthood (e.g., "Is often easily distracted"). Those for hyperactivity–impulsivity, in contrast, seem much more applicable to young children and less appropriate or not at all applicable to older teens and adults (e.g., "Often leaves seat in situations when remaining seated is expected"). This hypothesis is supported by the previously discussed findings that people show reductions in hyperactive–impulsive symptoms, but not inattentive symptoms, as they age. In other words, it may be that hyperactivity–impulsivity does not actually decline over time, but that instead DSM criteria become less sensitive to these constructs throughout development.

How, then, can clinicians handle these limitations of the DSM criteria related to developmental changes? Although only limited effort is made in DSM-5 to define "developmental inappropriateness," the ubiquity of well-normed behavior rating scales for ADHD symptoms argues for the use of such instruments to determine the extent of developmental deviance in a particular case (see Chapter 18 for a discussion of these scales). Although not wholly objective, such instruments do provide a means of quantifying parent and teacher opinions in the case of children, and self-report and other-report of symptoms in the case of adults being evaluated for ADHD (Barkley, 2011a; Conners, Erhardt, & Sparrow, 1999). Moreover, national norms are now available for the parent and teacher versions of these instruments for children (DuPaul et al., 1997; DuPaul, Power, McGoey, Ikeda, & Anastopoulos, 1998), and self and other ratings for adults (Barkley, 2011a). The use of such scales automatically provides a means for establishing deviance relative to both age and gender membership of an individual given that norms are provided separately for males and females by age groups. With such norms available, we must then specify a recommended threshold that is considered "inappropriate." It would seem prudent to establish a cutoff score

on these scales of at least the 90th percentile, and preferably the 93rd percentile, as the demarcation for clinical significance, given that the 93rd percentile (+1.5 standard deviations above the mean) is a traditionally employed cutoff point for this purpose (DuPaul, Power, McGoey, et al., 1998). This recommendation should be taken not as gospel but instead as a guideline for circumventing some of the limitations of DSM criteria.

The age-of-onset criterion in DSM-5 specifies that to be diagnosed with ADHD, a person must have shown evidence of symptoms producing impairment when he or she was 12 years of age or younger. In DSM-IV, this age restriction required evidence of impairment prior to age 7. This criterion was challenged by the results of its own field trial (Applegate et al., 1997), and a subsequent review confirmed that strict application of the DSM-IV age-of-onset requirement resulted in underidentification of people showing impairment (Kieling, Kieling, & Rohde, 2010). Although people with early-onset ADHD (i.e., prior to age 7) appear to have more severe and persistent conditions, with more problems with reading and school performance generally (McGee, Williams, & Feehan, 1992), those with later onset still demonstrate considerable functional impairment related to their symptoms (Faraone et al., 2006). In the original DSM-IV field trials (Applegate et al., 1997), the age 7 age-of-onset criterion resulted in underidentification of children with ADHD-PI, but it performed reasonably well for children with ADHD-C, perhaps because hyperactivity–impulsivity symptoms can result in disruptive behavior that is more salient than symptoms of inattention to teachers and parents. Overall, that DSM-5 requires symptom onset before age 12 rather than age 7 will likely result in fewer false negatives, although clinicians should be cautious if children present with symptoms of hyperactivity that were not present earlier in their development.

Clinicians may also want to view age of onset as a guideline that requires onset of symptoms in childhood or adolescence rather than as an empirically supported demarcation between real and false cases of disorder. We advise this for two reasons. First, research shows that at least 7–10% of children and adults meeting all other criteria for ADHD have an onset of symptoms after age 12 (Barkley et al., 2008). Second, self- and parental recall of childhood onset of these symptoms is quite unreliable among teens and adults, on average occurring 4–5 years later than what was established when they were children with ADHD entering a longitudinal study (Barkley et al., 2008).

Subtyping

Beginning with DSM-III, diagnostic specifiers have been used to distinguish among people whose symptoms are primarily in the inattentive cluster, those whose symptoms are primarily hyperactive–impulsive, and those who show symptoms in both clusters. There are differences, however, in how these symptom specifiers are described in each DSM edition. In DSM-IV, as previously mentioned, diagnostic subtypes were determined based on the pattern of symptoms endorsed. In DSM-5, the "subtype" terminology was dropped in favor of a more fluid "presentation" system. This change was a reaction to the finding that often children would be diagnosed with one subtype of ADHD, then meet criteria for another subtype of the disorder at follow-up (Lahey et al., 2005; Willcutt et al., 2012). Although this presentation system is clinically useful in that it allows clinicians to distinguish between children whose primary problems are attention-related and those who struggle with hyperactivity–impulsivity, the structure of this system has created numerous problems.

First and foremost is the concern that the diagnostic category ADHD-PI contains at least two diagnostic subgroups (Diamond, 2005; Milich, Balentine, & Lynam, 2001). One group includes children who demonstrate clinically significant symptoms of inattention and subclinical, but still considerable, levels of hyperactivity–impulsivity. Another group comprises children whose inattentive symptoms are linked to problems with arousal and sluggish cognitive tempo (SCT; McBurnett, Pfiffner, & Frick, 2001). Although we describe the SCT dimension later in this chapter and it is discussed more thoroughly in Chapter 17, suffice to say that there are a number of qualitative differences between individuals with the SCT subset of ADHD-PI and those with "subthreshold" ADHD-C; emerging research suggests that these groups suffer from qualitatively different disorders (Barkley, 2012c, 2013, 2014). Another subgroup that meets criteria for ADHD-PI is those people who originally met criteria for ADHD-C but experienced the previously described age-related reduction in hyperactive–impulsive symptoms. These individuals likely suffer from a disorder that is qualitatively distinct disorder from that of persons whose symptoms were always consistent with ADHD-PI but due to partial symptom remission in the hyperactive–impulsive cluster do not meet criteria for ADHD-C. One way to address this issue may be to develop a separate set of criteria for individuals with inattentive symptoms but no

hyperactive–impulsive symptoms (Adams, Milich, & Fillmore, 2010). This may improve classification accuracy and reduce heterogeneity among people diagnosed with ADHD-PI.

Another problem with the subtyping system is that very little is known about differences among the subtypes in terms of developmental trajectory, associated problems, and treatment response. Most of the research on children and adults with ADHD does not differentiate between the groups, so by default most of the participants show a considerable number of hyperactive–impulsive symptoms. There are, of course, studies that have specifically recruited an ADHD-PI group for comparison with children with ADHD-C (Nigg, Blaskey, Huang-Pollock, & Rappley, 2002); however, these studies are the exception rather than the rule, and even these studies may have limitation in their findings because the ADHD-PI groups typically include both children with "true" ADHD-PI and those with "subthreshold" ADHD-C. Indeed, studies that have attempted to identify groups of children with "pure" inattentive symptoms often report intriguing differences between the subtypes (Adams, Derefinko, Milich, & Fillmore, 2008; Carr, Henderson, & Nigg, 2010; Fillmore, Milich, & Lorch, 2009).

As a counterpoint to our view on the importance of subtypes, several studies have shown that children diagnosed with one subtype of ADHD are very likely to meet criteria for another subtype during a later assessment (Willcutt et al., 2012). This subtype instability calls into question the importance of research on the differences between subtypes of the disorder because if subtypes do not persist, then the differences among them are unlikely to be consequential in the long run. However, it should be noted that some of this subtype instability may result from small changes in symptom count (e.g., six hyperactive–impulsive symptoms during an initial assessment and five hyperactive–impulsive symptoms at follow-up). As discussed earlier, a way to improve subtype stability may be to develop a separate set of criteria for those with heightened inattentive symptoms and few or no hyperactive–impulsive symptoms.

A final issue concerns the validity of the ADHD-PHI subtype. This is by far the most uncommon subtype of this disorder; most children who show symptoms of hyperactivity–impulsivity also meet criteria in the inattentive symptom cluster. Those individuals who only meet criteria in the hyperactive–impulsive symptom cluster are mostly young and show the highest level of diagnostic instability over time (Lahey et al., 2005). One source of this diagnostic instability may be that ADHD-PHI is an earlier developmental stage of ADHD-C. Indeed, many children originally diagnosed with ADHD-PHI are diagnosed with ADHD-C during follow-up assessment. Another possible source of this diagnostic instability is that young children diagnosed with ADHD-PHI show symptom remission as they age from early to middle childhood. By far the largest proportion of these children do not meet criteria for ADHD at follow-up (Willcutt et al., 2012), which suggests that the original diagnosis reflected a typical developmental phase or even a time-limited behavior disorder.

To summarize, children and adults with ADHD-PI are a mixed group. Some of them (perhaps 30–50%) have an SCT form of attention disturbance, which may constitute a qualitatively unique disorder from the attention disturbance in ADHD-C. Others are older children and adults who were once diagnosed as having ADHD-C but have shown a decrease in the number and severity of their symptoms of hyperactivity with age, such that they now fall below the critical number of six such symptoms required for the ADHD-C diagnosis. Although the DSM decision rules would reclassify these individuals as having ADHD-PI, clinicians may wish to continue conceptualizing and treating them as having ADHD-C. Despite these limitations, whether people are diagnosed with ADHD-PI or ADHD-C is not entirely consequential at this time given the dearth of research on subtype differences in treatment response, developmental trajectory, and associated problems.

Functional Impairment as a Requirement for Diagnosing ADHD

The addition of a requirement of impairment as a criterion for diagnosis of a mental disorder is crucial, and its importance cannot be overemphasized. Simply because a child or adult may show a higher frequency or severity of symptoms related to ADHD than is typical of others does not by itself warrant a diagnosis of ADHD. Efforts to define the nature of a mental disorder typically incorporate such a requirement to distinguish a mental disorder from the wide range of normal human behavior and problems in living that do not necessarily lead to a harmful dysfunction or impairment (Wakefield, 1997). In treatment, it is aspects of functional impairment, rather than symptoms per se, that are tar-

geted for intervention (Pelham, 2001). As such, clinicians should remember that while symptom counts are means to an end for diagnostic purposes, clinical interventions should emphasize functional impairments that result from the disorder.

While the inclusion of an impairment criterion in ADHD diagnostic criteria is commendable for various reasons, defining the comparison standard for making such a determination has been left ambiguous. As discussed later in Chapter 33 on workplace accommodations for adults with ADHD, clinicians have sometimes used IQ as the standard against which to judgment impairment in high-IQ individuals, as if IQ were the "gold standard" against which all human abilities are to be compared for deviation. Such disparities are then seen as evidence that the person is not functioning up to his or her expected potential. Others have done the same thing by using high-functioning local peer groups as an index of what a person with ADHD should be expected to do. Any significant variation by an adult from the performance of this peer group is then viewed as evidence that the person is impaired (e.g., a medical student with ADHD who is doing poorly in organic chemistry relative to other medical students at that college). In neither of these cases does the individual have to place below the average of the population, which makes these standards questionable, if not laughable, for determining impairment. Inherent in that determination is that the individual must be functioning below the average, normal, or typical person in the population of that age group. To say otherwise mocks the very meaning of the terms "impairment" and "disorder." Future DSM editions need to do a better job of making explicit what is meant by "impairment" (e.g., functional ineffectiveness that leads to adverse consequences; Barkley, 2011c, 2012b) and against what standard it is to be judged (e.g., average person).

Sex Differences in ADHD

Sex differences in ADHD are covered in depth later in Chapter 9, but we should briefly mention here the (lack of) consideration of sex differences in DSM-5. Research evaluating gender differences in psychopathology using the DSM-IV criteria sets demonstrates that males in the general population display more symptoms of ADHD than do females (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007), more so in childhood than in adulthood. This gender difference results in females having to meet a higher threshold relative to other females to be diagnosed with ADHD than do males relative to other males. The problem is further accentuated by the fact that the majority of individuals in the DSM-IV field trial were males, making the DSM criteria primarily male-referenced. Nonetheless, a series of studies by Hinshaw (Miller, Sheridan, Cardoos, & Hinshaw, 2013) has shown that females with ADHD show equally if not more negative functional outcomes compared to their male counterparts (see Chapter 9). In light of these findings, an important future goal is for researchers to examine whether female-specific cutoffs or even a separate set of criteria better captures the disorder as it presents in girls. In the meantime, clinicians should be aware of these important sex differences in the nature of ADHD.

Symptom Persistence

A final issue concerns the requirement that people display symptoms of the disorder for at least 6 months to receive the diagnosis. This number was chosen mainly in keeping with the criteria set forth in earlier DSM editions and consistency with criteria used for other disorders; there is little or no research support for selecting this particular length of time for symptom presence in the case of ADHD. Nonetheless, given that ADHD is a lifelong disorder apparently resulting from neurological dysfunction, it is reasonable to expect the symptoms to persist. Yet specifying a precise duration is difficult in the absence of research to guide the issue. Research on preschool-age children might prove helpful here. Such research shows that many children age 3 years or younger may have parents or preschool teachers who report concerns about their activity level or attention, but that these concerns have a high likelihood of remission within 12 months (Campbell, 1987). It would seem that, at least among preschoolers, the 6-month duration specified in DSM-5 may be too brief, resulting in the possibility of overidentification of ADHD in children at this age (false positives). However, this same body of research found that for those children whose problems lasted at least 12 months or beyond age 4 years, a persistent pattern of behavior was established that was highly predictive of its continuance into the school-age range. The finding suggests that the duration of symptoms might be better set at 12 months or longer, to improve the rigor of diagnosis in detecting true cases of disorder.

Other Changes in DSM-5

The recent release of DSM-5 has presented an opportunity to address some of the ongoing problems with ADHD as a diagnostic category. Unfortunately, the changes in this DSM edition may have created more problems than they solve. Although we described many of the more pervasive problems in the structure of ADHD in DSM earlier in this section, there are changes in the DSM-5 that may further complicate the diagnosis and treatment of ADHD (Roberts & Milich, 2013).

One major change in DSM-5 is that the section of the manual containing ADHD was changed. In DSM-IV, ADHD was included in the section "Disorders Usually Diagnosed in Infancy, Childhood, or Adolescence," which included all of the disruptive behavior disorders of childhood. This section was omitted from DSM-5, and the disorders that previously were in this section have been reassigned to "Neurodevelopmental Disorders" and "Disruptive, Impulsive Control, and Conduct Disorders," based on the nature of the disorder in question. Although ADHD was included as a "Neurodevelopmental Disorder," this may not have been the most appropriate classification method. An immediate problem with this decision is that different subtypes of the disorder are appropriate for different sections. On the one hand, children with ADHD-C and ADHD-PHI clearly present with disruptive and impulsive behavior that often leads to conduct problems—making this subtype an excellent fit for a section entitled "Disruptive, Impulsive Control, and Conduct Disorders." Furthermore, ADHD-C is highly comorbid with other externalizing disorders in this section, such as ODD and conduct disorder (Lahey & Willcutt, 2002). ADHD-PI, on the other hand, does not fit well in this section because children with primarily inattentive symptoms rarely show hyperactivity or impulsivity. ADHD-PI is better categorized in the "Neurodevelopmental Disorders" section with other childhood disorders not on the externalizing spectrum. Clearly, ADHD-C combined with ADHD-PHI and ADHD-PI are best suited for different sections of DSM-5. Because the three subtypes are linked together under a single diagnostic category, however, at least one must be categorized in an inappropriate diagnostic section.

Another series of changes in DSM-5 will likely affect the prevalence of the disorder (Sibley et al., 2012). DSM-IV required that children show symptoms and impairment when they were age 7 years or younger to receive a diagnosis. As previously mentioned, DSM-5 raised the age-of-onset criteria to age 12 years. Additionally, DSM-5 requires a history of symptoms— evidence that this history of symptoms caused impairment is no longer necessary. A similarly subtle change was made to the requirement that the child show problems across multiple settings. In DSM-IV, a diagnosis required that children show symptoms and impairment across more than one setting. In DSM-5, however, it is only necessary that children show "several" symptoms across more than one setting, so impairment in one setting is sufficient for a diagnosis. Finally, in DSM-5, autism spectrum disorders are no longer exclusionary conditions for diagnosing ADHD. This change will result in increased prevalence of ADHD as children with autism spectrum disorders are diagnosed with comorbid ADHD.

THE NATURE OF ADHD

Is ADHD a Mental Disorder?

Social critics (e.g., McGinnis, 1997), some non-expert professionals (e.g., Timimi, 2004), and fringe political–religious groups (e.g., the Church of Scientology and affiliated groups) charge that ADHD is a myth—or, more specifically, that professionals have been too quick to label energetic and exuberant children as having a mental disorder, and that educators also may be using these labels as an excuse for simply poor educational environments. In other words, children diagnosed with ADHD are actually normal but are being labeled "mentally disordered" because of parent and teacher intolerance (Kohn, 1989), parental and cultural anxiety surrounding childrearing (Timimi, 2004), or some unspecified and undocumented conspiracy between the mental health community and pharmaceutical companies (Timimi, 2004).

If this claim of ADHD as myth were actually true, and not just the propaganda it often turns out to represent, we should find no differences of any cognitive, behavioral, or social significance between children with and without the ADHD label. We should also find that being diagnosed with ADHD is not associated with any significant later risks in development for maladjustment (impairments) within any domains of adaptive functioning or social or school performance. Furthermore, research on potential etiologies for the disorder should likewise come up empty-handed. This is hardly

the case. The first 12 chapters of this volume constitute a direct and monumental refutation of such claims. Differences between children and adults with and without ADHD are numerous. And, as shown later, numerous developmental risks await the children meeting clinical diagnostic criteria for the disorder. Moreover, certain potential etiological factors are consistently noted in the research literature as being associated with ADHD. Therefore, any claims that ADHD is a myth reflect either a stunning level of scientific illiteracy or outright attempts to misrepresent the science of ADHD so as to mislead the public with propaganda (Barkley, 2004).

The fact that ADHD is a valid psychological trait, however, does not necessarily mean that it is also a mental disorder. Determining whether ADHD is a valid disorder requires that some standards for defining "disorder" be available. Jerome Wakefield (1997) has provided the field with the best available criteria to date for doing so, in our opinion. He has argued that mental disorders must meet two criteria to be viewed as such: (1) They must involve the dysfunction of universal mental mechanisms (adaptations) that have been selected in an evolutionary sense (have survival value); and (2) they must engender substantial harm to the individual (mortality, morbidity, or impaired major life activities). It should be clear from the totality of information on ADHD presented in this text that the disorder handily meets both criteria. Those with ADHD, as described previously, can show dysfunction in adaptive cognitive mechanisms (e.g., inhibitory control, working memory; Castellanos, Sonuga-Barke, Milham, & Tannock, 2006). These functions are evolutionarily adaptive, helping individuals to organize their behavior relative to time and the social future, and thereby to prioritize long-term over short-term social consequences (Ardila, 2008). Moreover, these neurocognitive deficits result in harm to the individual (see Chapters 3–8). In summary, ADHD meets the criteria of a valid mental disorder because it includes harmful dysfunction in a set of cognitive mechanisms evolved to have a survival advantage and confers functional impairment on those with the disorder.

Is ADHD a Categorical or Dimensional Trait?

Whether psychopathology is best conceptualized as categorical diagnoses or dimensional traits received an increasing amount of attention prior to the release of DSM-5. The notion of applying categories for psychopathologies of children seems to derive from the medical model, in which such categories constitute disease states (Edelbrock & Costello, 1984). From this perspective, an individual either has a disorder or does not. The DSM, in one sense, uses this categorical approach (all or none) by requiring that a person meet certain thresholds to be diagnosed with ADHD. The view of psychopathologies as representing dimensions of behavior, or even typologies (profiles) of these dimensions, arises from the perspective of developmental psychopathology (Achenbach & Edelbrock, 1983). In this view, ADHD constitutes the extreme end of a dimension, or dimensions, of behavior that falls along a continuum with the behavior of typical children. The dimensional view regards ADHD not necessarily as a disease entity but as a matter of degree in what is otherwise a characteristic of typical children.

As with most psychological constructs, ADHD is most accurately understood as a dimension. Many of the items described in DSM that constitute the ADHD symptom set were derived from behavioral rating scales that measure attention problems and hyperactivity (Spitzer et al., 1990). These scales and their item pools are dimensional. The underlying dimensional nature of ADHD is also supported by genetics studies suggesting that ADHD represents a dimensional condition rather than a pathological category (Hay, Bennett, Levy, Sergeant, & Swanson, 2007; Sharp, McQuillin, & Gurling, 2009).

Nonetheless, ADHD is typically described as and understood among the lay public as a categorical condition. This misrepresentation of the true nature of ADHD is not without merit. With our current system of mental health and disability services, it is important that categorical decisions be made, so that corresponding yes or no decisions can be made regarding the disbursement of services. With this is mind, an immediate question is whether assigning categories to a continuous variable results in a significant loss of validity when measuring that construct, and if so, can this loss of validity be justified by the utility of artificially dichotomizing the condition? In one study addressing this issue, Lahey and Willcutt (2010) compared categorical diagnosis to a continuous classification method based on symptom count to determine which performed better in predicting functional impairment and remaining stable over time. They found that the continuous classification approach performed better than the categorical system on both accounts.

Overall, the dimensional approach to ADHD seems most consistent with the available evidence, whereas

the categorical approach remains one of convenience, parsimony, and tradition (Hinshaw, 1994). Clinicians would do well to be flexible in how they conceptualize the disorder because different scenarios likely call for different treatment of the subject. Along these lines, DSM-5 takes a mixed approach by including diagnostic modifiers (i.e., mild, moderate, severe) that can be used in addition to the categorical diagnosis. This provides clinicians with more latitude to describe patients' symptoms on a dimension. Whether these dimensional diagnostic modifiers are beneficial to clinical practice remains to be seen.

PRIMARY SYMPTOMS

An important distinction should be made at the outset. The term "symptom" as used here refers to a behavior (e.g., skipping from one uncompleted activity to another) or a set of behaviors that significantly covary together (e.g., inattention) and are believed to represent a dimension of a mental disorder. The term "symptom" must be distinguished from that of "impairment," because the two are often confused in clinical discussions of disorders. "Impairments" are the consequences or outcomes of symptoms or symptom classes, such as retention in grade, failure to graduate from high school, vehicular crashes, license suspensions, teen pregnancy, or criminal arrests. They reflect functional ineffectiveness in these various domains of major life activity and serve as signs of the environment "kicking back" in response to the display of the symptom(s). The various impairments associated with the disorder are discussed in later chapters of this volume.

Those with ADHD are commonly observed by others as having chronic difficulties with inattention and/or impulsivity–hyperactivity. They display these characteristics early in development and to a degree that is excessive and inappropriate for their age or developmental level. Their symptoms are most evident in situations that tax their capacity to pay attention, restrain their movement, inhibit their impulses, and regulate their own behavior relative to rules, time, and the future. As noted in Chapter 1, definitions have varied considerably throughout the history of this disorder, as have the recommended criteria for obtaining a diagnosis. In this section we first review the dimensions of behavior at the core of the DSM ADHD symptom clusters: inattention and hyperactivity–impulsivity. We then briefly discuss SCT, a construct that is closely related to and may overlap with ADHD. That condition receives far more consideration in Chapter 17.

Two dimensions of behavior are almost uniformly found when the symptoms of ADHD as rated by parents and teachers are factor-analyzed (Willcutt et al., 2012). These two dimensions are used to create and diagnose the disorder and to construct its subtypes, at least within the DSM. The first dimension comprises impulsive and hyperactive behaviors, and the second encompasses behaviors related to poor control of attention. These dimensions are found across ethnic and cultural groups (Rohde et al., 2005), supporting the notion that ADHD comprises two separate but correlated symptom clusters.

Hyperactivity–Impulsivity

The first dimension of symptoms that emerges from factor analyses of symptom ratings in both children and adults is that of poor inhibition and associated hyperactivity (Willcutt et al., 2012). Clinically, those with ADHD are often noted to respond quickly to situations, without waiting for instructions to be completed or adequately appreciating what is required in the setting, resulting in impulsive errors. These individuals may also fail to consider the potentially negative, destructive, or even dangerous consequences that may be associated with particular situations or behaviors. Taking chances on a whim or dare, especially from a peer, may occur more often than is typical. They may carelessly damage or destroy others' property considerably more frequently than do children without ADHD.

Waiting for their turn in a game or in a group lineup before going to an activity is often problematic for children with ADHD; indeed, waiting in general may be problematic for people of all ages with the disorder. When faced with tasks or situations in which they are encouraged to delay seeking gratification and to work toward a longer-term goal and larger reward, they often opt for the immediate, smaller reward that requires less work to achieve. They are notorious for taking "shortcuts" in their work performance, applying the least amount of effort and taking the least amount of time in performing tasks they find boring or aversive. When they desire something to which others control access and they must wait a while to obtain it, as in a parent's promise to eventually take them shopping or to a movie, they may badger the parent excessively during the waiting interval, appearing to others as incessantly demanding and self-centered. Situations or games that

involve sharing, cooperation, and restraint with peers are particularly problematic for these impulsive children. Verbally, they often say things indiscreetly, without regard for the feelings of others or for the social consequences to themselves. Blurting out answers to questions prematurely and interrupting the conversations of others are commonplace.

Impulsivity is multidimensional in nature (Nigg, 2000). Discussions of impulsivity often include constructs such as executive control, delay of gratification, effort, and even compliance (Olson, Schilling, & Bates, 1999). Others reorganize inhibition into executive (volitional), motivational (precipitated by fear or anxiety), and automatic attentional inhibitory processes (Nigg, 2000). Those forms of impulsivity often associated with ADHD involve the undercontrol of behavior (poor executive functioning); poor sustained inhibition; and the inability to delay a response, defer gratification, or inhibit dominant or prepotent responses (Nigg, 2001). But there is also evidence that children with ADHD have an equal or greater problem with delay aversion: They find waiting to be aversive and therefore act impulsively to terminate the delay more quickly (Johansen, Aase, Meyer, & Sagvolden, 2002).

Evidence that behavioral disinhibition, or poor effortful regulation and inhibition of behavior, is in fact a hallmark of the disorder is substantial (Barkley, 1997; Nigg, 2001). First, whereas heightened rates of inattentive behavior characterize a broad range of clinical groups, hyperactive–impulsive behaviors are relatively specific to ADHD and distinguish people with ADHD from other clinical groups much more consistently than do inattentive behaviors (Kofler et al., 2013; Lipszyc & Schachar, 2010). Second, when objective measures of the three sets of symptoms of ADHD are subjected to a discriminant function analysis (a statistical method of examining the variables that contribute most to group discrimination), it is routinely the symptoms of impulsive errors, typically on vigilance tasks or those assessing response inhibition, and excessive activity level that best discriminate between children with and without ADHD (Losier, McGrath, & Klein, 1996). A third source of evidence is derived from the field trial of the DSM-III-R symptom list (Spitzer et al., 1990), which tested these symptoms' sensitivity and specificity. These descriptors were rank-ordered by their discriminating power and presented in DSM-III-R in descending order. Careful inspection of this rank ordering revealed that, again, symptoms characteristic of disinhibition, such as poorly regulated activity and impulsivity, were more likely to discriminate children with ADHD from those with other psychiatric disorders or no disorder. These observations inform disinhibition-based theories of ADHD, which are described later in this volume.

Recent meta-analyses of studies using stop-signal tasks and continuous performance tasks confirm that adults with ADHD show inhibitory deficits similar to those of children with the disorder (Hervey, Epstein, & Curry, 2004; Lijffijt, Kenemans, Verbaten, & van Engeland, 2005). Murphy and Barkley (1996) indicated that adults diagnosed with ADHD report difficulties with impulse control, such as "blurting out answers" and "interrupting or intruding on others" (see Barkley et al., 2008, for more evidence). Overall the symptoms reported by these adults were consistent with those reported by children with the disorder. Additionally, these impulse control problems can interfere with adult-specific activities, such as driving (Barkley, 2004; see Chapters 11 and 29). Thus, it appears that the symptoms characterizing childhood ADHD are likely to be associated with its adult equivalent.

Related to the difficulties with impulse control in those with ADHD are symptoms of excessive or developmentally inappropriate levels of activity, whether motor or vocal. Restlessness, fidgeting, and generally unnecessary gross bodily movements are commonplace, both in the complaints received from parents and teachers and in objective measures (Wood, Asherson, Rijsdijk, & Kuntsi, 2009). These movements are often irrelevant to the task or situation and at times seem purposeless. Parents often describe such a child as "always up and on the go," "acts as if driven by a motor," "climbs excessively," "can't sit still," "talks excessively," "often hums or makes odd noises," and "is squirmy" (DuPaul, Power, McGoey, et al., 1998). Observers of such children at school or while working on independent tasks find them out of their seats, moving around the classroom without permission, restlessly moving their arms and legs while working, playing with objects not related to the task, talking out of turn to others, and making unusual vocal noises (Barkley, DuPaul, & McMurray, 1990). The restlessness is likely to be more problematic in boring or low-stimulation situations than in ones where greater stimulation is available (Antrop, Roeyers, Van Oost, & Buysse, 2000; Zentall, Falkenberg, & Smith, 1985). It is not uncommon for these children to narrate their activity, consistent with their generally excessive patterns of speech and movement (Berk & Potts, 1991).

Numerous scientific studies using objective measures of activity level support observations that children with

ADHD are more active, restless, and fidgety than nonclinical children (McGrath, Handwerk, Armstrong, Lucas, & Friman, 2004). This heightened activity level is not just secondary to impulsivity: Children with ADHD are even more active during sleep (Cohen-Zion & Ancoli-Israel, 2004). Their activity levels in early morning hours may not be different from those of nondisabled children, but they may become so by the afternoon (Dane, Schachar, & Tannock, 2000). As with poor sustained attention, however, there are many different types of hyperactivity (Barkley & Ullman, 1975), and it is not always clear exactly which types are the most deviant for children with ADHD. Measures of ankle movement and locomotion seem to differentiate them most reliably from nondisabled children (Barkley & Cunningham, 1979), but even some studies of wrist activity and total body motion found them to be different as well (Teicher, Ito, Glod, & Barber, 1996). Additionally, objective measurement of their activity level during tasks demanding sustained attention reveals them to move their heads and bodies more than others, to move further away from their chairs than others, to cover a greater spatial area in doing so, and to show more simplified or less complex movement patterns in doing so (Teicher et al., 1996). Their heightened activity level is most pronounced in low-stimulation environments, suggesting that this hyperactivity is a form of stimulation seeking (Antrop et al., 2000).

Although hyperactivity is *conceptually* distinct from impulsivity, there is a large enough correlation between hyperactive and impulsive symptoms to conclude that they form a single symptom factor, at least in children. Typically, studies that factor-analyze behavioral ratings find that items of restlessness or other types of overactivity load on a factor constituting impulsive or disinhibited behavior (Willcutt et al., 2012). Likewise, studies of objective measures or behavioral measures of hyperactivity load onto the same factor as do similar measures of impulsivity (Berlin & Bohlin, 2002). These findings mean that overactivity as a dimension of behavioral impairment is closely associated with the disinhibition factor for children with ADHD.

In adults with ADHD, on the other hand, symptoms of hyperactive or restless behavior are often present but appear to involve more difficulties with fidgeting, a more subjective sense of restlessness, and excessive speech than the more gross motor overactivity characteristic of young children with ADHD. Researchers (Barkley et al., 2008; Murphy & Barkley, 1996) have found that nearly 60% of adults with ADHD reported that they often talked excessively. This excessive talking, however, did not distinguish the adults with ADHD from a clinical control group, suggesting that excessive talking may be a general characteristic of adults with psychopathology rather than a specific symptom of ADHD. Furthermore, whereas among children hyperactivity and impulsivity load onto a single symptom dimension, hyperactivity appears to form its own symptom dimension in adults (Barkley, 2011a; Kooij et al., 2005; Murphy & Barkley, 1996). It is clear that hyperactivity in adults functions differently than that in children, and this hyperactivity dimension in adults may be less important than impulsivity (mainly verbal). Clinicians should place more emphasis on behavioral impulsivity in adults with ADHD because hyperactivity may be of relatively less importance for diagnosing the disorder in adults.

Inattention

Another hallmark that is characteristic of children and adults with ADHD is impaired control of attention. Parents and teachers often describe these attention problems in terms such as the following: "Doesn't seem to listen," "Fails to finish assigned tasks," "Daydreams," "Often loses things," "Can't concentrate," "Easily distracted," "Can't work independently of supervision," "Requires more redirection," "Shifts from one uncompleted activity to another," and "Confused or seems to be in a fog" (Barkley et al., 1990). Many of these terms are the most frequently endorsed items from rating scales completed by the caregivers of these children (DuPaul, Power, Anastopoulos, & Reid, 1998; Mahone et al., 2002), and this trait of children with ADHD has been confirmed by behavioral observation studies indicating that children with ADHD spend more time off task or not paying attention than do their nonclinical peers (Barkley et al., 1990; DuPaul & Stoner, 2003).

Although the behaviors underlying the construct of inattention are well documented, less is known about the source of cognitive dysfunction that contributes to inattention at the behavioral level. Attention as it is studied by neurocognitive scientists is multifaceted and can refer to many different cognitive processes that support the control of attention (Chun, Golomb, & Turk-Browne, 2011; Petersen & Posner, 2012). "Attention" is a broad term encompassing many different cognitive mechanisms that support information processing, and inattentive behavior can result from failure of one or more of any of these cognitive processes.

People with ADHD are often characterized by poor attentional vigilance (i.e., remaining focused by sustaining attention on a certain task), particularly when they are required to attend to a dull or repetitive task (Boonstra, Oosterlaan, Sergeant, & Buitelaar, 2005; Hoza, Pelham, Waschbusch, Kipp, & Owens, 2001). This is consistent with the general observation that children and adults with ADHD have trouble persisting in tasks that are not inherently stimulating or interesting. People with ADHD also are more distractible than their nonclinical peers. Laboratory studies using eye-tracking tasks have shown that people with ADHD are more likely than their nonclinical peers to shift their attention toward task-irrelevant stimuli that they are instructed to ignore (Roberts, Fillmore, & Milich, 2011; Ross, Harris, Olincy, & Radant, 2000). This distractibility is also well documented by studies of response-time distributions using simple and choice response-time tasks. These almost uniformly show that those with ADHD have a slower and more variable response style than controls (Lijffijt et al., 2005), and this increased variability in response time occurs because those with ADHD become distracted and disengaged from the task (Adams, Roberts, Milich, & Fillmore, 2011; Spencer et al., 2009).

Whether distractibility, poor vigilance, a combination thereof, or even another trait contributes to inattention in those with ADHD is not entirely clear and may vary on a case-by-case basis. For example, the neuropsychological problem underlying poor attention in children with ADHD-C is most often one of diminished persistence of effort or sustained responding to tasks that have little intrinsic appeal or minimal immediate consequences upon completion (Johansen et al., 2002). Thus, although casual observation of these children would suggest high susceptibility to distraction, their poor task persistence may result from a motivational problem given their inability to persist in tasks that are not immediately reinforcing. Other children may have trouble attending due to an inability to inhibit shifts in attention toward distracting stimuli. A third viable mechanism is that children and adults with ADHD have impaired working memory (holding information in mind that guides behavior toward goals or tasks). Distractions may so interfere with working memory that the individual forgets the original task or goal he or she was pursuing and switches to a new task, one that is often provided by the distraction. In this sense, the underlying cognitive dysfunction is quite different, but the resulting behavioral symptoms are similar. Multiple pathway models of ADHD have garnered substantial empirical support, and future conceptualizations of the disorder will likely acknowledge that no single cognitive impairment is sufficient to explain all cases of ADHD (Fair, Bathula, Nikolas, & Nigg, 2012; Sonuga-Barke, Bitsakou, & Thompson, 2010).

Research indicates that adults with ADHD experience many of the same attention problems that are seen in children with the disorder. Much of this work is based on studies using the same neuropsychological measures of attention, such as manual response tasks and eye-tracking tasks (Lijffijt et al., 2005; Roberts et al., 2011). Other researchers have examined how inattention manifests in adult-specific tasks, such as driving, and have shown that adults with ADHD have more lapses in attention during these activities, particularly under high-distraction conditions (Reimer, Mehler, D'Ambrosio, & Fried, 2010). Finally, studies (Barkley et al., 2008; Murphy & Barkley, 1996) indicate that adults with ADHD report many of the same attention problems seen in children with ADHD, and these self-reports were corroborated by parents and spouses. In summary, there is ample justification for believing that adults and children with ADHD suffer from many of the same attention problems.

Secondary Symptom Cluster: Sluggish Cognitive Tempo

SCT is a dimension of symptoms that are related but empirically distinct from the inattentive symptom cluster of ADHD (McBurnett et al., 2001). Emergence of this symptom cluster was based on comparisons of the attention deficit disorder (ADD) subtypes in DSM-III, which included ADD with and without hyperactivity. The ADD with hyperactivity group was described as inattentive by way of distractibility and sloppiness, whereas those with ADD without hyperactivity showed a qualitatively different form of inattention characterized by daydreaming, sluggishness, slow processing, lethargy, and physical hypoactivity (Carlson & Mann, 2000). Subsequent factor analyses of items derived from DSM-III criteria revealed that these items formed a separate factor than the inattentive items included in DSM-IV (Milich et al., 2001). Items derived from this SCT symptom dimension were included in the DSM-IV field trials, but they were not included in the final diagnostic criteria (Lahey et al., 1994). Although these items were removed from the official diagnostic system, in recent years there has been a renewed interest in

the role of SCT symptoms in ADHD and how these symptoms fit into the ADHD nosology (Barkley, 2012c, 2013, 2014).

One reason for the renewed interest is that SCT may explain diagnostic heterogeneity among people with ADHD-PI. As we previously argued, people diagnosed with ADHD-PI fall into one of two diagnostic categories: (1) those who endorse six or more inattentive items but are marginally below the diagnostic threshold in the hyperactive–impulsive symptom cluster, and actually represent just subthreshold ADHD-C-type cases, and (2) those who endorse six or more inattentive items and have few or no hyperactive–impulsive items. We have argued that the former group suffers from the same underlying pathology as individuals with ADHD-C, whereas those in the latter group have a qualitatively distinct disorder that appears to be characterized by SCT (Milich et al., 2001). It follows that a set of criteria including SCT symptoms would better differentiate between the subtypes and improve subtype stability.

Although there is a relative dearth of research on SCT compared to inattentive and hyperactive–impulsive symptom dimensions in ADHD, emerging evidence indicates that people with SCT only and ADHD + SCT show different patterns of impairment and comorbidities than those with ADHD only (Barkley, 2012c, 2013, 2014). For example, Carlson and Mann (2002) compared children with ADHD-PI, with and without SCT, and found that those with SCT had fewer externalizing problems and were rated by teachers as being more anxious and depressed, and as having more social dysfunction than those without SCT. Other studies have shown that the SCT symptom dimension is more strongly associated with internalizing symptoms than are the DSM-IV ADHD symptom clusters (Bauermeister, Barkley, Bauermeister, Martinez, & McBurnett, 2012; Garner, Marceaux, Mrug, Patterson, & Hodgens, 2010). In summary, there is substantial empirical evidence that SCT is a statistically valid clinical entity with different external correlates than DSM-IV ADHD, at least in children (Barkley, 2014; Becker, 2013). There is very little research comparing long-term outcomes of people with SCT symptoms and those with ADHD; however, Barkley (2012c) recently examined adults with ADHD only, with SCT only, and with ADHD + SCT. He found that that SCT was associated with more psychosocial impairment, particularly in the areas of employment and education. He also found that, unlike ADHD, SCT was not associated significantly with EF deficits in everyday life (ratings) once the overlap of SCT with ADHD symptoms was statistically controlled (Barkley, 2012c, 2013). This suggests that whereas ADHD is linked to substantial and pervasive EF deficits in everyday life, SCT is not. An important future direction for research will be to characterize SCT in terms of course, outcome, and treatment response in comparison to inattention and hyperactivity–impulsivity. For more on SCT, see Chapter 17.

SITUATIONAL AND TEMPORAL VARIATION IN ADHD SYMPTOMS

People's ADHD symptoms can become more or less pronounced as a function of their environment and/or the demands placed on them. As a clinical example, consider a hyperactive boy during an afternoon at school. During recess, his high level of activity would be appropriate for the situation and not unlike the activity level of his classmates. A casual observer may not be able to differentiate the boy with ADHD from his typically developing peers in this setting. Consider the same child when he returns to class. As the situation changes and his classmates begin to reign in their activity levels, the boy with ADHD may continue to exhibit hyperactivity. In this setting, his symptoms become more apparent and, more importantly, disruptive to himself and his classmates. This example describes a common observation that the behavioral problems demonstrated by children with ADHD are not equally present across different settings (Landau & Milich, 1988). When children are playing alone, when they are washing and bathing, and when the father is at home are less troublesome situations for children with ADHD, whereas instances when they are asked to do chores, when a parent is on the telephone, when visitors are in the home, or when they are in public places may be times of peak symptom severity (Porrino et al., 1983). In this section we review how common situational factors can influence the severity of ADHD symptoms in affected individuals.

Level of Environmental Demand for Inhibition

Some of the factors determining this variation have been delineated. One of these—the extent to which caregivers demand that children with ADHD restrict their behavior—appears to affect the degree of devi-

ance of these children's behavior compared to that of nondisabled children. In free-play or low-demand settings, children with ADHD are less distinguishable from typical children than they are in highly restrictive ones (Barkley, 1985). Related to this issue of setting demands is the effect of task complexity on children with ADHD. The more complicated a task, and hence its greater demands for planning, organization, and executive regulation of behavior, the greater the likelihood that children with ADHD will perform more poorly than nondisabled children (Marzocchi, Lucangeli, De Meo, Fini, & Cornoldi, 2002). Clearly, the symptoms of ADHD are most disabling when the demands of the environment or task exceed a child's capacity to sustain attention, resist distractions, regulate activity, and restrain impulses. Children with ADHD appear less deviant and certainly are viewed by others as less troublesome in environments that place few or no demands on their behavioral faculties than in settings or tasks that place high demands on these abilities.

Novelty and Task Stimulation

Children with ADHD display fewer behavioral problems in novel or unfamiliar surroundings or when tasks are unusually novel, but their level of deviant behavior increases as familiarity with the setting increases (Zentall et al., 1985). We would expect to find that the behavior of these children is rated as far better at the beginning of the academic year, when they are presented with new teachers, classmates, classrooms, and sometimes even school facilities. However, we would expect their behavioral control to deteriorate over the initial weeks of school. Even academic performance among children with ADHD can be improved by novel material. Beike and Zentall (2012) demonstrated that story novelty improved attention and recall of children with ADHD. In fact, although these children performed much more poorly than nonclinical children when reading a familiar story, their performance was indistinguishable from the nonclinical group when the story was novel. Situational novelty also can influence children's behavior outside of school. A common clinical example is when children with ADHD visit grandparents they see infrequently, who are likely to provide them with considerable one-to-one attention. In this type of novel and stimulating environment, one can expect a temporary reduction in children's symptomatology.

The degree of stimulation in the task also seems to be a factor in the performance of children with ADHD. Research suggests that highly stimulating educational materials are more likely than relatively low stimulation to improve the attention of these children (Lee & Zentall, 2002). Likewise, children with ADHD make fewer impulsive choices in a high-stimulation environment (Antrop et al., 2006) and are better able to inhibit behavioral impulses while performing a stimulating task (Shaw, Grayson, & Lewis, 2005). It should be noted, however, that the beneficial effects of stimulation only occur when the task itself is highly engaging. If environmental features outside of the task are stimulating, then these stimuli can compete for children's attention and degrade their performance, perhaps because the children are distracted by these highly salient objects (Landau et al., 1992; Lee & Zentall, 2002).

An important clinical application of this finding is that children with ADHD may not misbehave in novel settings, such as a physician's or psychologist's office. It is important to consider that such a setting is relatively new for the child, so his or her symptoms may not manifest until the novelty of the new situation wears off.

Caregiver Effects

Children who have ADHD appear to be more compliant and less disruptive with their fathers than with their mothers (Tallmadge & Barkley, 1983). They are certainly rated routinely as manifesting lower levels of symptoms by their fathers than by their mothers (DuPaul et al., 1998). There are several possible reasons for this. For one, mothers are still the primary custodians of children within the family, even when they are employed outside the home; therefore, they may be the ones who are most likely to make demands that tax or exceed the children's limitations in the areas of persistence of attention, activity regulation, impulse control, and rule-governed behavior. Getting children to do chores and schoolwork, perform self-care routines, and control their behavior in public remain predominantly maternal responsibilities. As such, mothers may be more likely than fathers to witness their children's ADHD symptoms (but see Webster-Stratton, 1988).

Another reason may be that mothers and fathers tend to view and respond to inappropriate child behavior somewhat differently. Mothers may be more likely to reason with children, to repeat their instructions, and to use affection as a means of governing child compli-

ance. Fathers seem to repeat their commands less, to reason less, and to be quicker to discipline children for misconduct or noncompliance. The larger size of fathers and their consequently greater strength, among other characteristics, may also be perceived as more threatening by children and are therefore more likely to elicit compliance in response to commands given by fathers. For whatever reason, the greater obedience of children with ADHD to their fathers than to their mothers is now well established. This should not necessarily be construed as a sign that a child does not actually have ADHD or that the child's problems are entirely the result of maternal mismanagement.

Timing and Magnitude of Consequences

Settings or tasks that involve a high rate of immediate reinforcement for compliance with instructions result in significant reductions in, or in some cases amelioration of, attention deficits (reviewed in Luman, Oosterlaan, & Sergeant, 2005). Differences in activity level between groups with and without hyperactivity while watching television may be less than in other activities, whereas such differences are substantially evident during reading and math classes at school (Porrino et al., 1983). Children with ADHD seem to prefer immediate to delayed rewards (Sagvolden, Aase, Zeiner, & Berger, 1998). It seems that when children with ADHD are engaged in highly reinforcing activities, they may even perform at levels close to those of typical children; however, when the schedule and magnitude of reinforcement are decreased, the behavior of these children may become readily distinguishable from that of typical children (Barkley, Copeland, & Sivage, 1980). Such dramatic changes in the degree of deviant behavior as a function of motivational parameters in the setting have led several scientists to suggest that ADHD involves a problem in the manner in which behavior is influenced by environmental contingencies (Johansen et al., 2002).

A situational factor related to motivation appears to involve the degree of individualized attention provided to the children with ADHD. During one-on-one situations, these children may appear less active, inattentive, and impulsive, whereas in group situations, where there is little such attention, the children may appear at their worst. For instanceresearchers (Draeger, Prior, & Sanson, 1986; Steinkamp, 1980) found that children with ADHD perform better on cognitive and academic tasks when they perform the tasks with an adult in the room. Both factors (response consequences and individualized attention) are often incorporated as treatment recommendations into home and school management programs (see Part III).

Fatigue

Fatigue or time of day (or both) may have an impact on the degree of deviance of ADHD symptoms. Zagar and Bowers (1983) studied children with ADHD in their classrooms and found that they performed significantly better on various problem-solving tasks in the morning, whereas their classroom behavior was significantly worse in the afternoon. These changes in behavior with time of day did not appear to be a function of boredom or fatigue with the task, as efforts were made to counterbalance the order of administration of the tests across mornings and afternoons. Performance in the afternoon was routinely worse, whether it was the first or second administration of the task. However, general fatigue (defined simply as time since the last resting or sleeping period) might still explain these results.

This is not to say that differences between children with and without hyperactivity do not exist in the early morning but emerge only as time of day advances. Antrop and colleagues (2005) compared time-of-day effects on noisiness and other disruptive behaviors in a group of children with ADHD and a group of comparison children. Both groups showed similar increases in out-of-seat behavior during the afternoon, and the hyperactive children were more often out of their seats than controls, regardless of time of day. Given their normal susceptibility to time-of-day effects, however, clinicians might expect children with ADHD to show increased rates of disruptive behavior during the afternoon. Likewise, educators would do well to schedule overlearned, repetitive, or difficult tasks that require the greatest powers of attention and behavioral restraint for morning periods, while reserving recreational, entertaining, or physical activities for the afternoon (Zagar & Bowers, 1983). Such findings challenge the seemingly common practice of scheduling homework periods for children with ADHD in the late afternoon or early evening. Furthermore, they highlight the importance of sleep hygiene in children and adolescents with ADHD, because these individuals often report sleep-related problems that may increase their problems associated with fatigue (Konofal, Lecendreux, & Cortese, 2010).

PREVALENCE

The current consensus of expert opinion is that approximately 5.0% of children and 2.5% of adults have ADHD (American Psychiatric Association, 2013). On what is this based? A multitude of published studies has attempted to estimate the prevalence of ADHD in the general population. The answer to this question, however, depends largely on the methods used in each study. Factors affecting estimates include diagnostic method, how ADHD is defined, whether or not the functional impairment criterion is considered, and geographic location of the survey (Polanczyk et al., 2007). We begin this section with a discussion of how different methodological decisions in studies can affect prevalence estimates and conclude with a review of studies estimating the prevalence of ADHD in the population.

Defining Deviance

A problem in establishing prevalence has always been deciding what cutoff point is needed along the dimension or distribution of ADHD symptoms to determine that a person's behavior is sufficiently deviant from the norm to justify a diagnosis. Some have used the criterion of 1.5 standard deviations above the mean for nondisabled children on parent or teacher rating scales of ADHD symptoms; however, this cutoff may overestimate the number of people who meet criteria for the disorder. One study using this definition classified 14% of the population as hyperactive (Trites, Dugas, Lynch, & Ferguson, 1979). Other investigators have used the cutoff of 2 standard deviations above the mean and provided a more realistic prevalence estimate of 2–9%.

Applying such a stringent statistical criterion as 2 standard deviations is consistent with tradition in defining other conditions (e.g., learning disabilities and intellectual disability) as deviant. It also ensures that an excessive number of children are not being given a psychiatric diagnosis and reserves the diagnosis for the most severely afflicted. When the 2 standard deviations cutoff is used, children who are identified are extremely impaired, and this impairment is stable over time (Barkley, Fischer, Smallish, & Fletcher, 2002). Although it may be preferable to utilize a conservative definition of a disorder in a research setting, it would be prudent to use a lower cutoff (i.e., 1.5 standard deviations above the mean) in a clinical setting, where it may be better to err on the side of caution.

The real issue, though, is the following: At what level of developmental deviance is impairment in one or more major life activities likely to be evident? In short, disorder begins where impairment begins. If all or nearly all of the children exceeding the 93rd percentile have evidence of impairment, we can rest assured that this cutoff score is diagnostically meaningful. If not, then the threshold needs to be set either higher or lower, until we find a threshold that achieves this purpose. And so, while the actual number chosen as the diagnostic threshold may be a bit arbitrary, it is hardly meaningless. The further above this threshold a child or adult scores, the greater the likelihood that he or she will experience impairment in major life activities and the more such activities are likely to be impaired. Establishing the presence or absence of functional impairment should be the main focus of the diagnostic process. It is fine to view cutoff scores with flexibility when patients show functional impairment alongside their symptoms.

Prevalence of ADHD in Children

Estimates from Symptom Rating Scales and Clinical Diagnostic Criteria

There is an enormous literature on the attempt to estimate the prevalence of ADHD, using various research methodologies, in children in different geographical regions. We provide in this section an overview of this literature by reviewing meta-analyses as well as selected high-quality, individual studies on the prevalence of ADHD in children.

First it is important to consider how cases are identified. Perhaps the most common method for estimating the prevalence of ADHD is to use a parent or teacher rating scale of the symptoms of the disorder, then survey large populations of children. In these studies, children who score above the DSM (or ICD) diagnostic threshold are considered to meet criteria for the disorder. An advantage to this approach is that data for large samples of children can be collected quickly. Because such an approach does not incorporate other important criteria relevant to a diagnosis, however, the prevalence figures it may yield are probably overestimates, if only because the approach does not invoke an impairment criterion. Such scales are useful in screening for disorder and suggesting an upper limit to prevalence, but alone they do not define the true prevalence of ADHD.

Other studies use clinical interviews in addition to parent- and teacher-report measures. Although these studies are typically more difficult to conduct, they are able to more rigorously apply the full diagnostic criteria by assessing for functional impairment and interviewing respondents. Because DSM-5 criteria also require early onset of symptoms (before age 13), pervasiveness across settings, the exclusion of other disorders, and impairment in one or more major domains of life functioning, prevalence estimates produced by these studies are likely closer to the "true" prevalence of ADHD in the general population than are estimates produced by other methods.

Several meta-analyses have tested how much diagnostic method (e.g., rating scale vs. clinical interview) influences prevalence estimates. Polanczyk and colleagues (2007) conducted a meta-analysis of 102 studies and found that one of the best predictors of heterogeneity in prevalence estimates is whether the impairment criterion was included in the diagnostic decision. Other individual studies have shown that drastic changes in prevalence emerge depending on whether the presence of clinical impairment is required for a diagnosis. Wolraich, Hannah, Baumgaertel, and Feurer (1998) found a prevalence rate of 16.1% in a group of schoolchildren by using symptom count criteria, but the reported prevalence rate dropped to 6.8% when functional impairment was required for a diagnosis. Other authors found significant, albeit less pronounced, drops in prevalence estimates when functional impairment is required for diagnosis (Jensen et al., 1995; Simonoff et al., 1997). Clearly, assessing for functional impairment is an important step in producing accurate prevalence estimates.

Another methodological factor that can influence prevalence estimates is the source of information upon which diagnostic decisions are made. Many studies gather information on children's behavior from only a single caregiver; other, more comprehensive studies use ratings from multiple sources (e.g., parent and teacher reports). Other studies that estimate prevalence in older children, adolescents, and adults do so by gathering self-reported symptom counts. Not surprisingly, the source of information influences prevalence estimates (Polanczyk et al., 2007). Prevalence estimates based on parent and teacher ratings are generally comparable (Magnusson, Smari, Gretarsdottir, & Prandardottir, 1999), although this is not always true. For example, Breton and colleagues (1999) reported prevalence estimates of 5.0% based on parent report and 8.9% based on teacher report. Prevalence estimates based on self-reported symptoms from older children and adolescents are typically lower than those based on caregiver report. Romano and colleagues (2001) reported a prevalence of 3.3% in a sample of adolescents based on parent report, but this prevalence rate dropped to 0.6% when the estimate was based on participants' self-reported symptoms. This is consistent with the finding that children and adolescents have trouble accurately reporting on their own behavior (Owens, Goldfine, Evangelista, Hoza, & Kaiser, 2007).

The prevalence of ADHD also appears to differ significantly as a function of how many people must agree on the diagnosis. This is not entirely surprising; it is almost always more likely for a single condition to be satisfied (i.e., meeting criteria according to a single rater) than for two independent conditions to be satisfied (i.e., meeting criteria according to two raters). This is especially true given that ratings of children's behavior from different caregivers are only modestly correlated. Lambert, Sandoval, and Sassone (1978) asked parents, teachers, and physicians of 5,000 children in elementary school to identify the children they considered to be hyperactive. Approximately 5% of these children were defined as hyperactive when the opinion of only one of these caregivers (parent, teacher, physician) was required—a prevalence figure close to official population estimates (Polanczyk et al., 2007). However, this prevalence figure dropped to approximately 1% when agreement among all three sources was required.

There are similar differences in prevalence estimates in studies that conduct evaluations in a single setting and those performing evaluations across multiple settings (e.g., school, home). Perhaps unsurprisingly, studies that require symptoms across more than one setting typically produce lower prevalence estimates than those assessing impairment in a single setting (Skounti, Philalithis, & Galanakis, 2007). This finding may be influenced by the fact that gathering evaluations across multiple settings is often operationalized as gathering data from different caregivers (e.g., parents report on behavior at home, and teachers report on behavior at school). As previously discussed, the poor agreement among caregivers sets a modest upward limit of prevalence when diagnosis is contingent on both sources.

The age range of the sample can influence prevalence estimates, with older samples producing lower prevalence estimates. Polanczyk and colleagues' (2007)

meta-analysis examining differences between children and adolescents reported estimates of approximately 3% for adolescents and 6% for children. As previously discussed, the declining prevalence of ADHD with age may be partly an artifact of the DSM items' being chiefly applicable to young children, although this may change with the age-related adjustments to the DSM-5 set of criteria.

Geographic location appears to have an effect on prevalence estimates (Faraone, Sergeant, Gillberg, & Biederman, 2003). Although the majority of prevalence estimates were conducted in the United States and Europe, there has recently been a surge of studies from other parts of the world. Meta-analysis suggests that there is no significant difference in prevalence rates among North America (6%), Europe (5%), South America (12%),[2] Asia (4%), or Oceania (5%). Estimates from the Middle East (3%) are significantly lower than those in the United States, and estimates from Africa (8%) are higher than those in the United States (Polanczyk et al., 2007).

Finally, characteristics of the community from which the sample was drawn can influence prevalence estimates. Although more representative sampling techniques (e.g., multistage sampling; Kessler et al., 2006) produce more generalizable prevalence estimates, such studies are logistically challenging. Many studies sample from limited geographic areas, such as a single metropolitan area or even a single school. There is mixed evidence regarding the relation between socioeconomic status (SES) and ADHD: Some studies report that children in lower SES settings are more likely to show hyperactivity (Boyle & Lipman, 2002), whereas other studies show no such relation (Szatmari, 1992). One reason for these discrepant findings may be that whereas some studies control for comorbid disorders, others do not. For example, Szatmari (1992) found that a relation between ADHD symptoms and SES disappeared when he controlled for comorbid conduct disorder (CD) symptoms. Whether or not it is appropriate to control for CD symptoms in this type of analysis is a debatable point (Beauchaine, Hinshaw, & Pang, 2010), so the nature of the relation among SES and ADHD and CD prevalence rates remains an unresolved issue.

Prevalence Determined by Cases Identified in the Community

A somewhat different approach to estimating the prevalence of ADHD is to review school records to determine the percentage of children identified to schools as having a clinical diagnosis of ADHD. There are serious flaws in such an approach, not the least of which is that schools may not be told by either parents or professionals that children have received the diagnosis. It is also quite possible that a child may have the disorder but never have been referred or diagnosed. In either scenario, the school records would miss detecting such cases. As such, studies that examine the number of cases in schools should not be considered measures of the true population prevalence of ADHD. These data, however, can be used to answer a different question: How often are children and adolescents being diagnosed with ADHD in the community? The number of children identified as having ADHD is more fluid and sensitive to social forces than is the "true" prevalence rate of the disorder. For example, in 1992 the U.S. Department of Education released a memorandum stating that students with ADHD should be provided with access to special education services. Although this policy had no effect on the actual prevalence of ADHD in the population, it almost certainly increased the number of children being identified as more parents sought evaluations for their children so they could receive additional services.

Given recent concerns about overdiagnosis of ADHD among school-aged children, these studies are important in their own right. In an initial study that raised concern about overdiagnosis of ADHD, LeFever, Dawson, and Morrow (1999) reported prevalence rates of ADHD in two southeastern Virginia school districts that were two to three times higher than the DSM-IV-based cited average prevalence range of 3–5% (American Psychiatric Association, 1994). LeFever and colleagues examined school-identified cases to estimate prevalence of ADHD in grades 2–5. In addition to these higher rates than those based on DSM-IV criteria, the researchers found a disproportionate percentage of white males (18–20%) diagnosed with ADHD in both districts. The results of the LeFever and colleagues study were touted by its authors and others (see Timimi, 2004) as evidence of ADHD overdiagnosis. The LeFever and colleagues study was also touted as evidence of overuse of psychostimulant medication to manage behavioral concerns (see Chapter 27). The researchers found a prevalence for stimulant treatment, as identified in school records, ranging from 7 to 10%, among the highest found anywhere in the United States.

The results of the LeFever and colleagues (1999) study are questionable, and a subsequent study attempting to replicate these findings failed to do so. In an un-

published study, Tjersland, Grabowski, Hathaway, and Holley (2005) attempted to replicate and extend the work of LeFever and colleagues in the same region of Virginia. They also used cases of ADHD identified in school records to determine prevalence of disorder and of psychostimulant treatment in a school district adjoining the two studied by LeFever and her colleagues. This district is highly similar, if not identical, demographically to those studied by LeFever and colleagues. Several sources of information were reviewed, including student information cards that contained medical history and listed ADHD as a known condition, if applicable. Information was also collected from an inspection of physician forms authorizing medication treatment at school. A second phase of the data collection involved a review of student cumulative files. Record reviews of student files were conducted for students with Section 504 plans and for students receiving special education services for learning disabilities, emotional disturbances, developmental delays, or the "other health impaired" category. As a consequence, this study was a more comprehensive review of school records than that undertaken by LeFever and colleagues; therefore, Tjersland and colleagues should have identified as many, if not more, cases of ADHD and stimulant treatment than did LeFever and colleagues.

The results of this second study completely contradicted the LeFever and colleagues (1999) results. The study found a prevalence rate for ADHD of just 4.4%, closely matching the DSM-IV-based estimated prevalence, as well as the average of studies using clinical diagnosis (to be reviewed below). The study also found that 4% of the children were being treated with psychostimulant medication—well below the 7–10% figure cited by LeFever and colleagues. Data on prevalence at each grade level from 1 through 12 indicated that the highest prevalence rates were evident in fourth (7.1%) and fifth (6.3%) grades. LeFever and colleagues claimed that national averages obscure the "clear overdiagnosis" of ADHD in some groups. They suggest that one in every three white elementary school boys is being diagnosed with the disorder in southeastern Virginia. The data from the Tjersland and colleagues (2005) study did not replicate this finding; it found that only 8.1% of white males received the ADHD diagnosis, based on the school records.

Although the LeFever and colleagues (1999) study probably overestimates the rate of ADHD diagnosis in school-age children, subsequent large-scale studies have confirmed that in some cases the rates of ADHD diagnosis observed in schools is higher than would be expected given the estimated population prevalence of the disorder. The Centers for Disease Control and Prevention estimated that 9.5% of children had at some point been diagnosed with ADHD, as reported by parents(Centers for Disease Control and Prevention, 2010). Boys (13.2%) were more likely to have received a diagnosis than girls (5.6%). Children from Southern states (e.g., Kentucky, 12.8%) are diagnosed at a much higher rate than children in other regions (e.g., California, 6.2%). More recent data collected by the Centers for Disease Control and Prevention analyzed and released in the *New York Times* estimated that 11% of high school-age children had received a diagnosis of ADHD at some point in their lives (Schwarz & Cohen, 2013). Among high school–age boys (ages 14–17) the rate of diagnosis was 19%. It is difficult to judge the veracity of these claims without knowing methods used by the *New York Times* to produce these figures, but their results are nonetheless provocative. Clearly the rate at which children are being diagnosed with ADHD exceeds the population prevalence of the disorder, particularly among high school-age boys. The gap between the true population prevalence of ADHD and diagnostic rates appears to be increasing over time (Centers for Disease Control and Prevention, 2010; Getahun et al., 2013). The forces driving the increasing rates of ADHD diagnosis are not entirely understood, but they should become more apparent as research is done to address this problem. In the meantime, clinicians should use well-validated assessment techniques to ensure that children meet criteria for ADHD before diagnosing them.

Prevalence of Adult ADHD

Since publication of the previous edition of this book there has been a large amount of research examining the prevalence of ADHD among adults. The most comprehensive study to date was conducted by Kessler and colleagues (2006), using a sample of 3,199 adults. This study combined a well-controlled population sampling approach (i.e., the National Comorbidity Survey Replication) and in-person clinical interviews to establish functional impairment among those who screened positive during a telephone interview. This study estimated a population prevalence of 4.4% among adults ages 18–44 years. Barkley (2012c) recently found a prevalence of approximately 5% in his large representative sample of U.S. adults. A meta-analysis

of smaller studies produced a lower estimate of 2.5% (Simon, Czobor, Balint, Meszaros, & Bitter, 2009), although the Kessler colleagues (2006) study was not included in their estimate due to methodological issues. A related meta-analysis examined the cross-national prevalence of adult ADHD (Fayyad et al., 2007) using methodology similar to that just described to estimate prevalence rates in Belgium (4.1%), Colombia (1.9%), France (7.3%), Germany (3.1%), Italy (2.8%), Lebanon (1.8%), Mexico (1.9%), Netherlands (5.0%), and Spain (1.2%). This study shows that the prevalence of ADHD in adults is relatively similar across cultures.

CONCLUSION

We have demonstrated in this chapter that ADHD is a legitimate mental health disorder whose diagnostic criteria are based on a substantial body of empirical evidence from hundreds of scientific studies. The fact that debate will always exist concerning the precise criteria that should be used to diagnose the condition reflects not so much a mistaken view that ADHD is some vague or invalid condition or myth as an evolving consequence of the scientific process itself applied to ADHD as earlier findings are further tested and revised as a function of later findings that produce an increasingly refined and rigorous set of criteria for disorder recognition. The symptoms of ADHD cohere into two highly related dimensions of behavior, and those symptoms are substantiated by various studies employing objective measures that demonstrate that children with ADHD do, in fact, display more such behavior than do children without ADHD. While most cases of ADHD are evident by age 12, some continue to emerge thereafter, in part as a consequence of the unreliability of retrospective recall of symptom onset, and because of the creation of new cases of ADHD in the population as a result of the accrual of new cases of neurological injuries that may give rise to new cases of ADHD over time. The symptoms of ADHD, particularly the ADHD-HI dimension, decline with age but remain present across the life course (Barkley, 2011a) and support the view that it is a lifelong disorder. And while boys are significantly more likely to manifest ADHD than girls by an average ratio of 3:1, this sex difference declines by adulthood to a nearly equal representation in both sexes. ADHD is a universal condition found in all countries and cultures studied to date with relatively consistent prevalence.

KEY CLINICAL POINTS

- ✓ ADHD is a common and well-recognized behavior disorder that affects millions of children, adolescents, and adults.
- ✓ The diagnostic criteria used to recognize ADHD (e.g., in DSM-5) are the most scientifically validated to date and are based on hundreds of studies, as well as expert consensus opinion.
- ✓ DSM-5 no longer conceptualizes ADHD as comprising three separate types; instead, it is presented as a single disorder that can vary in the population in each of its two symptom dimensions, and those relative severities can change over time, leading to the creation of three kinds of "presentations" of ADHD rather than subtypes.
- ✓ Although the symptom lists for ADHD in DSM-5 remain the same, qualifier symptoms have been added to help clinicians understand the expression of that symptom at older ages beyond childhood.
- ✓ The age of onset for ADHD has been adjusted upward to age 12 in DSM-5 but remains primarily a rough guideline to follow rather than a firm demarcation in what is otherwise the "shifting sands" of development. So long as cases meet all other criteria for the disorder, clinicians should be flexible in imposing an age of onset, recognizing that recall of onset is unreliable.
- ✓ The symptom threshold for diagnosing ADHD has now been reduced from 6 to 5 in DSM-5 for application to adults so as to retain the sensitivity of the diagnostic criteria to the detection of the disorder. Other research suggests that a threshold of 4 is even better.
- ✓ The disorder manifests itself across multiple settings and leads to impairment in various domains of major life activities.
- ✓ The behavioral symptoms used for diagnosis are not only substantiated in parent and teacher reports of these symptoms in children and self- and other-reports in adults, they are further confirmed by direct observational methods that demonstrate them to be excessive in people diagnosed with the disorder.
- ✓ ADHD severity may fluctuate somewhat across settings and time of day, and as a consequence of various factors in the situation, such as the schedule of consequences for behavior, novelty, adult supervision, and other factors.

- ✓ Although ADHD is presented as a categorical condition in DSM taxonomy, it is actually a dimensional disorder whose symptoms vary in severity across the entire human population and may become a disorder (produce impairment) at excessive levels of severity.
- ✓ The prevalence of ADHD in children appears to be on average between 5 and 7%, whereas in adults it ranges from 3 to 5%.
- ✓ The disorder is universal, having been identified in every country and culture in which it has been studied.

NOTES

1. Data from the DSM-IV field trials indicated that a diagnostic threshold of five, rather than six, hyperactive–impulsive symptoms best differentiated between impaired and nonimpaired children. However, the work group decided to use the more conservative threshold of six symptoms in order to "minimize the identification of normally active children as exhibiting attention deficit hyperactivity disorder" (Lahey et al., 1994, pp. 1676–1677), perhaps to make the resulting diagnostic rates more palatable for the general public. This decision documents how the DSM criteria are not infallible and are partly political in nature, so clinicians should approach diagnosis with some flexibility and avoid viewing these criteria as dogma.
2. Although the prevalence estimate for South America appears to be much higher than the estimates for other regions, Polanczyk and colleagues' meta-analysis found that the difference was not significant. Prevalence estimates from this region were highly variable, so the accuracy of the 12% estimate is suspect.

CHAPTER 3

Emotional Dysregulation Is a Core Component of ADHD

Russell A. Barkley

As the previous chapter has nicely documented, for over 40 years, clinical descriptions of the core nature of attention-deficit/hyperactivity disorder (ADHD) have focused exclusively on the two-dimensional structure of the disorder cited in clinical diagnostic criteria (inattention, hyperactivity–impulsivity), such as those in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III, DSM-III-R, DSM-IV, DSM-5; American Psychiatric Association, 1980, 1987, 1994, 2013). As noted in DSM-5, the essential feature of ADHD is a persistent pattern of inattention and/or hyperactivity–impulsivity that is more frequent and severe than is typically observed in individuals at a comparable level of development. Such official descriptions concerning the core nature of the disorder and the related symptom lists focus exclusively on a two-dimensional structure as being the central features of the disorder. Here I argue that this overemphasis on the most observable and objectively measurable features of the disorder has led to the exclusion or a deemphasis of another feature of the disorder that is just as central to its understanding yet considerably more difficult to quantify. This largely neglected element is a deficiency in both the effortful (executive or cognitive) inhibition and the top-down self-control of emotions in general and particularly those pertaining to the self-regulation of frustration, impatience, and anger. The most noticeable and initial consequence of this deficiency in people with ADHD is a striking propensity for failure to inhibit emotions, or emotional impulsivity (EI).

EI refers to the quickness or speed with which, and the greater likelihood that an individual will react with primary (particularly negative) emotions in response to events compared to others of the same developmental level or age. It is not the same as emotional intensity, which itself can vary across individuals and is not thought to be a problem in those with ADHD. The primary emotional reactions of those with ADHD are not so much more intense initially as they are less moderated by conscious, effortful executive self-regulation of those emotions. Others may have felt the same emotionally intense reaction to an event but are less likely to display the primary emotional behavior associated with it before moderating its expression and even generating secondary emotional states to counteract or supplant the initial primary ones.

The related component to emotional inhibition is emotional self-regulation, which represents a conscious, "top-down" and effortful (executive) moderation of the initial emotional reaction. Like Melnick and Hinshaw (2000), I defer to Gottman and Katz (1989) for their helpful definition of emotion regulation as the

ability to "(a) inhibit inappropriate behavior related to strong negative or positive emotion, (b) self-soothe any physiological arousal that the strong affect has induced, (c) refocus attention, and (d) organize for coordinated action in the service of an external goal" (p. 373). Its opposite is referred to here as deficient emotional self-regulation (DESR). Notice that the definition incorporates emotional inhibition as the first step in emotional self-regulation, which is consistent with the view to be taken here and that of my theory of executive functioning in ADHD (Barkley, 1997a, 1997c, 2012b). Yet it will prove helpful in the following discussion to identify them separately as EI and DESR, with the understanding that the former is the initial step contained within the latter. That is because one cannot self-soothe or otherwise moderate one's initial emotional reactions to events if he or she has not first inhibited the impulsive expression of those initial reactions. EI therefore interferes with subsequent efforts to engage in emotional self-regulation. It is also helpful to separate them because most of the available research in ADHD and emotions seems to be directed at documenting the first (EI) more than the second (DESR).

This chapter examines the importance of EI–DESR in understanding the nature of ADHD. It also seeks to explain why the explicit recognition of EI–DESR as a central feature of the disorder may prove useful in broadening our understanding of the emotional and social maladjustment evident in cases of the disorder. Apart from providing a more accurate clinical portrayal of the disorder for both greater professional and public understanding, this argument stresses that formally acknowledging the place of EI–DESR has a sound basis in (1) the history of ADHD; (2) the neuropsychological nature of the disorder; (3) the neuroanatomy of ADHD; (4) the empirical research on the symptoms of EI–DESR in ADHD; (5) the linkage of ADHD with oppositional defiant disorder (ODD), among other comorbidities; and (6) the concurrent and later impairments often seen in ADHD, especially in the domains of social functioning. Others have also argued that emotional dysregulation is an important component of ADHD based on lines of evidence other than those I summarize here (Martel, 2009; Skirrow, McLoughlin, Kuntsi, & Asherson, 2009).

Before addressing these issues, it is crucial for the arguments to be made here that the reader understand that this chapter addresses the nature of ADHD (previously, the combined type in DSM-IV) and not that group of inattentive subjects who have come to be characterized in research articles as having sluggish cognitive tempo (SCT; see Chapter 17; also see Barkley, 2012b, 2013, 2014; Milich, Balentine, & Lynam, 2001; special issue of the *Journal of Abnormal Child Psychology*, 2014) or what I have recently renamed as concentration deficit disorder (CDD; Barkley, 2014; Saxbe & Barkley, 2014). Individuals having SCT/CDD differ in important ways from those with ADHD (Milich et al., 2001; Saxbe & Barkley, 2014). This has led some researchers in the field to view it as a separate disorder from ADHD (Barkley, 2001, 2014; Diamond, 2005; Milich et al., 2001; see Chapters 2 and 17) or at least as a qualitatively different type of the disorder. And it has led theorists to exclude those with SCT from their efforts to build working models of ADHD and its underlying neuropsychology (Barkley, 1997c, 2012b, 2013, 2014; Castellanos, Sonuga-Barke, Milham, & Tannock, 2006; Nigg & Casey, 2005; Sagvolden, Johansen, Aase, & Russell, 2005). I do not focus on SCT/CDD in this review because it is the focus of Chapter 17. That is because SCT/CDD appears to include a distinct attention problem but no affiliation with the impulsive and poorly inhibited behavior inherent in ADHD (Barkley, 2012b, 2013, 2014; Diamond, 2005; Milich et al., 2001).

As I discuss below, it is especially this impulsive aspect of ADHD that provides a strong link between ADHD and EI–DESR through the disruption of emotional inhibition, item (a) in the definition of DESR, as noted earlier. As Martel (2009) reasoned, the hyperactive–impulsive (HI) dimension of ADHD is associated with a breakdown in the emotionality component (EI) whereas inattention is associated with a breakdown in the regulatory side (DESR). Martel further argued that breakdowns in regulatory control of emotion are a specific signature of ADHD, whereas increased negative emotionality may be nonspecific and shared across the disruptive disorders (ADHD, ODD, and conduct disorder [CD]) accounting for their comorbidity—a point with which I agree, as will be shown later.

THE IMPORTANCE OF EI–DESR IN THE HISTORY OF ADHD

Historical accounts of ADHD (Accardo & Blondis, 2000; Barkley, 1998, 2006, Chapter 1; Goldstein & Goldstein, 1998; Kessler, 1980; Ross & Ross, 1976, 1982; Schachar, 1986; Werry, 1992) have traditionally cited the three published lectures by George Still (1902) as the beginning of medical or scientific interest

in the disorder. However, Barkley and Peters (2012) located and translated a chapter on attention deficits in a German medical textbook by Melchior Adam Weikard in 1775. In his description of this attention disorder that closely resembles ADHD, Weikard noted on several occasions the problem subjects had with emotional dysregulation. Later, a chapter in a medical textbook by the Scottish physician Alexander Crichton (1798) was published on the subject of "diseases of attention" (Palmer & Finger, 2001).

Crichton (1798) saw attention as representing the central feature of one's awareness. It is what one has chosen to concentrate on, at least for the moment, be it an external stimulus or internal thought. This process was seen to be effortful, not automatic, requiring that one actively initiate the action of concentrating one's attention on something. And it was seen as being a volitional or willful activity. Crichton identified several different components of attention, one of which was inconstancy of attention. By this, he seems to have meant the inability to sustain one's attention for an adequate period of time on a particular object of attention, which results in skipping across various things to which one attends, spending little time with each. This component resembles the present concepts of sustained attention and, related to it, resistance to distractibility, both of which are believed to be central to attention deficits in ADHD. Chrichton (1798, p. 272) wrote that "in this disease of attention, if it can with propriety be called so, every imperfection seems to agitate the person, and gives him or her an unnatural degree of mental restlessness."

Crichton's second component of inattention involved the energy or power of the capacity to attend. This likely corresponds to modern notions of arousal and alertness because Crichton (1798) felt that attention could become fatigued or be affected by inadequate mental energy. Perhaps this component corresponds more closely to the nature of the attention problem believed to be involved in SCT/CDD, that of a more passive, sluggish, daydreamy, confused, and lethargic form of inattentiveness. More to the point of this discussion, Crichton observed that individuals prone to inordinate or excessive levels of distractibility often reacted to the myriad distractions in a situation "with a degree of anger that borders on insanity" (p. 272).

Later, Still (1902) noted the connection between problems with attention and difficulties with the control of emotions in his descriptions of subjects thought to have defective moral control of behavior. Still defined the moral regulation of behavior as the voluntary inhibition of behavior and subsequent consideration of one's actions for the good of one's self and the good of others. He described 43 children in his clinical practice who had serious problems with defective moral control, 23 of which were also believed to have impaired intellect (mental retardation). Still reasoned that the 20 cases that could not be attributed to impaired intellect or physical disease arose from a deficit in the voluntary inhibition of behavior, or impulsiveness. He also commented on their impaired capacity for sustained attention. Common to most of these subjects as well was that they were also quite overactive. These are the cases that most closely resemble the ADHD of today. Many were often aggressive, defiant, resistant to discipline, and showed little "inhibitory volition" over their behavior. Still proposed that the immediate gratification of the self was the "keynote" quality underlying all of the attributes of the children. Among all of those attributes, "an extreme degree of passionateness was the most common feature" (p. 1080), or being easily aroused to emotion. This "morbid exaggeration of emotional excitability" (p. 1165) was thought to arise from the same defect in volitional inhibition that characterized the other behavioral attributes of these children. Thus, if Still's cases represent ADHD, which many believe they do, then he was clearly linking the behavior to deficits in the volitional regulation of emotions, or EI–DESR. Indeed, he viewed EI–DESR as the most noteworthy attribute of these cases, not impaired attention or overactivity. Just as important, as I demonstrate later, Still attributed the EI features of cases to subjects' larger problem of volitional or executive (willful, effortful) inhibition rather than to some impaired feature of attention.

In the interim period from the beginning of the 1900s to 1950, little published medical or research interest in children resembled today's notions of ADHD. Certainly articles appeared on the striking deviations in behavior and personality that followed in children who survived the encephalitis epidemic of 1917–1918 and were labeled as having "post-encephalitic behavior disorder" (Ebaugh, 1923; Strecker & Ebaugh, 1924; Stryker, 1925). Most could be characterized as hyperactive, inattentive, impulsive, and easily aroused to emotion, but such children often experienced substantial brain damage, and loss of intelligence and adaptive functioning, to the extent that many of them would today be considered to be mentally retarded. This association of a brain disease with behavioral pathology ap-

parently led early investigators to study other potential causes of brain injury in children and their behavioral manifestations. Birth trauma (Shirley, 1939), lead toxicity (Byers & Lord, 1943), epilepsy (Levin, 1938), and head injury (Blau, 1936; Werner & Strauss, 1941) were studied in children and found to be associated with numerous cognitive and behavioral impairments, including ADHD symptoms. Other terms introduced during this era for children displaying these behavioral characteristics were "organic driveness" (Kahn & Cohen, 1934) and "restlessness" syndrome (Childers, 1935; Levin, 1938). Many of the children in these samples were also mentally retarded or more seriously behaviorally disordered than are children who today are considered to have ADHD. While these children manifested symptoms of ADHD as it is currently conceptualized, they clearly represent an acquired form of the disorder and therefore more closely resemble cases Still spoke about as arising from defective intelligence or as being secondary to physical disease. This is certainly true for a minority of cases of ADHD diagnosed today (Nigg, 2006). Such acquired cases of ADHD-like symptoms underscore the point that those symptoms can arise as a result of damage to particular brain regions, yet they shed little light on just how ADHD could arise in the absence of clear-cut evidence of brain damage.

Notable during this era was also the recognition of the striking similarity between hyperactive children and the behavioral sequelae of frontal lobe lesions in primates (Blau, 1936; Levin, 1938). In frontal lobe ablation studies of monkeys more than 60 years earlier (Ferrier, 1876), the lesions were known to result in excessive restlessness, poor ability to sustain interest in activities, aimless wandering, heightened emotional excitability or reactivity, and excessive appetite, among other behavioral changes. Several investigators, such as Levin (1938), would use these similarities to postulate that severe restlessness in children was likely the result of pathological defects in the forebrain structures, although gross evidence of such was not always apparent in many of these children.

Nevertheless, in the absence of such evidence, the concept of a brain-injured child syndrome was born (Strauss & Lehtinen, 1947) in which the behavioral symptoms of ADHD alone were taken to imply an underlying neurological etiology. The concept would evolve into that of minimal brain damage and further to minimal brain dysfunction (MBD) by the 1960s and 1970s (see Rie & Rie, 1980, for the most thorough treatment of MBD published at that time). The behavioral symptoms of MBD were thought to involve "(1) hyperactivity; (2) impulsiveness; (3) short attention span; (4) perseveration; and (5) *emotional lability*" (Schwalb, 1967, p. 2320, emphasis added). All were thought to be central to the diagnosis of the disorder and characterized the majority of children so diagnosed.

The diagnosis, however, came under severe criticism for being too inclusive (some monographs at the time attributed up to 99 symptoms to the disorder; Clements, 1966) and for lacking sufficient evidence of actual neurological etiologies. Chief among these early critics were Birch (1964), Herbert (1964), and Rapin (1964), who questioned the validity of applying the concept of brain damage to children who had only equivocal signs of neurological involvement, not necessarily damage. Rutter (1977) reviewed the evidence of psychiatric disorders in children with established brain injuries and the inverse evidence of brain damage among children with various psychiatric disorders, concluding "that the behavioural stereotype of the brain damaged child must be firmly rejected" (p. 11). Even so, he went on to state that the hyperactive child syndrome, while not a syndrome of brain damage, was associated with biological factors that "probably often play an important part in its aetiology" (p.12).

The totality of such criticisms led to an increasing preference for the more circumscribed diagnostic term of "hyperactive" or "hyperkinetic child syndrome," an increased focus on identifying and objectively measuring the behavioral features of the disorder, a move away from seeing brain damage as the sole etiology, and hence a decline in the use of the diagnosis of MBD. Despite this shift, the central behavioral tenets of the disorder remained much the same. In a classic article, Laufer, Denhoff, and Solomons (1957) described "hyperkinetic impulse disorder" as involving not only hyperactivity but also short attention span, poor concentration, impulsivity, unpredictable and explosive behavior, and low frustration tolerance.

Similarly, writing about hyperactive children for the widely read popular science magazine, *Scientific American*, Mark Stewart (1970, p. 94, emphasis added) stated that "a child with this syndrome is continually in motion, cannot concentrate for more than a moment, acts and speaks on impulse, *is impatient and easily upset*. At home he is constantly in trouble because of his restlessness, noisiness, and disobedience. In school he is readily distracted, rarely finishes his work, tends to clown and talk out of turn in class and becomes labeled a discipline problem." Citing one of his own studies of the

behavioral symptoms most common to the disorder, Stewart noted that up to 59% manifested difficulties that could be considered signs of EI–DESR including temper tantrums or being defiant, irritable, or impatient. His follow-up study of these children as teenagers indicated that they had changed little in terms of these behavioral characteristics.

Other researchers during this era preferred to focus almost exclusively on hyperactivity as the central feature of the disorder and went about studying the extent and kind of motor activity involved, relegating the other behavioral (attention, impulsiveness) and emotional features of the disorder to associated problems (Keogh, 1971). These included well-known investigators such as Stella Chess (1960), John Werry (1968), and Virginia Douglas (Werry, Weiss, & Douglas, 1964; Werry, Weiss, Douglas, & Martin, 1966), and Robert Sprague (Werry & Sprague, 1970). A plethora of studies in this era objectively measured various aspects of motor activity level (for reviews, see Barkley & Cunningham, 1979; Luk, 1985; Zentall, 1985) and attention span (Barkley & Ullman, 1975; Campbell, 1976; Douglas, 1972). Debates arose over whether the attention problems, distractibility, impulsiveness, and emotional excitability believed to have been involved in earlier notions of hyperkinetic impulse disorder were central to this hyperactive child syndrome or just associated features seen in some cases (Keogh, 1971). Despite this effort of clinical researchers to curtail the concept of hyperactivity to just an excessive degree of movement relative to one's developmental level or age (Chess, 1960), clinicians were not following suit. A survey of pediatricians, teachers, psychologists, psychiatrists, and social workers at the time by Schrager, Lindy, Harrison McDermott, and Wilson (1966) indicated that they continued to identify six features (not one) as characteristic of hyperactive children (fidgety and restless, inattentive, hard to manage, cannot sit still, easily distracted) including *cannot take frustration* (p. 103, emphasis added).

By the 1970s, this effort to isolate the nature of the hyperactive child syndrome to just a single central symptom involving activity level had failed. Reviews at the time continued to emphasize the central features as involving restlessness, distractibility, short attention span, and impulsivity (Barkley, 1981, 1982; Campbell, 1976; Pelham, 1982) in line with the diagnostic criteria espoused in DSM-II and DSM-III (American Psychiatric Association, 1968, 1980). Others, however, continued to include low frustration tolerance, emotional lability, and aggression with these other core features (Cantwell, 1975; Weiss & Hechtman, 1979; Wender, 1971). As Jan Loney (1980, p. 265, emphasis added) memorably phrased it in her own review, "Numerous experts . . . have painted the diagnostic picture of a child in perpetual motion; a child who flits around and blurts out but doesn't finish assignments or chores; *a child with a short and highly flammable fuse*; a child of the present, who neither benefits from the past nor plans for the future."

Even so, a bifurcation was becoming evident during this historical period 1970–1980. There were some clinical researchers, principally psychologists, who saw the disorder as involving mainly problems with hyperactivity, inattention, and poor impulse control (Barkley, 1981; Campbell, 1976; Douglas, 1972; Pelham, 1982). These experts typically placed little emphasis on the problems with emotional self-regulation in their concept of the disorder, seeing it as only an associated feature and evident in only some cases. In contrast, other experts, mainly child psychiatrists, continued to view symptoms of EI–DESR as being just as central to the disorder as the holy trinity noted earlier, including Paul Wender (1971, 1973). Wender saw the symptoms of EI–DESR as involving four forms: increased lability, altered reactivity, increased aggressiveness, and dysphoria. Wender's colleague, David Woods, also include symptoms of EI–DESR as part of the core features of adults with ADHD (Woods, 1986). Likewise, Dennis Cantwell (1975) wrote in his classic book, *The Hyperactive Child*, that the disorder involved emotional excitability as a "core" feature in addition to the emerging customary triad of inattention, hyperactivity, and impulsivity. He stated that "the excitability of the hyperactive child is manifested by temper tantrums and fights over trivial matters, low frustration tolerance and a tendency to become overexcited" (p. 6). He also noted that the majority of these children manifested depression and low self-esteem. And in the United Kingdom, other psychiatrists continued to write about the main features of the disorder as including poor toleration of frustration, temper tantrums, and lability of mood (Sandberg, Rutter, & Taylor, 1978).

As one who began studying ADHD during this era, it has become evident to me in retrospect that several reasons may account for this growing abandonment of symptoms of EI–DESR as being a central feature of ADHD. One reason was its greater difficulty of measurement in laboratory studies attempting to clarify the psychology of ADHD. Research at the time was replete

with various methods for objectively recording activity level, attention, and impulsive behavior. Far less effort was given to measuring the emotional manifestations of the disorder, most likely owing to the fact that emotions are less easily recorded than movement. One need only scan the historically important theoretical research paper by Virginia Douglas (1972) to see this nearly complete abandonment of EI–DESR in ADHD. In an article based on her Presidential Address to the Canadian Psychological Association, Douglas exemplified the largely commendable preoccupation at the time to use objective laboratory measures to document symptoms in this disorder. Her paper contributed heavily to the view that ADHD involves a triad of symptoms (inattention, impulsivity, and hyperactivity), one that did not include emotional excitability, low frustration tolerance, or quickness to anger—encapsulated here as EI–DESR.

The focus on symptom measurement at the time was understandable and laudable. Investigators were striving to put ADHD research on a solid footing of scientific facts that could be objectively recorded and statistically analyzed. One uses what one has measured, and at the time no one had much in the way of measures of emotional self-regulation. Clearly, symptoms of EI–DESR do not lend themselves as well to being measured and analyzed as do activity level, attention, and behavioral impulse control. One exception to this rule was the symptom of aggression, which could be observed and quantified in social interactions and subsequently was found to be a major characteristic of the peer social interactions of ADHD children (Whalen & Henker, 1985). It, along with dimensions of negative temperament (Prior, Leonard, & Wood, 1983), came to be quantified initially via parent and teacher rating scales (Conners, 1969) and later self-ratings (Milich & Okazaki, 1991). Studies using such ratings clearly showed the marked differences between ADHD and control groups in measures of social aggression, task frustration, and mood and intensity. A few investigators succeeded at objectively counting statements of negative emotion during task performance, though often as mere incidental measures in an array of laboratory tasks that focused on the ADHD symptom triad. Yet they were not disappointed to find the difficulties with emotion to be quite divergent between ADHD and control children (Rosenbaum & Baker, 1984). Others used laboratory paradigms involving delay of gratification to index signs of low frustration tolerance, as suggested by Mischel (see Mischel, Shoda, & Rodriguez, 1989). They likewise found success in distinguishing ADHD and control groups (Homatidis & Konstantareas, 1981; Rapport, Tucker, DuPaul, Merlo, & Stoner, 1986). But by then, it was too late to reintroduce problems with emotional self-regulation back into the core features of ADHD, and no one really seemed to have tried to do so. Why?

That answer comes from a second likely reason for the splintering of EI–DESR from the core features of ADHD at the time, and that was clearly the publication and promotion of diagnostic criteria for ADHD in the DSM. Beginning with DSM-II's definition of hyperkinetic reaction of childhood and continuing through to the present, the disorder has been conceptualized as involving the three core features of hyperactivity, inattention, and poor impulse control. Symptoms of EI–DESR are excluded as being such a central feature, though some DSM editions, such as DSM-IV-TR (American Psychiatric Association, 2000, p. 80), do mention such symptoms as "associated features" including low frustration tolerance, temper outbursts, mood lability, demoralization, and dysphoria. If anything, these symptoms of EI–DESR were used to create in DSM-III an entirely new disorder—oppositional defiant disorder (ODD)—that even then was recognized as having a robust association with ADHD. Nevertheless, for the past 35 years, part of this psychiatric disorder's official taxonomic doctrine has been that problems with emotional regulation were not a central feature of ADHD, though they could be construed as associated features occurring some of the time. I believe that this taxonomic neglect of EI–DESR and its relegation to a secondary or associated status in conceptualizing ADHD may have been driven in large part by the first reason cited earlier—the problem of measurement of poor emotion regulation. As far as most clinicians and researchers have been concerned, this official taxonomic neglect sealed the fate of symptoms of EI–DESR as being merely an associated feature of ADHD, even though historically it was been viewed otherwise even back to the earliest reports of the disorder.

One of the purposes of this chapter is to question the wisdom of having disconnected EI–DESR from the core triad of ADHD symptoms, despite its close involvement in one of them—impulsive and poorly inhibited behavior. After all, if emotions are behavior, then emotional expressions should be as impulsive as gestural and verbal behavior in those afflicted with ADHD given that one of its central deficits is "volitional inhibition," which even Still (1902) argued was

the case. However, the musings of clinicians and theorists on the essential features of ADHD, while suggestive of the central nature of in the conceptualization of ADHD and its precursor disorders, are by themselves not sufficient evidence that this is actually so. Historical commentaries aside, what other reasons are there to consider EI–DESR as a central feature of ADHD?

THE IMPORTANCE OF EI–DESR IN THE NEUROPSYCHOLOGY OF ADHD

The past 16 years have witnessed a renewed interest in the difficulties with emotion regulation in ADHD among theorists grappling with model building. I have previously attempted to set forth a more comprehensive neuropsychological theory of ADHD (Barkley, 1997a, 1997c, 2012a, 2012c) that went beyond those at the time that stipulated the central feature of ADHD to be a problem with behavioral inhibition (Quay, 1987, 1997) or of an energetic pool of motivation or arousal (Sergeant, 1988; van der Meere & Sergeant, 1988). Five executive functions (EFs) were identified in my initial theory that could be implicated in ADHD: behavioral inhibition, nonverbal working memory (chiefly visual imagery and private audition), verbal working memory (primarily private self-speech), the self-regulation of emotion–motivation–arousal (using these working memory systems), and reconstitution (generating multiple response options through a process of mental play [analysis and synthesis]). To this I have more recently added self-awareness (Barkley, 2012c).

These executive functions provide for human "self-regulation," defined as (1) any action one directs at oneself (2) in order to change subsequent behavior (3) so as to alter a distant or delayed consequence and thereby maximize those consequences. Each EF, in fact, was argued to constitute a specific form of self-control or self-directed activities (e.g., self-directed attention, self-restraint, self-imaging, self-speech, self-emoting, and self-play). All functioned in concert for the overarching purpose of guiding behavior across time delays toward future goals that served to maximize delayed rather than immediate consequences. The executive deficits associated with ADHD led to a seventh nonexecutive deficit in the control of motor behavior via the EFs that disrupted its coordination, temporal sequencing, and hierarchical structure during goal-directed activities.

This EF-based theory of ADHD reinserted EI–DESR into a central theoretical position in understanding the nature of the disorder. It viewed emotional inhibition and the subsequent self-regulation of emotion as being one among the five (now six; Barkley, 2012a, 2012c) major EFs and argued that ADHD involved a disruption in it. In essence, this EF operated in conjunction with that of behavioral inhibition chiefly to accomplish four purposes very similar to the components of the earlier definition of emotional regulation by Gottman and Katz (1989). First, the inhibitory function served to delay (inhibit) the initial prepotent or dominant responses to an event, including their emotional tone and other emotional behavior, so that both the motor response *and* related emotional behavior were deferred. This set the stage for the second purpose of this EF, which was the modification of the initial emotional state to make it more congruent with and supportive of the individual's long-term goals. In part, this involved the use of the working memory systems (self-directed visual imagery and self-speech) to assist with self-soothing of emotional arousal and to create hindsight. The latter allowed the individual to consider consciously what had previously been experienced in similar situations and so guide the construction of the eventual response to the event informed by such prior information. This retrospective function of the working memory systems led to foresight or the prospective function. That function was the construction of an expectation about the situation and a consideration of potential future consequences that would arise for responding in various ways. This led to a conscious anticipation of that hypothetical future, and the selection and construction of a preparatory set of responses of what to do and when that would be more consistent with the longer-term welfare (goals) of the individual. In using the working memory systems in this way, the individual automatically has the additional capacity to delay the prepotent *emotional* response to that same event and use visual imagery and private speech to create alternative, competing secondary emotional states to it. This is because covert visual imagery and covert self-speech, among other forms of covert self-directed behavior, produce not only private images and verbalizations but also the private emotional charges associated with them (Damasio, 1994, 1995; Fuster, 1997). Such use of private action to countermand or counterbalance the initial emotional charge of external events contributes to self-soothing of emotional arousal and the formation of more socially appropriate emotional responses. They also contribute to the development of *emotional self-control* (Kopp, 1982). In short, the indi-

vidual possesses not only a means to consider and construct alternative motor responses to an event that will better maximize future consequences but also a capacity to construct alternative *emotional* responses joined to those behavioral actions that serve to achieve the same ends.

To summarize, this theory predicts two interrelated emotional problems for those with ADHD: one inhibitory and the other self-regulatory. The first problem is likely to be far more related to the HI symptom dimension and less so to the inattention dimension, whereas the second may be more related to the inattention dimension given its close connection to working memory systems and the manipulation of their content. Those with ADHD will be as impulsive with their primary emotions as they are with their motor or behavioral responses because they are essentially a single unitary event: Action and emotion are united in the response. And the person with ADHD will not be able to generate the countervailing secondary emotion needed to quell the primary one provoked by the event or to self-soothe primary emotional arousal to moderate the expression of his or her emotions so that he or she is more socially acceptable, much less to provide the emotional support needed for the alternative goal-directed behavior. This is the self-regulatory aspect of the executive system that is contingent on the inhibitory action and is also viewed as deficient in ADHD.

According to this theory, to the extent that an individual with ADHD displays a deficiency in *behavioral* inhibition or impulsiveness, he or she will automatically display an equivalent degree of deficiency in *emotional* inhibition or emotional impulsiveness. From this perspective, emotional impulsiveness, or EI, and the associated subsequent deficiency in the self-regulation of emotions, are just as much a part of ADHD as behavioral impulsiveness, and the associated problems with behavioral self-regulation. Still (1902) had reached the same conclusion for similar reasons.

But there are two other purposes to the EF of emotional inhibition/self-regulation. To understand them we must first dissect the concept of emotion. Emotions are motivational states. They can be regarded as arising from a two-dimensional process (Gray, 1994; Lang, 1995): One dimension is motivational and comprises approach–avoidance valences concerning any analysis of our actions and their attendant consequences (reinforcement–punishment); the other, a dimension of arousal that is orthogonal to the motivational one, contributes to the degree of activation, force, or intensity of the motivational state. Largely unappreciated to date by many researchers in the field of ADHD is that this view of emotion would lead to the prediction of both motivational and arousal problems inherent in those with ADHD. If one's emotional responses to events are as impulsive as his or her behavioral ones, then so will be his or her motivational and arousal responses. Given that these features of emotion form a unity (emotion–motivation–arousal), the more impulsively one's emotions are directly elicited by environmental events, the more one's motivation and arousal will be determined by and dependent on those events. As argued in this theory, the more one is able to manage, moderate, and manipulate one's emotional states via self-regulation in the service of their future goals, the more one automatically is capable of manipulating one's own motivational and arousal states to achieve those same ends. This is because the latter states (motivation and arousal) are the basis for the former one (emotion). ADHD must therefore involve a deficit in self-motivation and the self-regulation of arousal in support of future, goal-directed behavior as surely as it involves a deficit in the regulation of emotion for this self-same end. It is the capacity to self-motivate that serves to bridge gaps across delays and longer periods of time in the absence of consequences and therefore motivates delayed gratification and future-directed behavior (Fuster, 1997; Mischel et al., 1989). The evidence for such motivational deficits in ADHD is long-standing (Glow & Glow, 1979) and substantial (Luman, Oosterlaan, & Sergeant, 2005), and is supported below in the neuroanatomical network(s) underlying ADHD, especially the role of the anterior cingulate cortex in governing the amygdala specifically and the limbic system more generally. But the existence of and theoretical basis for this emotional–motivational component of ADHD goes largely unnoticed in current diagnostic conceptualizations of the disorder.

My theory of ADHD is not the only one that posits that difficulties with emotion regulation are likely to arise in ADHD. More recently, Nigg and Casey (2005) suggested that three distinguishable neural networks are to be found in the neuroanatomical regions implicated in ADHD, and that these cortical–subcortical loops or networks account for both the cognitive *and affective* response regulation problems seen in ADHD. Nigg and Casey posit that disruption of the frontal–limbic pathway would give rise to difficulties with emotion regulation in ADHD, while the frontal–striatal (working memory and response selection) and frontal–cerebellar

pathways (temporal organizing and timing of behavior) would be associated with the more cognitive deficits of knowing the "what" and "when," respectively, of preparing for and responding to events in various situations. They argued that affect regulation, motivation, and emotionally reactive responding are important in ADHD, and that dysfunction in the frontal–limbic–amygdala circuit probably accounts for it. A short time later, Sagvolden, Johansen, Aase, and Russell (2005) published their dopaminergic theory of ADHD, which predicted difficulties with impulsive emotion and low frustration tolerance as a consequence of hypodopaminergic activation in at least one of the three dopamine networks in this model (the mesolimbic pathway). This pathway is similar to the frontal–limbic pathway in the Nigg and Casey model, and is said to produce much the same emotional consequences in ADHD. This frontal–limbic pathway has more recently been identified as that mediating the "hot" or emotional–impulsive, hyperactive, and motivational features of ADHD (and EF) as distinguished from the "cool" pathways (frontal–striatal, frontal–cerebellar) believed to mediate the attention, disorganization, working memory, and timing problems in ADHD (Castellanos, Sonuga-Barke, Milham, & Tannock, 2006).

The central dogma on the nature of ADHD prevailing at the moment, and captured in DSM descriptions and criteria (see Chapter 2), does not acknowledge such deficits in emotion regulation as an inherent part of ADHD. It views problems with emotional control as merely associated features. But there are not only good historical grounds for correcting this abandonment of EI–DESR in the nature of ADHD, as shown earlier, but as the previous discussion attests, there are also good theoretical reasons for doing so.

THE IMPORTANCE OF EI–DESR IN THE NEUROANATOMY OF ADHD

Regardless of, or apart from, theoretical predictions about the role of EI–DESR in the central nature of ADHD, the growing body of evidence on the neuroanatomical networks that underlie the disorder provides further justification for the inclusion of EI–DESR as a core feature of this disorder. The networks believed to give rise to the inattentive, hyperactive, and impulsive behavior of those with ADHD, reflecting their deficient self-regulation, are also the networks that govern the inhibition of reactive emotion and the subsequent cognitive, effortful, top-down, or executive control of emotion. Specifically, these are the lateral prefrontal cortex (LPFC) and the anterior cingulate cortex (ACC). It is not my purpose in this chapter to give a detailed and critical review of the results of neuroimaging studies of ADHD. Suffice to say here, detailed reviews and meta-analyses of the research appear to support the conclusion that at least five brain regions are involved in ADHD (Bush, Valera, & Seidman, 2005; Cortese et al., 2012; Hart, Radua, Nakao, Mataix-Cols, & Rubia, 2013; Hutchinson, Mathias, & Banich, 2008; Mackie et al., 2007; Paloyelis, Mehta, Kuntsi, & Asherson, 2007; Valera, Faraone, Murray, & Seidman, 2007): (1) the LPFC, (2) the ACC, (3) the basal ganglia (and particularly the caudate of the striatum), (4) the splenium of the corpus callosum, and (5) the cerebellum (especially the vermis). Where asymmetries are found in these regions, evidence suggests greater involvement of the right hemisphere than left in the disorder (Valera et al., 2007). Noteworthy is that differences in the size and functioning of these regions have been found in the unaffected first-degree relatives of people with ADHD, which suggests that they may be part of a familial endophenotype for the disorder. The deficits found in relatives often fall intermediate between affected people with ADHD and control groups (Mulder et al., 2008). Several of these affected brain regions are also found to distinguish among people with ADHD, those with CD (Rubia et al., 2009), and those with bipolar disorder (Biederman, Makris, et al., 2008). Also of importance is that the size and level of activity within these regions are correlated with the degree of ADHD symptoms (Casey et al., 1997).

Studies of the cognitive or conscious regulation of emotion have implicated the LPFC, medial PFC, and ACC, along with its connections to the amygdala (and limbic system more generally) in this executive function (Ochsner & Gross, 2005). Of interest to this analysis is that the little research that exists has found that the generation of emotion from an aversive external stimulus was largely driven by activation in the amygdala in a bottom-up fashion of brain activation. In contrast the conscious and volitional generation of an emotion to a mentally represented event held in mind (working memory) revealed a more top-down activation of the LPFC, the medial PFC, the ACC, then the amygdala. Except for the amygdala, the remaining brain regions have also been implicated in ADHD, as noted earlier.

From this vantage point, studies indicate that the neuroanatomical network involved in conscious emo-

tional self-regulation in normal brain functioning would be disturbed in those with ADHD given the association of ADHD with deviations in most of the same regions involved in that network. This disturbance would constitute a top-down problem in the conscious regulation of emotions and not a bottom-up problem of an overactive amygdala–limbic system. In essence, ADHD creates a state in which the normal emotion-generating properties of the limbic system and particularly the anger-, frustration-, and aggression-generating properties of the amygdala are inadequately regulated by higher cortical regions and intermediate structures (nucleus acumbens, etc.). These higher level regions provide for self-control and take over the emotions in the service of longer-term goal-directed, hierarchically organized, and socially acceptable behavior.

One key to understanding how EI–DESR may arise in ADHD is the ACC. As reviews have noted, this brain region traditionally has been associated with the limbic system, and it is likely through the ACC, in part, that a top-down cortical (conscious or volitional) regulation of the emotional system (limbic system) is achieved (Bush, Luu, & Posner, 2000). Such a top-down hierarchical regulation of conscious, complex, goal-directed behavior has been attributed to a caudal-to-rostral, anterior-to-posterior organization of the PFC (Badre, 2008). This makes clear why the smaller size and functional deficits in the PFC in ADHD would give rise to a breakdown in self-regulation and in the hierarchical organization of goal-directed actions. Concerning the specific thesis of this chapter, these reviews suggest that it may be via the connections to the ACC that this top-down control by the PFC is exercised over emotional behavior and its support of goal-directed actions (Etkin, Egner, Peraza, Kandel, & Hirsch, 2006; Ochsner & Gross, 2005).

The ACC can be subdivided into two regions, dorsal (upper) and rostral–ventral (lower), that may distinguish between the cognitive–executive activities and the emotion regulation activities of the ACC, respectively (Bush et al., 2000). Neuroimaging studies of ADHD have not made much of an effort to distinguish between these two functional zones of the ACC. But a few studies suggest that both zones of the ACC are involved in ADHD (Bush et al., 2000; Krauel et al., 2007). This helps to explain partially both the difficulties with behavioral and emotional self-regulation associated with this disorder.

As some reviews have noted, it is also likely that it is through the ACC that drive and motivation have an influence over motor functioning (Paus, 2001). This would be consistent with the theoretical positions staked out earlier that ADHD, which seems to arise in part from deficits in the ACC, would involve impaired drive and motivation along with those of EI–DESR. For the time being, the reliable finding of ACC involvement in ADHD, in addition to that of the LPFC, suggests that this may be one of the neuroanatomical bases for anticipating that EI–DESR would be as much of a core deficit associated with ADHD as would the other EFs regulated by this network. This hypothesis of problematic top-down management of the amygdala–limbic system by the executive brain (PFC) in ADHD gained recent support in findings of dysfunctional connectivity in amygdala–LPFC networks in ADHD that were directly associated with the degree of emotional lability (Hulvershorn et al., 2014).

EVIDENCE FOR EI–DESR IN ADHD

So far, it has been shown that there are sound historical, theoretical (neuropsychological), and neuroanatomical reasons for believing that EI–DESR should be a central deficit in ADHD. But is it? What is the evidence for such emotion regulation problems apart from the clinical observations of historically significant figures, the theoretical propositions, or the neuroanatomical findings in the field of ADHD? The growing body of evidence that has begun to accumulate on this topic suggests that ADHD is associated with emotional dysregulation. Until the past few years, very few studies bothered to focus on this issue. And, of course, this seems to be due in part to difficulties involved in the measurement of emotional behavior relative to the more easily assessed motor and attention behaviors involved in the disorder, as noted earlier. It may also be yet another indication that removing these emotional aspects of the disorder from clinical diagnostic criteria beginning with DSM-II and relegating them to the status of associated features in DSM-III onward may have led to relatively less interest among researchers in their involvement in ADHD.

Rating Scales

Certainly the largest body of evidence comprises studies that used ratings scales of emotional problems in children with ADHD relative to control groups. Since it is not so much anxiety or depression that seems to

be problematic in most cases of ADHD, apart from existing as comorbid disorders in a minority of cases (Barkley, 2006; Brown, 2000), I am ignoring evidence for the involvement of these problems in ADHD. The evidence reviewed so far suggests that the inhibition of frustration, impatience, anger, hostility, and even reactive social aggression, as well as more general emotional arousability, excitability, or lability, is more closely involved in the emotional self-regulation problems associated with ADHD. It is clear from reviews of research on the commonly available behavior rating scales employed in the field of ADHD, such as the Child Behavior Checklist, Conners' Parent and Teacher Rating Scales, Behavior Problem Checklist, IOWA Conners Rating Scales, and Personality Inventory for Children (Barkley, 1990, 1998), that the disorder is nearly uniformly associated with elevations in parent and teacher ratings of these negative emotions. Typically, items assessing these emotions are found on subscales that are labeled as conduct problems or aggression and usually together comprise a broad-band externalizing dimension, along with subscales assessing hyperactivity and inattention (Achenbach & Edelbrock, 1986). The relationships among these scales are quite high, as demonstrated by correlations of .60–.83 and higher between Aggression and Hyperactivity scales and loadings on the Externalizing broad-band factor of .70–.76 (Achenbach, 1986). Ratings of inattention often share a much lower relationship with aggression (.20–.56; Achenbach & Edelbrock, 1986). It is also telling from the standpoint of earlier arguments that items assessing impulsiveness load as high or higher on factors measuring aggression and the negative emotions of interest here (frustration, hostility, temper, anger) than they do on factors assessing hyperactivity or inattention. In short, the more severe one's ADHD symptoms are, particularly those related to hyperactivity and impulsivity, the more severe are ratings of frustration, temper, anger, hostility, and aggression. It is certainly possible that this simply reflects comorbidity between ADHD and disorders such as ODD and CD, so this evidence could be dismissed as not necessarily showing an inherent core problem in ADHD with EI–DESR. But this line of argument can just as easily be turned around and used to explain why there is such strong comorbidity between ADHD and especially ODD: It is the overlapping shared variance between these disorders in their problems with EI–DESR that provide the explanatory linkage, as I discuss below. This is not merely conjecture. Recent research shows that the emotional lability often seen in ADHD is linked to the same shared genetic variance that underlies the traditional ADHD symptom dimensions (Merwood et al., 2014). In other words, there is a common genetic liability to ADHD inattention, HI symptoms, and emotional lability.

Far more evidence than this exists on the link between ADHD symptoms and emotion regulation difficulties. The Behavior Rating Inventory of Executive Functioning (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000) is an 86-item rating scale developed to provide parent and teacher ratings of children's executive abilities. It contains eight narrow-band scales, three of which are pertinent to the present discussion, those being Inhibit, Working Memory, and Emotional Control. The Inhibit scale contains items reflecting not only impulsiveness but also hyperactivity. The Working Memory scale includes items related to sustained attention and distractibility, among other ADHD-like symptoms, such as disorganization and forgetfulness. The Emotional Control scale contains the following items, most of which bear directly on the argument being made here: Overreacts to small problems; Has explosive, angry outbursts; Becomes tearful easily; Has outbursts for little reason; Mood changes frequently; Reacts more strongly to situations than other children; Mood is easily influenced by the situation; Angry or tearful outbursts are intense but end suddenly; Small events trigger big reactions; and Becomes upset too easily. The Working Memory and Inhibit scales correlate highly with the respective ADHD scales of Inattention (r = .60) and Hyperactive–Impulsive (r = .73) using the DSM-IV items (Gioia et al., 2000). The Emotional Control scale is also significantly correlated with the HI items from DSM-IV (.56). Indeed, when these three scores from the BRIEF are factor-analyzed with parent and teacher ratings of ADHD symptoms, they comprise just two factors, reflecting the DSM symptom dimensions. ADHD inattention scores load highly on the same factor, as do Working Memory scores, while ADHD Hyperactive–Impulsive scores load highly on the same factor as items from the Inhibit scale. More pertinent to my point here, the Emotion Control scale of the BRIEF loads nearly as highly (.78) on the factor containing the BRIEF Inhibit (.87) and ADHD Hyperactive–Impulsive items (.76) as do the latter two scales, indicating that it is clearly as much an inherent part of this aspect of ADHD as hyperactive and impulsive behavior. Noteworthy as well is that the Emotional Control scale shows a substantially lower relationship to Working Memory and ADHD Inatten-

tion items, supporting the point made earlier that it is the impulsivity dimension of ADHD that is involved in its EI problems. Not surprisingly, research by the developers indicates that children with ADHD combined type are rated significantly more highly on all three of these BRIEF scales (Working Memory, Inhibit, and Emotional Control) relative to control children. Others have found similar results (Mahone et al., 2002). Both children with ADHD and those with ADHD + Tourette syndrome were found to have significantly elevated scores on the Emotional Control scale, along with those for Inhibition and Working Memory, compared to a control group. And this study also found, once again, that the broad-band ratings of Behavioral Regulation (Inhibition and Emotional Control) were substantially correlated with ratings of hyperactive and impulsive ADHD symptoms (*r*'s = .70) and less so with ratings of ADHD inattention (.57).

The BRIEF narrow-band scales have been found to comprise two larger, broad-band dimensions or factors labeled as Metacognition (containing the Working Memory scale, among others related to planning, shifting, organization, etc.) and Behavioral Regulation (containing the Inhibit and Emotional Control scales). The latter is the evidence with a bearing on the issue of this chapter. Problems with emotional inhibition and its self-regulation are part of the same dimension as problems with HI behavior. In summary, problems with inhibition of behavior are highly associated with problems with inhibition and self-regulation of emotion.

The same pattern of findings is evident in the research used to develop the Conners Adult ADHD Rating Scales (Conners, Erhardt, & Sparrow, 1998). Symptoms assessing emotional dysregulation were found to load on the same factor as symptoms of impulsiveness, supporting the argument made here for their coexistence. And this factor is strongly related to DSM-IV symptoms of ADHD on this scale and especially the HI dimension of the disorder.

More evidence of emotional dysregulation comes from a study that followed children diagnosed with ADHD into adolescence using multiple self-report measures of anger, hostility, verbal, and physical aggression at the follow-up evaluation (Harty, Miller, Newcorn, & Halperin, 2009). The initial sample was classified as having ADHD only, ADHD with ODD, and ADHD with CD in childhood. At follow-up, the groups did not differ in hostility. Only the ADHD with ODD and ADHD with CD groups demonstrated more anger and verbal and physical aggression relative to a non-ADHD control group at follow-up, with those with CD showing the highest levels, particularly for physical aggression. This might suggest that symptoms of EI in ADHD are a consequence of comorbid ODD and CD. However, the authors found that all of their group differences were accounted for by the severity of ADHD in childhood and by its persistence into adolescence. When these were statistically controlled, the only remaining group difference was greater physical aggression at adolescence in the subgroup that had CD in childhood. These results indicate that it is severity of ADHD in childhood and its persistence into adolescence that is associated with high levels of anger, hostility, and verbal aggression in adolescence, while CD makes an additional contribution to later risk for physical aggression. Such results are in keeping with the hypothesis here that ADHD accounts for the emotional component of ODD and for the persistence of emotions such as anger, hostility, and verbal aggression over time (discussed further below).

Research on adults with ADHD using items reflecting EI–DESR has likewise shown that such adults manifest significant problems in this domain (Barkley, Murphy, & Fischer, 2008). In comparison to a community control group, clinic-referred adults diagnosed with ADHD were significantly more likely to endorse problems with EI symptoms, as shown in Figure 3.1 (also see Barkley & Murphy, 2010). These same symptoms were also significantly more common in adults with ADHD than in a clinical control group not diagnosed with ADHD. Just as telling, the frequency of these symptoms was just as common in the adults with ADHD as those for DSM-IV inattention (74–97%) and often occurred more frequently than the HI symptoms in DSM-IV (30–79%). More recent studies also found that adults with ADHD had higher rates of emotional impulsivity and dysregulation, similarly assessed, than did control adults, and that these were not a function of comorbidity with depression or ODD (Mitchell, Robertson, Anastopoulos, Nelson-Gray, & Kollins, 2012; Surman et al., 2011, 2013). Important to note is that these symptoms of EI–DESR are not redundant with the cold cognitive executive deficits (typically working memory) often associated with ADHD and in fact are not associated with those EF deficits at all (Surman et al., in press). Thus, they serve as an additional component to the nature of ADHD in adults not represented in other neuropsychological deficits traditionally associated with the disorder.

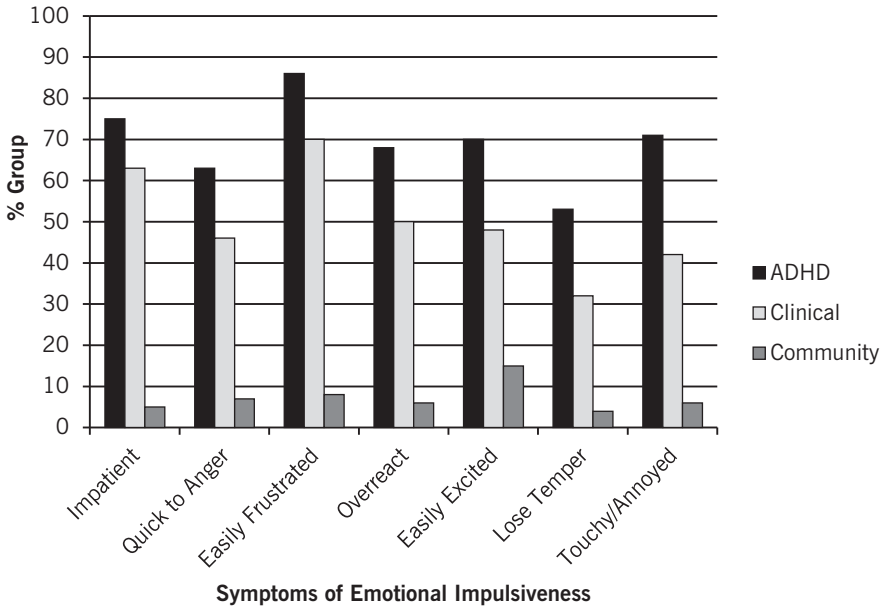

FIGURE 3.1. Percentage of adults with ADHD compared to clinical and community control adults showing each of seven symptoms of emotional impulsivity. Data used to construct the graph are adapted from Barkley, Murphy, and Fischer (2008).

In a follow-up study in that same book that reported on children with ADHD to young adulthood (Barkley et al., 2008), we found that children whose ADHD had persisted to a mean age of 27 years were significantly more likely to endorse these same items of EI–DESR than were those whose ADHD had not persisted or those in a control group followed to adulthood as well, as shown in Figure 3.2 (also see Barkley & Fischer, 2011). Again, these symptoms of impulsive emotion were as common as the DSM-IV symptoms of inattention and as common or more so than those for HI behavior in the group with persistent ADHD. We also found that these items loaded onto the same dimension as symptoms of hyperactivity–impulsivity from the DSM-IV, but not on those symptoms of inattention. This demonstrates that symptoms of EI–DESR are just as common if not more so than the DSM-IV symptoms that represent the disorder.

More evidence of a link between ADHD and emotional dysregulation comes from the development of my own scales evaluating EF for children (Barkley 2012b) and adults (Barkley, 2011), which contain five dimensions. The three that are most pertinent to this review are Self-Restraint (inhibition), Emotional Self-Regulation, and Self-Motivation. Results of comparisons between ADHD and control cases in the population normative samples routinely revealed that the vast majority of children and adults with ADHD score in the impaired range on these scales (Barkley, 2011; Barkley, 2012b). And the majority of children with ADHD that persisted to young adulthood (Barkley & Fischer, 2011), and clinic-referred adults with ADHD (Barkley, 2011; Barkley & Murphy, 2011) also scored in the impaired range on the Self-Restraint and Self-Motivation scales (the Self-Control of Emotion dimension was not yet available for use in these studies). Evidence from the development of these scales also indicated that impulsive emotions loaded on the Self-Restraint scale, as hypothesized earlier, while difficulties with self-regulation of emotions formed their own separate but related dimension.

Other recent studies have likewise found that children with ADHD are rated by parents as having significantly more problems with emotional functioning

than control cases, and that these problems are distinct from those EF deficits associated with the "cool" EFs, such as working memory (Sjöwall, Roth, Lindqvist, & Thorell, 2013).

In keeping with these results, higher rates of "road rage" (anger, hostility, and aggression while using a motor vehicle) have been found in adults with ADHD or many ADHD symptoms than in control groups (Richards, Deffenbacher, Rosen, Barkley, & Rodricks, 2006). Also, Ramirez and colleagues (1997) found that adults with many ADHD symptoms expressed more anger, did so in more dysfunctional ways, and were more labile in terms of anxious/depressed moods than those with fewer ADHD symptoms. Likewise, Able, Johnston, Adler, and Swindle (2007) found similar results among nonreferred adults who met criteria for ADHD in a population screen of 21,000 managed care plan members. These adults reported significantly greater interpersonal anger and conflict toward others they considered close to them and greater frequency with which their emotional symptoms interfered with the work, social, or family/home life than adults who did not have ADHD (Able et al., 2007). Dowson and Blackwell (2010) similarly found ADHD in adults to be linked to hot temperedness and impulsive aggression. The evidence to date therefore demonstrates that both children and adults with ADHD have considerable difficulties with frustration, anger, hostility, and aggression.

Research using rating scales of emotional reactivity, lability, and regulation likewise finds that these behaviors are problematic in both children and adults with ADHD (Jensen & Rosén, 2004). Kitchens, Rosén, and Braaten (1999) reported that children with ADHD rated themselves and their mothers rated them as more angry and depressed than did mothers of children without ADHD; the greater depression ratings were more typical of males than of females with ADHD. In a subsequent study, Braaten and Rosén (2000) reported that boys with ADHD expressed lower levels of empathy and exhibited more sadness, anger, and guilt than control boys. Similarly, Maedgen and Carlson (2000) found that children with ADHD have significantly more problems with emotional self-regulation than control children. And in several recent studies based on children's self-reports, children with ADHD had

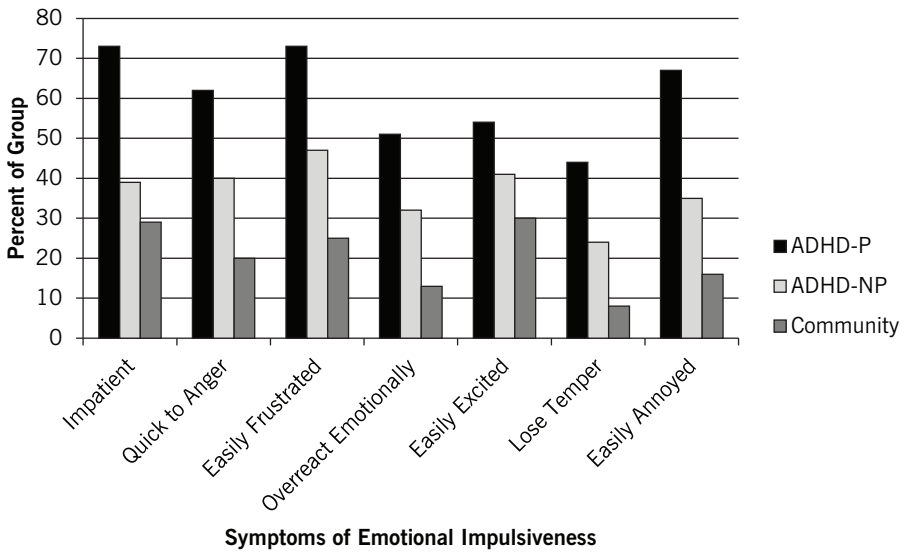

FIGURE 3.2. Percentage of children followed to adulthood (mean age 27 years) showing each of seven symptoms of emotional impulsivity for children with ADHD that persists to adulthood (ADHD-P), for those whose ADHD did not persist to adulthood (ADHD-NP), and for the control group. Data used to construct the graph are adapted from Barkley, Murphy, and Fischer (2008).

more difficulties with emotion regulation and emotional instability and less emotional maturity than control children (Ciuluvica, Mitrofan, & Grilli, 2013; Jogsan, 2013). Once more, such problems with emotion reactivity and regulation were associated more with the HI dimension and far less with inattention in ADHD (Ciuluvica et al., 2013) as has been found in preschoolers with ADHD as well (Miller, Miller, Healey, Marshall, & Halperin, 2013). The largest study to date that used ratings of emotional lability in children with ADHD, involving 1,186 children with the disorder and 1,827 siblings, revealed that children with ADHD on average place at or above 1.5 standard deviations above age and sex comparisons groups in their emotional lability (Sobanski et al., 2010). Emotional lability above the 75th percentile for age and sex norms significantly increased the risk that children with ADHD would also manifest ODD, affective disorders, and substance use disorders. Similar results are evident in adults with ADHD. Skirrow and Asherson (2013) recently studied 500 adults referred to a clinic for adult ADHD and found that emotional lability was significantly greater in those diagnosed with ADHD. Yet again, in both studies, the problems of emotional lability were associated with core ADHD symptoms, primarily the HI dimension (Skirrow & Asherson, 2013; Sobanski et al., 2010). As noted earlier, research on 1,920 child twins found that a common or shared genetic pathway exists between traditional ADHD symptom dimensions and the dimension of emotional lability (Merwood et al., 2014).

Other evidence for the centrality of EI–DESR in ADHD comes from the small but growing body of research on the link between early childhood temperament and ADHD (Nigg, Goldsmith, & Sachek, 2004). "Temperament" is the global term for a set of early emerging traits in development that form a basis for later personality. Most of the constituent traits are thought to be affective in nature (Goldsmith et al., 1987) and can be distinguished as involving either reactivity or regulation. In the area of reactivity, most theories distinguish between withdrawal (fearfulness) and approach (hostile–angry) components of negative affectivity and between approach and nonapproach positive affectivity (i.e., exuberance, contentment). Within the regulatory domain of temperament lie processes that attenuate, amplify, or sustain elicited emotions, such as comforting behavior, self-distraction, cognitive self-statements and imagery, and other instrumental voluntary and effortful behaviors that serve to modify or moderate elicited emotions (Nigg et al., 2004). These self-modifying activities of this domain are often subsumed under the term "emotional regulation." It should now be evident how extremes of early childhood temperament in both the reactivity (hostile–angry) and emotional regulatory domains may serve to link research on temperament to ADHD, as Nigg et al. have argued.

Nigg et al. (2004) cited several studies of the overlap or link between negative temperament in early development and risk for the psychopathological dimension of externalizing behavior more generally and ADHD specifically. First, studies have revealed significant relationships among negative affectivity, poor self-regulation, and impulsivity as correlates of this broad-band externalizing dimension (Campbell, Pierce, March, Ewing, & Szumowski, 1994; Huey & Weisz, 1997; Sanson, Stuart, Prior, & Oberklaid, 1993). Longitudinal studies have likewise found that early ratings by mothers of children's temperamental difficultness were significantly predictive of degree of externalizing behavior at ages 5, 6, and 8 years (Bates & Bayles, 1988; Bates, Bayles, Bennett, Ridge, & Brown, 1991). A later longitudinal study of pregnant women that followed women through their children's deliveries and early development to first grade found that both maternal ratings and direct observations of child behavior involving early temperament were linked to later risk for ADHD (Goldsmith, Lemery, & Essex, 2004). Specifically, they found that the areas of hostile and aggressive behavior, anger, and difficulties with inhibitory control were significantly predictive of severity of children's ADHD symptoms by entry into kindergarten. Of relevance to the thesis of this chapter is that early maternal ratings of children's anger and irritability during the first 3.5 years of development were significantly predictive of later ratings of severity of ADHD symptoms, as well as inhibitory control at age 4.5. The relationship of anger and irritability to ADHD was found to be mediated by their link to poor inhibitory control and its relationship to ADHD. Indeed, the cross-sectional correlations of ADHD symptoms with relevant temperament ratings were .6 to .7 (Lemery, Essex, & Smider, 2002). The inverse has also been demonstrated: Children with ADHD manifest significant elevations on measures of several temperamental traits, including negative affectivity (Foley, McClowry, & Castellanos, 2008; Martel & Nigg, 2006).

Such research provides supporting evidence for the thesis presented here that problems with inhibiting emotion and its subsequent self-regulation are strongly associated with concurrent ADHD and are predictive

of later ADHD severity. They further illustrate that it is chiefly through the symptom dimension of impulsivity that this link between emotional reactivity and poor emotion regulation and ADHD is likely to occur, as evidence reviewed earlier has already suggested (Martel, 2009). And it shows that these constructs of emotional control are important in understanding or more clearly illustrating the relationship of ADHD to other psychological problems and even comorbid psychiatric disorders. The two symptom dimensions of ADHD in DSM-IV simply do not make such linkages evident or understandable without the explicit acknowledgment that EI–DESR is related to them and is a central component of ADHD.

Direct Observations

Direct evidence of problems with EI–DESR comes from observational studies of emotional behavior in children with ADHD. Rosenbaum and Baker (1984) found that greater negative affect was expressed by children with ADHD during a concept learning task involving noncontingent negative feedback. Cole, Zahn-Waxler, and Smith (1994) found that levels of negative affect were significantly and positively correlated with symptoms of and risk for ADHD, but only in boys. Greater emotional responsiveness has been reported as well in the social interactions of children with ADHD. Johnston and Mash (2001) found that children with ADHD displayed greater emotional intonation in their verbal interactions with their mothers. Studies of peer interactions also revealed children with ADHD to be more negative and emotional in their social communications with peers. This greater level of expressed negative emotion in children with ADHD is most salient in the subgroup that has high levels of comorbid aggression (Hinshaw & Melnick, 1995). Consistent with such findings, Keltner, Moffitt, and Stouthamer-Loeber (1995) recorded the facial expressions of adolescent boys during a structured social interaction. Four groups of boys were created; the first was rated as having high levels of externalizing symptoms (hyperactive–impulsive–inattentive–aggressive behavior); the second comprised boys rated as having more internalizing symptoms (anxiety, depression, etc.); the third group comprised boys having elevations in ratings of both types of symptoms; and the fourth group comprised nondisordered adolescent boys. Boys showing high levels of externalizing symptoms were found to demonstrate significantly more facial expressions of anger than the other groups, which were low in externalizing symptoms. These results suggest the possibility that the commonly noted association of ADHD with defiant and hostile behavior (see Hinshaw, 1987, for a review) may, at least in part, stem from a deficiency in emotional self-regulation in those with ADHD. Again, however, these findings merely suggest rather than confirm a link between ADHD and EI–DESR, and tend to imply that the poorest emotion modulation may be within the aggressive subgroup of children with ADHD.

Several studies have specifically evaluated frustration tolerance and anger responses in children with ADHD. Milich and Okazaki (1991) presented children with ADHD and control children with both solvable and unsolvable puzzles, and noted that children with ADHD were more likely to give up on solving either set of puzzles, especially those that were unsolvable, presumably because they became more frustrated with the latter puzzles. As evidence of this, they noted that the children with ADHD reported higher levels of frustration during these tasks than did the control children. In a separate study, Milich, Carlson, Pelham, and Licht (1991) found that these difficulties with frustration were ameliorated by the stimulant methylphenidate. Walcott and Landau (2004) evaluated boys with ADHD during a frustrating peer competition task in which half of the boys in each group were instructed to try to hide their feelings if they became upset. Boys with ADHD were more likely than control boys to become upset and were less effective at hiding their feelings, even when instructed to do so, in keeping with the EI and DESR components hypothesized to exist in theories of ADHD discussed earlier (Barkley, 1997b, 2012a). Similarly, Waschbusch and colleagues (2002) found that children with ADHD manifested more anger in response to behavioral provocation than did children without ADHD, regardless of comorbidity with ODD and CD (Waschbusch et al., 2002). As noted earlier, Rapport et al. (1986) also studied children with ADHD and control children, using a delayed gratification task presumed to assess frustration tolerance. They found the children with ADHD to be markedly less able to handle the frustration associated with delayed rewards. This evidence that children with ADHD quit or fail to persist at activities that demand problem solving is also evident in studies of their academic performance (Hoza, Pelham, Waschbusch, Kipp, & Owens, 2001). Such studies provide evidence that low frustration tolerance and quickness to anger seem to be associated with ADHD.

However, Melnick and Hinshaw (2000) observed children with ADHD during a family problem-solving task that elicited frustration. They found that only a highly aggressive subgroup of boys with ADHD demonstrated greater emotional responding to the emotional induction of the task and a less constructive pattern of emotional coping compared to nonaggressive boys with ADHD or controls. The extent to which the involvement of family members as part of this task added extra elements of either parental control or opportunities for family conflict (and aggression) might explain the discrepancy between this finding and those from the three studies discussed earlier. Also problematic in the study was the lack of information on the subtypes of ADHD enrolled and how they related to the subgrouping of children into aggressive and nonaggressive ADHD groups. As noted earlier, children with ADHD predominantly inattentive type (ADHD-PI) and especially those with SCT may not have symptoms of EI or DESR given that the latter are highly associated with the HI dimension in DSM-IV, a dimension on which such children with ADHD-PI-type would be low or even normal. A surprising finding of the study was that boys with ADHD assigned to the nonaggressive group fell within the normal range on all measures of emotion regulation. This is highly unlikely given evidence reviewed earlier if that group contained an equal percentage of children with ADHD combined presentation (ADHD-C) of equal severity to the children in the aggressive ADHD group. Nevertheless, the weight of the evidence suggests a link between ADHD and impulsive and poorly regulated emotion, specifically that of frustration.

Some evidence also demonstrates that this problem with emotional self-regulation arises from difficulties in the management of one's own emotions and not in its perception in others. Shapiro, Hughes, August, and Bloomquist (1993) found that children with ADHD did not differ from a normal control group in their ability to identify and process emotional cues in others. This may be true, however, only in "cool" situations, such as identifying facial expressions in pictures in storybooks or photos. This has certainly been observed in other studies of emotion recognition and understanding in which children with ADHD do not differ from controls, whereas children with Asperger syndrome or nonverbal learning disabilities are deficient (Semrud-Clikeman, Walkowiak, Wilkinson, & Minne, 2010). When in actual "hot" or live situations involving emotions of others, children with ADHD are more likely to show "emotional contagion" (adopting the emotional expressions of others) and more emotion in response to provocation, and are less accurate in identifying both their own emotions and those of others (Casey, 1996; Norvilitis, Casey, Brooklier, & Bonello, 2000). It is possible that this distinction between hot and cool situations involving emotional evaluation stems from live emotions generating more emotional reactions in those with ADHD, which may overwhelm their already deficient executive or cognitive ability to focus attention on their own emotions or the emotional cues of others when they are emotionally aroused. Regardless, whether those with ADHD have problems perceiving the emotional states of others is unimportant to the present argument because this chapter focuses on the capacity for emotional inhibition and its subsequent self-regulation as being central to ADHD, and not the perception of emotions in others.

Psychophysiological Research

Very few studies have focused on the use of psychophysiological measures of the sympathetic and parasympathetic nervous systems to evaluate emotion regulation problems in children with ADHD. One study that did so during tasks involving negative emotion induction and suppression reported that children with ADHD show ineffective and high levels of parasympathetic activity, and reduced flexibility or adaptation in this activity across these tasks than do control children, who show greater ability to adapt their parasympathetic activity to setting demands (Musser et al., 2011).

The foregoing evidence from rating scales, direct observation, and psychophysiological studies largely demonstrates that the link between ADHD and poor emotion regulation is not hypothetical but actual. The vast majority of the prevailing evidence pertains to the EI component of the emotional dysregulation associated with ADHD, and shows that it is more related to the HI dimension of ADHD than to its inattention dimension, as expected in the earlier theoretical review. There has been far less research on the capacity of those with ADHD to self-regulate their emotional states actively and consciously, which is the more executive aspect, or the DESR component, of ADHD. I have hypothesized that this executive element of emotion regulation may well be associated with the inattention dimension of ADHD. For instance, Knouse and associates (2008) found the inattention dimension of ADHD symptoms to be more highly predictive of

lower positive and higher negative mood on their measures of emotional well-being than were symptoms of hyperactivity–impulsivity in their adult samples. As Hinshaw (2003) concluded in his review of poor emotion regulation in ADHD, the problems with EI appear to be largely independent of the EF deficits often associated with the disorder, at least when EF is psychometrically tested (indexing of the "cool" EF components). But the problems with DESR have rarely been studied in those with ADHD and may well be associated with working memory difficulties and the EFs more generally that are often found to be more closely linked to the inattention dimension of ADHD symptoms.

In summary, we see here objective evidence of clinical observations dating back through history to Crichton (1798), showing that disorders of attention and inhibition also involve problems with low frustration tolerance, anger, and negative emotional reactivity. While more research on this issue is clearly warranted, it is obvious even from this limited array of research findings that ADHD is associated with symptoms of EI–DESR. The argument that this merely reflects comorbidity with other disorders, particularly ODD, is not persuasive given that the symptoms of EI correlate highly with and load on the same behavioral dimensions as the DSM symptoms of hyperactivity–impulsivity, while being substantially less associated (though not unassociated) with the inattention–working memory symptoms of ADHD. If mere comorbidity were the explanation for these findings, the problems with EI should have formed their own separate dimension reflecting a distinct yet overlapping disorder with ADHD, as is the case with CD, depression, or anxiety. That has not typically been the case in the research reviewed here. Even so, this evidence suggests that future research would do well to examine the role of comorbidity in EI–DESR symptoms, if only to clearly rule out comorbid disorders such as CD, depression, and anxiety. ODD, on the other hand, may not be just an overlapping disorder with ADHD; it may be a direct consequence of it. This issue is explored next.

THE IMPORTANCE OF EI–DESR SYMPTOMS IN UNDERSTANDING COMORBIDITY WITH ODD

ODD is characterized in DSM-5 as "a frequent and persistent pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness . . ." (American Psychiatric Association, 2013, p. 463). It comprises a set of eight symptoms, at least three of which reflect negative affect (loses temper, touchy or easily annoyed, angry and resentful), while four reflect social conflict with others (argues with adults, defies or refuses to comply, deliberately annoys others, blames others for his or her own mistakes). The final symptom likely relates to both an affective and a social component of the disorder (acts spiteful or vindictive) and may be more related to CD. ODD has a point prevalence of 1.4% of girls and 3.2% of boys in children ages 5–16 years, with 36% of girls and 43% of boys with ODD having another disorder (Maughan, Rowe, Messer, Goodman, & Meltzer, 2004). Lifetime prevalence of ODD is 10.2%, with over 92% of such cases having another comorbid disorder (Nock, Kazdin, Hiripi, & Kessler, 2007). The most common comorbidity is ADHD or impulse control disorders (Maughan et al., 2004; Nock et al., 2007; Speltz, McClellan, DeKlyen, & Jones, 1999).

The inverse is also true. ODD is the most common comorbid psychiatric disorder seen in conjunction with ADHD, occurring on average in 65% of cases and in as many as 84% of clinic-referred cases in childhood (see Chapter 5). It is possible that this may even be an underestimate given that such studies may not distinguish among ADHD subtypes. It is ADHD-C with which ODD is likely to have a far greater affiliation than with ADHD-PI or SCT/CDD (Milich et al., 2001; see also Chapter 17). ODD is 11 times more likely to coexist with ADHD than to occur at its base rate in the general population even in epidemiological samples (Angold, Costello, & Erkanli, 1999). ODD has also been found to be a common comorbidity in children with ADHD followed to adulthood (50% of those with persistent ADHD) and in clinic-referred adults with ADHD (Barkley et al., 2008), occurring in up to 35–53% of these adult cases according to self-reported information. This source of information may lead to underestimates of disorder among patients with ADHD (Barkley et al., 2008).

It is certainly possible that ADHD is one of several causes or contributing factors to the risk for ODD. Suggestive evidence for such a causal or contributory relationship comes from several lines of research findings. First, the severity of ADHD is certainly significantly and substantially correlated with the risk for and severity of ODD, with correlations between the two dimensions rising to as high as .91 in teenagers (Barkley, Guevremont, Anastopoulos, DuPaul, & Shelton, 1993) and ranging from .68 to .86 in younger children (Burns & Walsh, 2002; Gadow & Nolan, 2002; Harvey,

Friedman-Weieneth, Goldstein, & Sherman, 2007). Using data from my various studies, I analyzed available data for this review and found correlations between ADHD and ODD symptoms to be .72 in our study of kindergarten children with high levels of disruptive behavior and a control group (Shelton et al., 1998), .71 in self-reports of retrospective childhood symptoms in our follow-up study of hyperactive children to age 21 (Fischer, Barkley, Smallish, & Fletcher, 2002), .70 in the employer ratings of those participants' current symptoms at work, and .77 in participants' own ratings of those same symptoms in the workplace. All of these results show a robust relationship between the severity of symptoms of these two disorders. Others have also found that the severity of ADHD is predictive of the severity of later anger and verbal aggression in adolescence among children diagnosed with ADHD (Harty et al., 2009). And it is the persistence of ADHD from childhood to adolescence that explains these difficulties with anger and verbal aggression in adolescence (Harty et al., 2009).

Second, the prevalence of ODD alone is most common in the preschool age group and becomes relatively less common by school age and onward, occurring in just 1–3% of children after age 5 (Maughan et al., 2004; Bauermeister, 1992; Lavigne et al., 2001). After this age, approximately half or more cases of ODD are comorbid with ADHD. ADHD is therefore associated with the persistence of ODD over development, which may further imply a causal connection between the two disorders.

Third, some longitudinal research using preschool children shows that initial ADHD symptoms, particularly the HI dimension, are predictive of higher ODD scores 1 and 2 years later, whereas initial ODD scores were not predictive of later HI or inattention symptoms (Burns & Walsh, 2002). These findings hold even after statistically accounting for the ability of each symptom dimension to predict itself over time. As those authors noted, this suggests that the HI dimension of ADHD influences the development of ODD behavior in some way. This is consistent with substantial research showing that impulsivity or response inhibition, not hyperactivity, is linked to risk for and severity of conduct problems or externalizing behavior generally, both concurrently and longitudinally into adolescence (Berlin & Bohlin, 2002; Olson, Schilling, & Bates, 1999). Any initial link of hyperactivity to conduct problems seems to be accounted for by its association with poor inhibition (Berlin & Bohlin, 2002). Other follow-up research with this age group suggests that early-onset ODD *is* predictive of both later ODD and later ODD with ADHD, but that its stability over development when occurring alone was quite low, with approximately half of all cases remitting every 1–2 years (from 24% in preschool to 5% at 5-year follow-up; Lavigne et al., 2001). Speltz and colleagues (1999) found that early-onset ODD predicted later risk for ADHD as well. With development, ODD shows an increasing affiliation with ADHD, and especially persistent ADHD (Lavigne et al., 2001). And when ODD occurs with ADHD, it is significantly persistent over the next 4- to 10-year period (August, Realmuto, Joyce, & Hektner, 1999; Biederman, Petty, Dolan, et al., 2008; Speltz et al., 1999).

Fourth, studies of preschool children with hyperactivity (HYP) alone, ODD alone, and both disorders find that only the HYP groups are associated with greater pre- and perinatal risk factors and with a family history of both ADHD and ODD, whereas ODD alone is not (Harvey et al., 2007). Noteworthy as well is that children with HYP alone still had relatives with higher rates of ODD, whereas children with ODD alone did not. Further study of these preschool groups showed that both the children with HYP and HYP/ODD had greater levels of parental ADHD symptoms, maternal Axis I psychiatric disorders, negative life events, paternal Axis II psychiatric disorders, marital status, couple conflict, or the use of low intensity couples' conflict tactics (Goldstein, Harvey, Freidman-Weieneth, Pierce, et al., 2007). (Only ODD was not further studied in this subsequent research because it was not found initially to be assosciated with biogenetic risk factors.) Yet these two groups did differ in the degree of maternal Axis II psychopathology, paternal Axis I psychopathology, and the use of more severe couple conflict tactics. This suggests that genetic and biological contributors to disorder are chiefly linked with ADHD (HYP) whether it occurs with or without ODD, and not with ODD alone. It further suggests that there exists a genetic predisposition to ADHD that also seems to create a risk factor for ODD in relatives. It further implies that social-environmental factors may be more responsible for preschool ODD when it occurs alone than is the case with ADHD or ADHD with ODD.

Obviously this suggests that ADHD is not the only contributor or cause of ODD, especially in the preschool age group in which ADHD can exist alone (Bauermeister, 1992; Gadow & Nolan, 2002). But it does suggest that when ODD exists alone, it is not an especially developmentally persistent disorder unless it

is linked to ADHD. It also intimates that the nature of ODD when it occurs alone in the preschool age group may have more to do with both the behavioral or social conflict component of the disorder and its greater situation specificity toward parents than its EI component, as the more detailed investigation on the nature of ODD by Hoffenaar and Hoeksma (2002) suggests. And that social component of ODD alone may explain why it is associated with disrupted parenting and family stress both concurrently (Cunningham & Boyle, 2002) and over development (Burke, Pardini, & Loeber, 2008), whereas ADHD alone shows no such reciprocal effects of parent–child interactions over development (Burke et al., 2008). All this could explain the very low level of concurrent validity (interjudge agreement and discrimination on observational measures) of ODD only relative to ADHD and especially their combination, which has substantially greater concurrent validity (Harvey et al., 2007). Research on ODD rarely separates these two components (emotional, social conflict) out for an examination of their development, correlates, stability, and contributors/causes. The behavioral–social component of ODD may be more likely to arise from disrupted parenting and family stressors, along with associated mismanagement of the gambits of preschool children's sporadically defiant behavior (Barkley, 1997c; Burke et al., 2008; Cunningham & Boyle, 2002; Lahey & Waldman, 2003; Moffitt, 1993; Patterson, DeGarmo, & Knutson, 2000). The emotional component of ODD may involve an underlying neuropsychological deficit in emotional impulsiveness and perhaps to a lesser extent its deficient self-regulation, as is argued here and by others (Martel, 2009) to be the case in ADHD.

In my opinion, it is the underappreciated EI–DESR symptoms of ADHD that are most likely to explain this high level of comorbidity of ADHD with ODD as categories of disorders and their strong relationship when assessed dimensionally. This is evident in the fact that the three symptoms reflecting negative emotion in the ODD symptom list are very similar to those believed to comprise EI noted earlier (low frustration tolerance, quickness to anger, impatience, and emotional excitability). As shown earlier, these EI symptoms and related problems with DESR are more common in children with ADHD. Research on the construct of oppositionality using a larger range of items identifies two large trait factors as more likely representing this construct or disorder, along with a set of situation-specific factors (parents, other authorities, peers) (Hoffenaar & Hoeksma, 2002). As noted earlier, these two trait factors are emotional and behavioral (social conflict). DSM-5 now reflects this dichotomy of the ODD symptoms. Others have also argued for viewing ODD as having two components (emotional and social behavioral; Burke, Loeber, & Pardini, 2009). They seem most likely to represent the components of negative affectivity and social behavioral conflict discussed earlier for DSM-5 symptoms. Supporting this distinction between these components are recent findings that the emotional symptoms of ODD are more predictive of later internalizing disorders, and particularly depression, whereas social conflict symptoms are more related to the developmental risk for CD (Burke, 2009).

Given that three of the symptoms of ODD appear to involve EI–DESR, children with ADHD-C could be considered to be virtually borderline or subthreshold cases of ODD as a consequence. Their low frustration tolerance, impatience, and quickness to anger set them up for patterns of reactive verbal aggression during provocative encounters with parents and peers, perhaps explaining why reactively aggressive children often show significantly higher rates of ADHD symptoms than do proactively aggressive children or control groups (Vitaro, Brendgen, & Tremblay, 2002). Indeed, as Martel and Nigg (2006) found, it is the temperamental trait of negative affectivity associated with ADHD in children that is most closely linked to their risk for ODD. As Ambrosini, Bennett, and Elia (2013) also observed, children with ADHD who also manifest irritable mood are those most likely to be at risk for ODD and mood disorders, and such irritable mood is closely linked to having ADHD-C. Children with ADHD would therefore require the development of just one or two additional symptoms from the social interaction conflict component before crossing the requisite diagnostic threshold of four symptoms for ODD. Indeed, given that verbal aggression has been shown to be part of the greater anger evident in ADHD (Harty et al., 2009), a fourth symptom of ODD may already exist in those with ADHD (stubbornness, defiance, refusal to obey). Further supporting this view that it is the negative emotionality dimension of ADHD that links it to ODD, genetic studies using twins indicate that a substantial portion of the additive genetic, nonadditive genetic, and nonshared environmental contributions to ADHD, ODD, and CD are in fact shared with negative emotionality (Singh & Waldman, 2010). This rise in the occurrence and severity of the social-interactional component of ODD in children with ADHD and its

persistence over time may have as much to do with the severity of ADHD and parenting stress, parental psychopathology, its relationship to disrupted parenting, and severity of parent conflict as with biogenetic contributors associated with ADHD and the EI–DESR component of ODD (August et al., 1999; Burke et al., 2008; Goldstein, Harvey, & Friedman-Weieneth, 2007; Goldstein, Harvey, Friedman-Weieneth, et al., 2007; Johnston & Mash, 2001).

It may well be that this rise in the social conflict component of ODD further accounts for its developmental linkage to concurrent and later CD, and the reason that ADHD is often seen as a precursor to CD. The link between ADHD and CD appears to be largely mediated by the development of ODD in that developmental pathway (Angold et al., 1999; Biederman, Petty, Dolan, et al., 2008; Biederman, Petty, Monuteaux, et al., 2008; van Lier, van der Ende, Koot, & Verhulst, 2007; Rowe, Maughan, Pickles, Costello, & Angold, 2002; Whittinger, Langley, Fowler, Thomas, & Thapar, 2007), at least in males, and between ADHD and major depression–anxiety in both males and females with ADHD and ODD (Biederman, Petty, Dolan, et al., 2008; Biederman, Petty, Monuteaux, et al., 2008; van Lier et al., 2007; Rowe et al., 2002).

The causal or at least contributory link of ADHD to ODD is also evident in the earlier findings that it is largely the poor inhibition symptoms (impulsivity) of ADHD that show the strongest link to risk for ODD specifically and its reflection in the more general ratings of conduct problems (Martel & Nigg, 2006). Symptoms of EI–DESR have been repeatedly shown to be an inherent part of the impulsive dimension of ADHD (see earlier discussion) and therefore may easily provide the explanatory link of this dimension to ODD symptoms. In fact, some factor-analytic studies of both ADHD and ODD symptoms reveal that the impulsive symptoms in ADHD also gross-load substantially onto the factor representing ODD nearly as much as they do on the HI factor of ADHD (Burns, Boe, Walsh, Sommers-Flanagan, & Teegarden, 2001). Intervention studies likewise show that improvements in ADHD symptoms are closely associated with improvements in ODD symptoms (Biederman et al., 2007; MTA Cooperative Group, 1999). These findings are consistent with the hypothesis presented here that some ODD symptoms are a consequence of ADHD itself and especially its EI–DESR component. Thus, reducing ADHD symptoms using medications should result in nearly comparable reductions in symptoms of ODD.

The available evidence can at least be taken to suggest that the high comorbidity between ADHD and ODD is most likely driven in large part by the EI–DESR component of ADHD as part of the larger impulsivity dimension of ADHD. This problem with emotional impulsiveness and poor self-regulation of elicited emotions is especially problematic for negative affectivity, and specifically for low frustration tolerance, quickness to anger, emotional excitability or reactivity, and hostility or reactive aggression. Thus, ADHD strongly predisposes children toward the emotional component of ODD requiring that they simply need to develop just one symptom from the behavioral social conflict component of ODD to become fully diagnosable as having ODD. It seems likely that this evolution of ADHD with subthreshold emotional ODD to full ODD with the additional social conflict component may be associated with or a consequence of the family environment (specifically, disrupted parenting and related parental psychopathology, family stressors, and more severe marital conflict tactics). The point here is that this link would be far less obvious if the role of EI–DESR as a core element of ADHD were not made explicit.

This pathway by which ADHD contributes to risk for ODD through the former's EI–DESR component not only helps us better to understand the comorbidity of ADHD with ODD across development, but it also suggests one pathway through which EI–DESR then contributes to the risk for depression and anxiety later in adolescence. As noted earlier, research indicates that it is the emotional dysregulation component of ODD that is associated with those downstream developmental risks, and that component is largely a function of the coexistence of ADHD with ODD. As Martel (2009) also noted, the EI component of ADHD is part of a general liability for all three externalizing disorders. As I argue here, it may also be an indirect pathway for later risks for other emotion-related comorbidities evident in ADHD.

THE IMPORTANCE OF EI–DESR IN IMPAIRMENTS OF ADHD

So far, I have argued in this chapter that EI-DESR is a core feature of ADHD, and that this creates a significant overlap with the negative emotional component of ODD, thus predisposing those with ADHD to a high risk for developing ODD, among other disorders. This emotional feature of ADHD, however, and its link

to ODD, may also provide a clearer understanding of some of the social impairments that are likely to arise in conjunction with ADHD. My purpose here is not to review the extensive literature on social impairment in ADHD but simply to suggest that one contributor to it is likely to be the EI–DESR component of ADHD.

Within the family, the impulsive emotions and their poor self-regulation of children with ADHD would be expected to increase parental controlling responses and parental expressed emotion as part of the reciprocity involved in parent-child interactions (Danforth, Barkley, & Stokes, 1991; Johnston & Mash, 2001; Mash & Johnston, 1990). As discussed earlier, these interactions, if not dealt with constructively by parents, may foster children's transition from just having the EI–DESR and associated emotional component of ADHD to the behavioral or social conflict component and therefore the likelihood of receiving a formal diagnosis of ODD. Certainly, the excessive activity, poor sustained attention, and verbal and motor impulsiveness in ADHD would by themselves be expected to result in increased controlling responses from parents, as they clearly seem to do, with a commensurate diminution in such responses when the child is treated with stimulants (Danforth et al., 1991). Longitudinal studies likewise are in keeping with a greater effect of child ADHD on parental behavior than of parental behavior on child ADHD (Burke et al., 2008; Lifford, Harold, & Thapar, 2008). The evidence is substantial that ADHD in children is associated with significantly elevated reports of parenting stress and family conflict, poorer parenting practices, greater parental commands and punishment, vacillation between lax and harsh punishment, and a reduced sense of parenting competence (Fischer, 1990; Johnston & Mash, 2001; Mash & Johnston, 1990). Observational studies of parent–child interactions find that increased levels of parental commands and instructions, reduced parental responsiveness to child-initiated interactions, greater parental negativity, and greater levels of parental rejection and coercion yield poorer child compliance (Johnston & Mash, 2001). While these findings for ratings and observations are often more severe in families having children with both ADHD and ODD (or conduct problems), they are higher in families with children who have ADHD only than in control groups. This illustrates the point that ADHD alone is sufficient to increase parent–child conflict and stress.

It is quite possible that the degree of child EI–DESR is one contributor to such conflicts, along with the more traditional dyad of ADHD symptoms, and that ADHD medication management that results in changes in the EI–DESR component contributes to improved parent–child interactions. Suggestive evidence of this is found in the further increases in parent–child conflict and parenting stress that are often found when ODD symptoms are also elevated (Barkley et al., 2008; Johnston & Mash, 2001). The effect of ADHD medications on parent–child interactions is largely to reduce both the child's negative behavior and noncompliance, and it is these changes that result in reduced parental controlling behavior and negativity toward the child (Danforth et al., 1991; Johnston & Mash, 2001). Although far less studied, the same appears to be true of the teacher–child interactions of children with ADHD and the effects of medication treatment (Whalen, Henker, & Dotemoto, 1980). It is not unreasonable to assume that the EI–DESR component of ADHD contributes partially to children's interaction problems with adult authorities and that it is the resulting changes in this component by ADHD medications that partially result in improvements in these interactions.

Also supportive of the argument made here are findings that children with ADHD-C have higher levels of family conflict and parenting stress than do children with ADHD-PI (Lewis, 1992; Paternite, Loney, & Roberts, 1996). Since the EI-DESR element of ADHD has been shown to be most closely linked to the HI symptom dimension and this is more severe in children with ADHD-C than in those with ADHD-PI, this would imply that such EI–DESR problems may be a contributor to these problems with family functioning. Unfortunately, studies of both ADHD and its comorbidity with ODD and their impact on parenting and parent–child relations have not usually singled out the EI–DESR component of ADHD for its contribution to these problems, so its specific role in these family conflicts remains conjectural at the moment. It may remain so if the EI–DESR component of ADHD is not made more explicit, so as to encourage greater care in future research to examine it relative to the other well-known symptom dyads of ADHD.

The majority of children with ADHD are likely to experience peer rejection (52-80%; Hoza, 2007). They are often rated as scoring lower in terms of peer social preferences, higher in their negative impact on peer relations, and they are less well liked and more likely to have fewer close friends. These problems are not simply a function of comorbidity with other disorders; they appear to arise from ADHD specifically (Hoza et al., 2005; Nijmeijer et al., 2008). And they do not appear

to result from overall lower rates of positive behavior exhibited by children with ADHD because these rates are often close to those found in control children. It is the higher rates of negative interactions they initiate that distinguish between ADHD and control groups (Abikoff et al., 2004; Whalen & Henker, 1985). As noted by Whalen and Henker (1992), the emotional dysregulation seen in children with ADHD is a major contributor to disrupting the smoothness, reciprocity, and cooperative activities involved in peer relationships. Recent evidence suggests that peer relationship problems in children with ADHD are best predicted specifically by their difficulties with following rules, their reduced helping behavior, their *whining*, and their inattention (Mrug, Hoza, Pelham, Gnagy, & Greiner, 2007). Other studies have also found both the level of child impulsiveness and verbal and physical anger and aggression to be important predictors of peer interaction problems and rejection (Buhrmester, Camparo, Christensen, Gonzalez, & Hinshaw, 1992; Melnick & Hinshaw, 2000; Hinshaw, 2003). Such findings support Whalen and Henker's (1992) conclusions about the source of peer relationship problems in children with ADHD and specifically imply that EI–DESR is at least one of the contributing factors to peer relationship difficulties associated with ADHD. This is also the case for typically developing children. Negative emotionality is a major predictor of peer likability (Dougherty, 2006; Schultz, Izard, Stapleton, Buckingham-Howes, & Bear, 2009). As with parent–child and teacher–child interactions, the effects of ADHD medications are largely to reduce such negative emotions, thereby resulting in improved peer relations, often with little or no added benefits to be gained from adding social skills training (Abikoff et al., 2004; Cunningham, Siegel, & Offord, 1985; MTA Cooperative Group, 1999). But as with studies of parent–child relations, the link here between EI–DESR and peer relationships problems in ADHD needs more study, but it is likely to be proven correct given the evidence that in typical children negative emotionality is a major predictor of social status (Dougherty, 2006).

Other domains of functional impairment, particularly in adults, may also be related at least in part to the degree of EI–DESR present in cases of ADHD. Skirrow and Asherson (2013) found that emotional lability in adults with ADHD is a significant predictor of impairment in daily life independent of the other two ADHD symptom dimensions. Later research by Surman and colleagues (2013) found similar results, and that EI–DESR predicted lower quality of life and social adjustment. My colleagues and I also examined predictors of being fired or dismissed from employment and those of poor work performance as rated by supervisors in adults with ADHD. We found that the degree of ADHD symptoms significantly predicted the latter work performance problems, but level of emotional impulsiveness was predictive of occupational impairment generally and the percentage of jobs from which the adult had been fired specifically (Barkley & Fischer, 2010; Barkley & Murphy, 2010). Others have also found emotional problems to be a major pathway from ADHD to impaired occupational outcomes (Gjervan, Hjemdal, & Nordahl, in press).

Just as symptoms of EI–DESR may impair the peer and cohabiting relationships of adults with ADHD, they may also interfere with their cohabiting/marital relationships. There are only a few studies of the dating and marital relations of teens and adults with ADHD, but they indicate greater levels of conflict and dissatisfaction relative to control samples (Barkley et al., 2008). It seems quite likely that problems with EI–DESR may be one factor in such relationship strife, as might persistent ODD that is related to it. This was indeed found to be the case in subsequent analyses of these two large databases of adults with ADHD and children growing up with ADHD followed as adults (Barkley & Fischer, 2010; Barkley & Murphy, 2010). Surman and colleagues (2013) later replicated these findings in their large study of adults with ADHD.

Parenting may also be adversely affected by the problems with EI–DESR in adults with ADHD. Studies of parents with ADHD have revealed higher levels of family conflict more generally and lower levels of cohesion (Biederman, Faraone, & Monuteaux, 2002). Research using more specific measures of parenting find greater negative parenting, higher ratings of expressed negative emotion, and lower levels of positive parenting in mothers with high levels of ADHD symptoms (Chronis-Toscano et al., 2008; Psychogiou, Daley, Thompson, & Sonuga-Barke, 2008) and more negative, critical, overreactive, and authoritarian parenting in fathers with higher symptom levels of ADHD (Arnold, O'Leary, & Edwards, 1997). Adult self-reports of EI symptoms on the Conners Adult ADHD Rating Scale were found to be significantly associated with the findings for both negative and positive parenting (Chronis-Tuscano et al., 2008), supporting the argument here that EI–DESR is one factor contributing to the parenting problems of adults with ADHD. While one factor in such disrupted

parenting is certainly the fact that 40–60% of the children of adults with ADHD have the same disorder, as well as ODD, or at least more symptoms of both than do control groups (Barkley et al., 2008), problematic parenting remains evident even after controlling for related disorders in the children (Murray & Johnston, 2006), suggesting that EI–DESR may be one contributor to impaired parenting in adults with ADHD. It is certainly a predictor of both parenting stress among adults with ADHD and the degree of oppositionality in their offspring (Barkley & Murphy, 2010) and siblings (Sobanski et al., 2010; Surman et al., 2011).

Research on the driving of people with ADHD indicates not only numerous deficits and adverse outcomes in this domain of major life activity (Barkley & Cox, 2007) but also has specifically noted elevated rates of driving anger, hostility, and aggression (road rage) among both adults with ADHD and college students showing elevated rates of ADHD (Richards et al., 2006). Road rage is a major contributor to risk for traffic citations and car crashes (see Richards et al., 2006) above and beyond factors such as driver inattention. This implies that problems with EI–DESR may make a specific contribution to the driving problems of adults with ADHD, above and beyond just their problems with attention. Subsequent research indeed has found this to be the case, with EI making unique contributions to crash risk (Barkley & Fischer, 2010; Surman et al., 2013) and to driving while intoxicated, above and beyond contributions made by traditional ADHD symptoms.

Likewise, a few studies have found a link between EI–DESR in adults with ADHD and their higher risk for arrest rates (Barkley & Fischer, 2010; Barkley & Murphy, 2010; Surman et al., 2013). Important to note, once again, is that these contributions are over and above those made by the traditional ADHD symptom dimensions in predicting these adverse outcomes.

Although all this evidence is suggestive of a link between EI–DESR problems inherent in ADHD and these various areas of impairment, such a link has not been established directly. This is largely because the EI–DESR aspects of ADHD have not been considered to be a central component of ADHD and are therefore not likely to be evaluated directly in research in these and other areas of impairment arising from the disorder. So long as a central role of emotional dysregulation is unacknowledged or at least underappreciated as being a part of ADHD, as Harty and colleagues (2009) suggested, its importance in research on impairment may remain understudied.

CONCLUSIONS AND CLINICAL IMPLICATIONS

In this chapter I have argued that EI–DESR is a core feature of ADHD that deserves to be represented in its own right both in conceptualizations of the disorder, as it is in current theories, and in diagnostic criteria for the disorder, as it has not been since DSM-II. A similar stance has been taken by other reviewers as well (Corbisiero, Stieglitz, Retz, & Roster, 2013; Martel, 2009; Skirrow et al., 2009). This argument is based on the historical record over its initial 175-year history, until the 1960s and 1970s, which considered problems with emotion regulation to be part of the disorder. At that time, this component of the disorder was split off from its conceptualization and relegated to the status of an associated feature, if mentioned at all. However, current theories of the disorder have resurrected its place in the nature of ADHD itself and in doing so is supported by findings on the neuroanatomical basis of ADHD and the association of that neural network with EI–DESR. This EI–DESR element of ADHD is probably a specific consequence of the neurodevelopmental abnormalities evident in the frontal–limbic pathway (dorsolateral PFC and ACC) of the brain and particularly the top-down governing (cognitive–effortful) influence of these structures (via the ACC) over the amygdala specifically and the limbic system more generally(emotional brain). As shown here, there is a growing body of evidence that both children and adults with ADHD actually do have significant EI symptoms. Problems with DESR also seem evident but have been far less studied in research on ADHD.

Acknowledging the place of EI–DESR in ADHD also contributes to our understanding of the high comorbidity of ADHD and ODD, and the social impairments associated with the disorder. Having ADHD-C virtually creates a borderline case of ODD in children because these EI symptoms constitute at least three to four of the eight symptoms on the diagnostic symptom list for ODD (DSM-5). I have attempted to clarify that EI–DESR is not just an associated feature of ADHD or a mere function of comorbidity, that it is inherent in the disorder itself. Making its presence explicit in our conceptualizations of ADHD and its diagnostic criteria can serve to better illustrate just why ADHD shows such a high rate of comorbidity with ODD and with reactive aggression. ADHD is surely not the sole or exclusive cause of ODD, but it does strongly predispose those with the disorder to at least the three to four emotion-based symptoms of ODD (its emotional component).

When combined with disrupted parenting and other social and situational factors, it is but a small step (one symptom) to developing the behavioral or social conflict component of ODD, and thereby crossing the diagnostic threshold into clinically diagnosable ODD.

Research on the family, teacher, and peer relations of individuals with ADHD suggests that the EI–DESR aspects of ADHD are major contributors to the problems experienced in these relationships. Therefore, as noted in Chapter 23 on social skills training, one major component of such intervention must target the emotional dysregulation that so often drives the social rejection of these children and adults, in addition to more traditional social behaviors such as sharing, cooperation, taking turns, and so forth.

Adding EI–DESR back into ADHD also helps one to understand the impact ADHD medications may have on this domain. If ADHD includes this EI component, then medical treatments that succeed in reducing ADHD symptoms should likely impact the emotional ones as well. Research on the medications for ADHD has long suggested just that; the reduction of ADHD symptoms by medications is also associated with a reduction in associated ODD symptoms; the two reductions are highly correlated with each other. This, as I have argued, likely occurs through the impact of medications on the "hot" EI–DESR executive network component of ADHD. But the different ADHD medication types may well achieve this effect on EI–DESR via different routes. The foregoing neuroimaging research implies that stimulants may act on emotion largely by dampening or even suppressing limbic system activity, an effect that does not seem to occur with the nonstimulants. Hence, high dosing with stimulants could lead to emotional blunting or constriction of normal affect. In contrast, nonstimulants such as atomoxetine may work by activating anterior cingulate and frontal executive networks, thus facilitating the executive management of emotions generated via the limbic system rather than suppressing them. Guanfacine XR (extended release) and related drugs may achieve their emotion-regulating properties through finer tuning of the $alpha_2$ receptors in the frontal cortex and therefore achieve clearer neuronal signaling that results in executive control over emotional states. All this is admittedly speculative, based on a very limited set of findings on the differences in effects of ADHD medications evident in functional neuroimaging studies. But for now it may help clinicians better understand the differing impacts of ADHD medication types on emotion regulation.

Future revisions to the diagnostic criteria for ADHD (i.e., DSM-6) would do well to list explicitly at least the EI symptoms evident in ADHD, most likely on the impulsivity dimension, in order to underscore the importance of this aspect of ADHD beyond just the inattention and HI symptoms now showcased in these criteria. Along with reducing the overemphasis on hyperactivity and verbal impulsiveness on this symptom dimension and explicitly adding impulsive behavior and decision making to it, the inclusion of symptoms of EI–DESR would serve to represent better our current conceptualization of the disorder. This would also encourage investigators to study this aspect of ADHD explicitly in their research on comorbidity, impairments, and treatment response.

Regardless of what the next DSM may include, clinicians need to be cognizant of the EI–DESR symptoms inherent in ADHD and evaluate them as much as they evaluate the traditional ADHD symptoms during their initial assessment of a patient for ADHD. Doing so can provide not only a clearer and more comprehensive account of the patient's current status but also a richer understanding of the basis for many of the impairments the patient may be experiencing that are partly or largely a consequence of this emotional component of ADHD. That ADHD includes such a component likewise needs to be explained by clinicians to their patients with ADHD and their families, so that they, too, gain such a better, more complete understanding of the condition and why patients may emote as they do. Interventions need to target this component of ADHD in addition to the ongoing efforts to develop both psychosocial and medical interventions that focus on the traditional symptom complex of ADHD and its related "cold" cognitive executive deficits, and how best to help family members cope with and assist the patient with ADHD in the effective management of their emotional dysregulation.

Yet none of this is to suggest that all of the emotional difficulties seen in a patient with ADHD can be written off to the emotional dysregulation component championed in this chapter. As subsequent chapters make plain, ADHD is certainly associated with an elevated risk for various mood and anxiety disorders. How, then, are we to distinguish which affective disturbances belong to ADHD and which require the search for a comorbid affective disorder to account for them? There is little direct research on the issue, but the findings to date suggest some tentative clinical guidelines for such differential diagnosis. First, con-

sider that the emotional disturbances in ADHD are just that—emotions, and not moods. Emotions are of short duration, are provoked, and often are situation-specific to the setting of the provocation. They are also largely rational, which is to say understandable, to others given that typical people would have had the same subjective reaction to the provocation. But the difference is that the typical person would have acted to suppress the voluntary aspects of the emotion over which they have some volitional control rather than express it publicly. They would then have engaged in the self-regulatory steps to down-regulate or otherwise alter the emotion to make it more compatible with the situation, others, and the person's longer-term goals and welfare. Recovery from such a provoked change in emotional state can be relatively quick compared to a change in mood, though perhaps not as easily as is seen in typical people given that those with ADHD have more difficulties down-regulating strong emotions using executive self-control. In contrast, a mood is just that—a long-duration change in emotional state that is often cross-situational and may arise without provocation or from trivial events that would often not have led others to react in this fashion. It can be described as capricious, as well as extreme. Consequently, it is not rational in the sense that other people would have the same emotional state under these circumstances over such an extended period of time and across settings. Admittedly, the dividing line between an emotion and a mood is not as crisp as is portrayed here. But the previous guidelines seem sensible at this time to guide clinicians in sorting out what affective symptoms of a patient with ADHD belong to that disorder and its EI–DESR problems, and what symptoms are likely to be attributable to a comorbid disorder.

In summary, it is time to return EI–DESR to its rightful place in the core or central components of ADHD.

KEY CLINICAL POINTS

- ✓ During the first 170 years of its medical history, ADHD and its precursor disorders were believed to involve deficits in emotional inhibition and self-regulation, along with the core problems with attention and HI behavior.
- ✓ Beginning in the 1960s, especially with DSM-II, the symptoms of EI and DESR were divorced from the core deficits of ADHD, and treated as merely associated problems that may arise in some cases.
- ✓ Compelling evidence now argues for the return of EI–DESR to the status of a core component of ADHD in its conceptualization and DSM diagnostic criteria. The argument is based on six lines of reasoning and evidence:
  1. EI–DESR has a long history of being a central feature of ADHD in its clinical conceptualization.
  2. Current neuropsychological theories of ADHD consider EI–DESR to be just such a central component.
  3. The neuroanatomical findings associated with ADHD would have to give rise to commensurate symptoms of EI–DESR.
  4. Ample evidence now exists that children and adults with ADHD are highly likely to manifest EI–DESR (low frustration tolerance, impatience, quickness to anger, and being easily excited to emotional reactions more generally).
  5. Returning EI-DESR to a central place in ADHD would more clearly show the basis for its high comorbidity with ODD and probably several related disorders.
  6. Promoting EI–DESR back to the status of a core component would also clarify one basis for the frequent social interaction problems and impairments in several other domains of major life activities (work, driving, marriage/cohabiting, and parenting) seen in ADHD.
- ✓ Understanding the role of EI–DESR in ADHD would assist with differential diagnosis and reduce misdiagnosing emotional problems in ADHD as entirely arising from comorbidity.
- ✓ ADHD medications appear to reduce the EI–DESR component of ADHD as much as they do traditional ADHD symptom dimensions, yet they may do so through different neural mechanisms and networks.
- ✓ Psychosocial interventions for ADHD should include programs targeted at helping patients with EI–DESR specifically rather than just traditional ADHD symptom dimensions.

CHAPTER 4

Developmental and Neuropsychological Deficits in Children with ADHD

Lisa L. Weyandt and Bergljot Gyda Gudmundsdottir

As discussed in Chapter 2, attention-deficit/hyperactivity disorder (ADHD) is characterized by developmentally inappropriate levels of inattention, impulsivity, and/or hyperactivity, and the degree to which these symptoms are manifested varies by presentation. In addition to deficits in these core areas, children with ADHD often have developmental and neuropsychologically related difficulties. Our purpose in this chapter is to discuss developmental and neuropsychological findings, and to address implications of this body of literature for clinicians. It is important to note that the material covered is a selective rather than a systematic or exhaustive review, and references are provided for additional information. The developmental areas we cover include general adaptive functioning, motor coordination, deficits associated with language and learning, self-regulation, and self-perceptions. Neuropsychological topics include findings from intellectual and executive function studies. Last, we review methodological limitations of the current literature and advance suggestions for future research.

DEVELOPMENTAL FUNCTIONING

In terms of developmental functioning, summarized in Table 4.1, ADHD is commonly conceptualized as a dynamic disorder as opposed to a static condition that unfolds across the lifespan (Halperin & Healey, 2011). It emerges in early childhood and in many cases continues into adulthood (see Chapter 9; also see Barkley, Fischer, Smallish, & Fletcher, 2006; Barkley, Murphy, & Fischer, 2008; Faraone, Biederman, & Mick, 2006; Kessler et al., 2006). Due to its dynamic nature, researchers and clinicians have argued that ADHD is best viewed within the context of a developmental trajectory, wherein many of the factors contributing to the diverse outcomes of individuals with ADHD may be identified (Halperin & Healey, 2011). Throughout the years, research has identified numerous developmental deficits associated with ADHD that can greatly impact the outcomes of individuals with the disorder (Barkley, 2006).

Adaptive Functioning

As children progress through the various stages of development into adolescence and adulthood, they are expected gradually to attain "adaptive skills," typically defined as the ability to function in everyday activities. Adaptive skills include, for example, independence and self-help skills, self-knowledge, motor skills, and social and communication skills (Sparrow, Balla, & Cicchetti, 1984). Given the functional impairment associated

TABLE 4.1. Summary of Developmental Functioning

Adaptive functioning

- Adaptive functioning is generally poorer in children with ADHD than in typically developing children.
- Deficits are common in the areas of daily living and social communication (e.g., organizing information, effective communication).
- Difficulties appear to be related to ADHD symptomatology and not limited to externalizing symptoms of ODD and CD.

Motor coordination

- A large percentage of children with ADHD exhibit some type of motor coordination problems.
- Impairments often appear in the motor skills domains of strength, visual–motor coordination, adjusting speed, and dexterity.
- Evidence suggests that ADHD inattentive or ADHD combined subtypes are more likely to display motor coordination difficulties compared to those with the ADHD hyperactive–impulsive subtype.
- Manual dexterity difficulties are often the most impaired domain of motor coordination (e.g., writing, drawing, and playing a musical instrument).
- Stimulant medication and physical therapy are often effective at improving motor deficits in children with ADHD.

Language ability

- Linguistic difficulties are prevalent in children with ADHD and may be identified as early as during the preschool years.
- Difficulties are often evident with receptive, expressive, and pragmatic language skills
- Linguistic deficits may cause difficulty comprehending instructions, making inferences about social context, and initiating, maintaining, and ending a conversation.
- Language ability may have an impact on the social functioning of children with ADHD.
- Social difficulties may further exacerbate the language deficits associated with ADHD.
- Subtypes of ADHD may be differentially associated with difficulties in different domains of language ability.

Learning difficulties

- Learning disabilities and academic underachievement are more common in children with ADHD than in the general population.
- Comorbidity rate of LDs and ADHD may be as high as 45%.
- Children with ADHD who do not meet diagnostic criteria for an LD often have some degree of learning difficulties.
- Common coexisting learning problems include lower academic achievement, use of special education services, grade retention, higher rates of high school dropout, and lower rates of postsecondary education.
- Evidence suggests behavior-based strategies are the most effective in addressing the academic difficulties of children with ADHD.

Self-perceptions

- Studies suggest that children with ADHD often display an inflated self-esteem.
- Internalization of speech may be an important component of self-regulation.
- Children with ADHD appear to demonstrate a different, potentially less-developed pattern of private speech than children without ADHD.

with ADHD (American Psychiatric Association, 2013) numerous investigations have explored the extent to which ADHD affects adaptive functioning. In general, studies have found that the adaptive skills of children with ADHD are poorer than those of their typically developing peers (Jarratt, Riccio, & Siekierski, 2005; Reynolds & Kamphaus, 2002; Stein, Szumowski, Blondis, & Roizen, 1995). Specifically, children with ADHD have been found to have difficulties in multiple areas of daily living and in social communication (Stein et al., 1995). Manifestations of such difficulties include deficiencies in organizing information and communicating it effectively, responding inappropriately to others, and excessive talking (Roizen, Blondis, Irwin, & Stein, 1994).

For instance, Stein and colleagues (1995) compared children with ADHD to those with a mild intellectual disability or pervasive developmental disorder and found that the discrepancy between intelligence and adaptive functioning was *greater* for children with ADHD in the areas of communication and daily living, even after they controlled for externalizing symptoms of oppositional defiant disorder (ODD) and conduct disorder (CD). With regard to the socialization domain of adaptive functioning, however, group differences disappeared after the authors accounted for symptoms of ODD and CD. In contrast, Clark, Prior, and Kinsella (2002) reported that in adolescents with ADHD, socialization was impaired not only in those with ADHD and ODD/CD combined, but also in those with ADHD without externalizing problems. The findings by Clark and colleagues corroborate results from an earlier longitudinal epidemiological study by Taylor, Chadwick, Heptinstall, and Danckaerts (1996) suggesting that adolescents both with and without ODD/CD experience difficulties with social adjustment. Furthermore, Clark and colleagues found that executive functions (EFs) significantly predicted adaptive functioning in the domains of communication and socialization, and compared to measures of verbal intelligence, EFs (see discussion of EFs as they relate to ADHD later in this chapter) were a stronger predictor of socialization skills. Stavro, Ettenhofer, and Nigg (2007) further explored the relationship between EFs and adaptive behavior, and found that symptoms of inattention accounted for more variance in adaptive functioning than hyperactive–impulsive symptoms. Although EF was initially found to be associated with adaptive functioning, the relationship disappeared after researchers controlled for ADHD symptoms. In addition, when adult participants retrospectively rated ADHD symptoms in childhood, the findings revealed that only inattention was related to EF or adaptive functioning. Stavro and colleagues concluded that EF may exert its effects on adaptive functioning through the behavioral path between inattention and adaptive functioning. Alternatively, ADHD symptoms can be viewed as a subset of and are highly correlated with EF behaviors in daily life, as detected by EF rating scales (Barkley, 2012a, 2013). In that case, controlling for ADHD symptoms would remove much of the variance in adaptive functioning owing to EF deficits. Recently, Ware and colleagues (2012) compared adaptive and EF functioning in children with ADHD and children exposed to prenatal alcohol, and found that both groups had adaptive behavior deficits. The adaptive behavior deficits in children with ADHD, however, were more general than those found in children with prenatal exposure to alcohol.

A number of other studies also found children with ADHD to have diminished overall adaptive functioning in comparison to normal or control groups of children (Barkley, Fischer, Edelbrock, & Smallish, 1990; Greene et al., 1996; Shelton et al., 1998; Ware et al., 2012). Collectively, these studies suggest that children with ADHD are more likely to display poorer adaptive functioning, especially in the areas of communication and socialization, than their same age peers. These findings remain robust even after researchers control for IQ (Stein et al., 1995). Furthermore, the disparity between cognitive functioning and adaptive skills appears to be greater for children with ADHD than for those with other developmental disabilities, suggesting that ADHD symptoms may have a specific detrimental effect on adaptive skills. Additionally, the greater the disparity between adaptive functioning and IQ, the more severe the ADHD, risk for comorbidity, and deficits in academic functioning (Shelton et al., 1998). Clinicians should therefore be especially attentive to possible adaptive behavior deficits when working with children with ADHD and include interventions to address these deficits in their treatment protocols.

Motor Coordination

One of the most prominent theories of ADHD, proposed by Barkley (1997, 2012b), stated that a primary impairment of ADHD involves diminished behavioral inhibition that leads to deficits in four domains: (1) nonverbal working memory, (2) self-regulation of

affect, motivation and arousal, (3) internalization of speech, and (4) reconstitution. Barkley (1997) further asserted that impairment in these four domains adversely affects motor control. Indeed, impaired motor control is a common co-occurring condition in ADHD, with studies suggesting that more than 50% of children with ADHD manifest some type of motor coordination deficit. In addition, research suggests that a large percentage of children with ADHD also meet criteria for developmental coordination disorder (DCD), perhaps up to 50% (Brossard-Racine, Shevell, Snider, Bélanger, & Majnemer, 2012; Watemberg, Waiserberg, Zuk, & Lerman-Sagie, 2007). Several studies have documented that even in the absence of DCD, children with ADHD demonstrate deficient motor coordination compared to their peers, although not all studies substantiate this finding (Brossard-Racine et al., 2012). In a review of 49 studies, Harvey and Reid (2003) concluded that many children with ADHD are at a risk for compromised motor skills, including strength, visual–motor coordination, speed, and dexterity; in many cases these impairments may be lifelong. Harvey and Reid also noted, however, that some children with ADHD may demonstrate excellent motor coordination and/or skills comparable to those of their peers. Interestingly, limited evidence indicates that those with inattentive or combined DSM-IV subtypes were more likely to display poor motor coordination than those of the hyperactive–impulsive subtype (Pitcher, Piek, & Hay, 2003; Watemberg et al., 2007).

Manual dexterity, including writing, drawing, and playing a musical instrument, is frequently cited as the most impaired domain of motor coordination in children with ADHD (Brossard-Racine et al., 2012; Flapper, Houwen, & Schoemaker, 2006; Pitcher et al., 2003). In addition, time perception, which frequently is impaired in individuals with ADHD, can affect motor coordination in various tasks, for example, when playing sports or driving (Barkley, Murphy, & Bush, 2001; Yang et al., 2007). For example, Chen and colleagues (2013) compared small groups of children with and without ADHD on a jump rope task and found that children with ADHD tended to have poorer hand–foot coordination, greater difficulty modifying their pace, and more trouble adjusting to the speed of the task than the comparison children.

Fliers and colleagues (2008) investigated whether the co-occurrence of ADHD and motor problems was comparable across age, ADHD DSM-IV subtype, and gender, using teacher and parent ratings of motor coordination skills of children and adolescents with and without ADHD. Results suggested that males and females were equally affected by motor coordination deficits, although females without ADHD were rated as having fewer motor problems than males without ADHD, resulting in a larger discrepancy between females with and without ADHD than between males with and without ADHD. Additionally, inattention was a stronger predictor of motor deficits than hyperactivity–impulsivity, and, as stated previously, this finding has been reported in other studies (e.g., Martin, Piek, & Hay, 2006). It is important to note, however, that some studies have also found that hyperactivity/impulsivity predicts motor skills (Fliers et al., 2008). For example, Piek, Pitcher, and Hay (1999) found that inattention was a better predictor of fine motor skills deficits, but there was also evidence to suggest that hyperactivity–impulsivity symptoms were a better predictor of gross motor skills. Although preliminary, findings suggest that stimulant medication (Bart, Daniel, Dan, Bar-Haim, 2013; Brossard-Racine et al., 2012; Flapper et al., 2006) and physical therapy (Watemberg et al., 2007) may ameliorate the motor coordination difficulties commonly found in ADHD.

In summary, studies suggest that the motor skills of children with ADHD are often poorer than those of their peers, and in many cases these children meet diagnostic criteria for DCD. Of course, variation exists, and some children with ADHD do not have motor coordination difficulties, or they may even have excellent motor coordination. The contribution of different DSM-5 subtypes or symptom dimensions of ADHD to motor deficits is unclear, although preliminary evidence suggests that the association between inattention, rather than hyperactivity–impulsivity, and motor difficulties is stronger. Clinicians should be aware of the co-occurrence of ADHD and motor coordination deficits, and consider this information when assessing children for ADHD and addressing treatment interventions. Last, preliminary evidence supports the possibility that stimulant medication and physical therapy may be helpful interventions for improving the motor skills of individuals with ADHD.

Language Ability

Language ability is one of the foundations for effective social communication and, overall, successful development and research have found that linguistic difficulties are prevalent in children with ADHD (Peterson et al.,

2013). For example, Tirosh and Cohen (1998) reported a 45% rate of language deficits among children in a community sample identified as having ADHD, using "nonconservative criteria" (p. 495). In a clinical sample of children with ADHD, Bruce, Thernlund, and Nettelbladt (2006) reported ratings indicating that compared to typically developing peers, 67% of participants had linguistic problems above the 90th percentile. Both receptive language (Bruce et al., 2006; McInnes, Humphries, Hogg-Johnson, & Tannock, 2003; Wassenberg et al., 2010) and expressive language (Humphries, Koltun, Malone, & Roberts, 1994; Kim & Kaiser, 2000) appear to be affected. "Receptive language" concerns the understanding of language or messages produced by others, whereas "expressive language" refers to the production of messages sent to others (Wicks-Nelson & Israel, 2009). In addition, findings reported by McInnes and colleagues (2003) suggest that children with ADHD *without* any apparent language impairment also demonstrate subtle listening comprehension deficits. Specifically, McInnes and colleagues found that despite having adequate language abilities, as measured by a standardized language test, the children demonstrated minor comprehension deficits while listening to spoken passages. For example, the children with ADHD had more difficulty comprehending instructions and making inferences from the passages, even when the researchers controlled for decoding and sentence formulation abilities, although they comprehended factual information as well as typically developing children. In another study, Staikova, Gomes, Tartter, McCabe, and Halperin (2013) examined "pragmatic" use of language in children with ADHD, which can be defined as the conversational use of language, including both verbal and nonverbal skills, and found that the children had a number of pragmatic language deficits. More importantly, these deficits were evident when researchers controlled for general language functioning, and they were observed in the areas of discourse management (initiating, maintaining, and ending a conversation), presupposition (i.e., theory of mind, assumptions about the social context of conversation), and narration. Additionally, Staikova and colleagues found that discourse management mediated the relationship between ADHD and social difficulties, suggesting that ADHD symptoms lead to difficulties with language communication, particularly conversation management, which in turn lead to social difficulties.

Language difficulties associated with ADHD may be detected as early as the preschool years. Specifically, Gremillion and Martel (in press) recently compared preschoolers with ADHD to those with comorbid ODD and to preschoolers with no disability and found that preschoolers with ADHD had significantly poorer expressive and pragmatic language compared to both typically developing children and children with ODD only. Symptoms of hyperactivity–impulsivity were found to contribute primarily to poor language skills, while symptoms of inattention were more strongly associated with weaker receptive and expressive vocabulary.

Collectively, the literature supports the notion that language difficulties often co-occur with ADHD, particularly in the areas of expressive and receptive language, and the pragmatic use of language. Although the language skills of many children with ADHD may be considered age-appropriate according to results of standardized tests, they may nevertheless have slight linguistic difficulties, such as with understanding instructions and making inferences. In addition, difficulties with the pragmatic use of language, such as conversation management, are likely to lead to social difficulties. This relationship is likely to be bidirectional, however, as social communication can significantly contribute to language proficiency (Gremillion & Martel, in press). These findings suggest that initial linguistic problems of children with ADHD can lead to social difficulties, which in turn can limit their opportunities for advancing their language skills, thereby compromising their social skills even further. Clinicians need to be aware of the different types of language difficulties that often beset children with ADHD and to consider this information during assessment and when designing interventions.

Learning Difficulties

It has been well established that language ability is strongly associated with reading ability (Catts, Fey, Tomblin, & Zhang, 2002; Snowling, Bishop, & Stothard, 2000). Not surprisingly, reading disabilities, as well as other types of learning disabilities, are more common in individuals with ADHD than in the general population (Sexton, Gelhorn, Bell, & Classi, 2012). In a recent review of 17 studies assessing the comorbidity of ADHD and learning disabilities (LDs), DuPaul, Gormley, and Laracy (2013) concluded that the comorbidity rate is as high as 45%, which is higher than previous estimates have indicated. DuPaul and colleagues noted, however, that changes to DSM-5 criteria for both

ADHD and LDs may affect these numbers, although it is unclear in which direction. In a population-based sample, Carroll, Maughan, Goodman, and Meltzer (2005) reported that 18.9% of children with ADHD had a comorbid reading disability, whereas Pastor and Reuben (2008) using a population-based sample found reading disability prevalence rates of 44% in children with ADHD. Mayes and Calhoun (2006a) examined the reading abilities of clinic-referred children with ADHD and reported that 33% scored significantly lower on a reading test than predictions based on their Full-Scale IQ. In a similar study investigating LDs in general (not focusing specifically on reading ability), Mayes, Calhoun, and Crowell (2000) found that 70% of clinic-referred children with ADHD had an LD in reading, spelling, writing, or math and that children with both ADHD and an LD had more severe learning problems than children with a learning disability only. Furthermore, the results suggested that many children with ADHD who did not meet diagnostic criteria for an LD had some degree of learning difficulties (Mayes et al., 2000). Conversely, in a prospective, longitudinal study, Washbrook, Propper, and Sayal (2013) found that preschool children with elevated symptoms of inattention and hyperactivity–impulsivity who did not meet diagnostic criteria for ADHD were still at a heightened risk for academic underachievement in adolescence. In a longitudinal study by Scholtens, Rydell, and Yang-Wallentin (2013), ADHD symptoms measured in grades 6, 11, and 12, were stable over time and negatively associated with *both* concurrent and future academic outcomes.

The totality of the findings in the voluminous literature on the overlap of ADHD with LDs documents the overall diminished academic functioning of individuals with ADHD (Weyandt, 2007). Studies have indeed shown that children with ADHD are more likely to demonstrate lower academic achievement, require special education services, experience grade retention, have higher rates of high school dropout, and lower rates of postsecondary education than their peers without ADHD (Chapters 6 and 12; also see Barkley, Fischer, Edelbrock, & Smallish, 1990; Mannuzza, Gittlman-Klein, Bessler, Malloy, & LaPadula, 1993). With regard to academic interventions for children with ADHD, DuPaul and Weyandt (2006) reviewed studies on school-based interventions for students with ADHD and concluded that there is substantial evidence for the effectiveness of behavior-based strategies, and potential support for peer-tutoring and certain recent social skills training strategies to enhance the academic outcomes of children with the disorder (see also Chapters 23 and 24). The implications of this body of work for clinicians are that many children with ADHD have comorbid learning difficulties and/or disabilities, and thorough assessments of both are required. In addition to interventions that target reducing ADHD symptomatology, clinicians should be sensitive to the unique educational needs of children with ADHD and particularly their comorbid LDs.

Self-Perception

Previously, it was generally believed that children with ADHD have low self-esteem due to the numerous challenges they face in everyday activities, and some studies have supported this notion (e.g., Dumas & Pelletier, 1999; Edbom, Lichtenstein, Granlund, & Larsson, 2006). In contrast, many other studies indicate that children with ADHD display an inflated self-esteem or a *positive illusory bias* in perceptions of their own competence, although the evidence regarding this issue has at times been inconclusive (Hoza, Pelham, Dobbs, Owens, & Pillow, 2002). Hoza and colleagues (2002) compared the self-perceptions of boys with ADHD and teacher ratings in academic, behavioral, and social domains, and found that the boys tended to overestimate their ability in all areas. Specifically, boys with ADHD with more externalizing behaviors overestimated their social and behavioral functioning, whereas boys with ADHD who demonstrated academic underachievement overestimated their academic competence in comparison to controls and other boys with ADHD who were functioning well academically. In addition, boys with ADHD and comorbid depressive symptoms had significantly lower ratings of self-worth than control boys except in the behavioral domain, where self-ratings were higher than those of controls. Hoza and colleagues speculated that divergent findings on self-perceptions in children with ADHD may in part stem from whether or not the effects of internalizing disorders, such as depression, on self-perceptions are taken into account. In a more recent study, Hoza and colleagues (2004) found further evidence for the positive illusory bias among children with ADHD who grossly overestimated their competence, particularly in areas where they were the most deficient, regardless of who was used as a comparison rater of competence (i.e., mother, father, or teacher). Both boys and girls overestimated their ability, although girls with and with-

out ADHD had less inflated perceptions compared to teacher ratings in the domains of behavior and physical appearance. It is not so much that children with ADHD view themselves as far more competent than others (grandiosity) as that they report themselves as being as competent as others when they are clearly deficient in that task or activity. Some theorists have speculated that the positive illusory bias serves a protective function, allowing children with ADHD to cope better with the difficulties they experience (Diener & Milich, 1997). Ohan and Johnston (2002), however, only found partial support for this hypothesis, suggesting that it holds true only for perceptions of social competence, as opposed to academic competence.

Internalization of Speech

Factors that may mediate self-regulation and promote problem solving have been explored, and several theorists have argued that the internalization of speech is an important factor in this process (Barkley, 1997; Berk & Landau, 1993; Corkum, Humphries, Mullane, & Theriault, 2008; Ostad & Sorensen, 2007; Vygotsky, 1978). Berk and Landau's (1993) observation that children with LD and ADHD symptoms actively used task-relevant private speech does not support previous ideas regarding a lack of private speech in children with learning difficulties. More recent studies have also corroborated such findings among children with ADHD (e.g., Kopecky, Chang, Klorman, Thatcher, & Borgstedt, 2005). However, Kopecky and colleagues noted that children with ADHD produced more private speech during failure than success than did comparison children. Similarly, in the study by Corkum and colleagues (2008), children with ADHD demonstrated a different pattern of private speech than comparison children in problem-solving and inhibition tasks. On the problem-solving tasks, children with ADHD displayed more task-irrelevant private speech, whereas on the inhibition task, they produced more task-relevant private speech, although their performance on the inhibition tasks was poorer than that of peers. Corkum and colleagues concluded that children with ADHD possess less developed private speech and self-regulation strategies than do children without ADHD, which leads to impaired self-regulation. What remains unclear, however, is whether private speech is a causal factor in the development of successful self-regulation or simply one of several indicators of self-regulation.

In summary, studies reveal that children with ADHD may have inaccurate and positively biased perceptions of self-competence, especially in areas in which they experience the most significant problems, although findings regarding this issue have been inconclusive. The internalization of speech has been proposed as a significant contributing factor to self-regulation, and indeed, children with ADHD demonstrate a different pattern of private speech during problem-solving tasks, although causal inferences regarding the impact of private speech on self-regulation are unwarranted at this time.

Conclusions and Clinical Implications of Developmental Findings

Many children with ADHD demonstrate developmental impairments in the domains of adaptive functioning, motor coordination, language skills, learning ability, and self-regulation of emotion (see Chapter 3), often meeting diagnostic criteria for a disorder in the area in question (e.g., DCD). The severity of ADHD symptoms is positively associated with such impairments, and evidence suggests that ADHD subtypes (or presentations, as in DSM-5) may be differentially associated with adaptive behavior deficits. (e.g., inattention has been more strongly associated with poor motor coordination than with hyperactivity–impulsivity). Research clearly indicates that developmental deficits can worsen the functional impairment of children with ADHD and subsequently lead to increased use of interventions and support services such as medication and individual therapy.

Despite substantial evidence of poorer adaptive functioning among individuals with ADHD compared to normal controls, adaptive skills are generally not an area targeted by ADHD assessment or intervention (Jarratt et al., 2005). Researchers, however, have called for a greater emphasis on addressing adaptive functioning (e.g., Roizen et al., 1994; Stein et al., 1995) when designing intervention programs for individuals with ADHD given that poor adaptive functioning is likely to exacerbate the functional impairment inherent in ADHD. Assessing adaptive functioning specifically may inform interventions and shed light on the strengths and weaknesses of individuals with ADHD. Similarly, motor coordination may be an important prognostic indicator that warrants the attention of clinicians and others working with children and adolescents with ADHD (Fliers et al., 2008). With regard

to ADHD and LDs in particular, evidence-based strategies that address *both* ADHD and LD symptoms should be implemented in school and home settings (DuPaul et al., 2013).

NEUROPSYCHOLOGICAL AND COGNITIVE FUNCTIONING

A summary of neuropsychological and cognitive functioning is presented in Table 4.2.

Intellectual Development

Over the years, authors have touted in books and more recently on blogs and websites that it is advantageous to have ADHD. Some have claimed that individuals with this disorder have more intelligence than their nondisabled peers, or have suggested that children with ADHD are more creative and gifted than their peers (e.g., Hartmann, 1997). Research, however, presents a different picture. Numerous studies have indicated that children with ADHD often obtain significantly lower IQs than children without the disorder. For example, McConaughy, Ivanova, Antshel, and Eiraldi (2009) evaluated over 177 children ages 6–11 using the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV) and found that those with ADHD performed significantly lower on the Full-Scale IQ and composite scores than children without ADHD. The difference on standardized intelligence tests is often substantial, with an average difference of approximately 9 points (Barkley, Karlsson, & Pollard, 1985; Faraone et al., 1993; Fischer, Barkley, Fletcher, & Smallish, 1990; Frazier, Demaree, & Youngstrom, 2004; Mariani & Barkley, 1997; McGee, Williams, Moffitt, & Anderson, 1989; Moffitt, 1990; Prior, Leonard, & Wood, 1983; Stewart, Pitts, Craig, & Dieruf, 1966; Tarver-Behring, Barkley, & Karlsson, 1985; Werry, Elkind, & Reeves, 1987). It is important to note, however, that although children with ADHD obtained lower IQ scores than comparison students in a variety of studies, their IQs were generally within the average range and not substantially below average. These findings support the view that, as a group, individuals with ADHD are *not* more intelligent than the general population and often score lower on standardized IQ tests than their nondisabled peers. The bottom line is that levels of intelligence vary among individuals with ADHD just as they do in the general population.

The reasons for the lower levels of intellectual performance often found in children with ADHD relative to their nondisabled peers (and even their siblings) are unclear. Some have suggested that coexisting LDs may account for the difference (Bohline, 1985), or familial factors may be involved (Biederman, Fried, Petty, Mahoney, & Faraone, 2012), whereas others have attempted to determine the influence of attention problems and EF deficits on IQ scores. For example, during administration of the WISC-III, children with ADHD displayed significantly higher levels of aberrant test behaviors, including inattention and externalizing behaviors (McConaughy et al., 2009). To help determine whether ADHD symptoms were related to IQ performance, Sharp and colleagues (2003) studied a sample of 25 monozygotic twins, 10 pairs of whom were discordant for ADHD. Contrary to expectations, the Full-Scale IQ of the discordant pairs was similar, suggesting that attention deficits do not substantially impair IQ test performance. Other studies have also found weak to poor correlations between severity of inattention and impulsivity–hyperactivity symptoms and IQ scores (e.g., Chae, 1999; Naglieri, Goldstein, Delauder, & Schwebach, 2005). The literature is mixed, however, as earlier studies did report a relationship between impulsive–hyperactive behavior and lower IQ scores (Halperin & Gittelman, 1982; Hinshaw, 1992; McGee, Williams, & Feehan, 1992; Sonuga-Barke, Lamparelli, Stevenson, Thompson, & Henry, 1994; Werry et al., 1987). More recently, researchers at the University of Copenhagen reviewed the literature and concluded that the mean influence of attention deficits and ADHD on IQ amounts to 2–5 IQ points (Jepsen, Fagerlund, & Mortensen, 2009). Interestingly, these findings are similar to those found in the general population when ADHD symptoms, not the disorder, are correlated with IQ, suggesting that symptoms of inattention and impulsivity–hyperactivity may affect intellectual test performance in all children, not simply those with ADHD (Goodman, Simonoff, & Stevenson, 1995).

It is also important to note that children with ADHD as a group do not typically perform *better* than their same-age peers on IQ tests (i.e., in the gifted range). An IQ of 120 or higher on the Wechsler scales is considered to be superior and is sometimes used as a cutoff score for giftedness. Operationalization of the construct of giftedness varies, however, and IQ is often only one of many criteria used to determine eligibility for gifted programs. As mentioned previously, many studies have indicated that the performance of children

TABLE 4.2. Summary of Cognitive and Neuropsychological Functioning

Intellectual functioning

- Children with ADHD often perform lower on IQ tests than children without the disorder, and the difference can be as much as 9 points.
- Children with ADHD, however, generally have IQ scores in the average range and not substantially below average.
- Levels of intelligence vary among individuals with ADHD just as they do in the general population.
- Many children with ADHD obtain lower scores on IQ tests; however, some may score above average, below average, or in the gifted range of intelligence.
- Symptoms of inattention and hyperactivity–impulsivity may affect cognitive test performance in all children, not just those with ADHD.
- Profile analysis, although common practice among school psychologists, is controversial and largely criticized by psychometric theory.
- The FDI and other forms of profile analysis of IQ are neither reliable nor valid methods for diagnosing ADHD.

Executive function

- EF encompasses a variety of cognitive abilities that allow for impulse control, strategic planning, cognitive flexibility, and goal-directed behavior.
- EF deficits are characteristic of many, but not all, individuals with ADHD and are present in other childhood disorders.
- Evidence suggests that children with EF deficits have lower academic achievement.
- EF deficits are likely to emerge early in life in children with ADHD, and the impairments tend to persist into adolescence and young adulthood.
- EF deficits are routinely more common and more severe on rating scales of EF than on psychometric EF tests.

Planning

- The EF construct of planning has been conceived in a number of ways, including visual–spatial and strategic planning.
- Deficits in planning are characteristic of some, but not all, children with ADHD.
- Planning deficits are also found in children with other types of clinical disorders and are neither unique to nor diagnostic of ADHD.

Inhibition

- The literature indicates that a variety of EF tasks have been used to measure behavioral inhibition, and the psychometric properties of these tasks vary.
- Many, but not all, children with ADHD perform more poorly on inhibition tasks than do children without the disorder.
- Inhibition tasks do not differentiate reliably between different subtypes of ADHD, although findings are inconclusive, and they are not diagnostic of ADHD.

Working memory

- Many studies have found that children with ADHD perform more poorly than their nondisabled peers on working memory tasks that require memory for digits forward and backward.
- Differences between children with and without ADHD in working memory are even larger when tasks are complex.
- Verbal working memory problems are not unique to ADHD; children with other disorders show similar difficulties. Some studies suggest that nonverbal working memory of children with ADHD may be substantially more impaired than verbal working memory.
- Individuals with ADHD may have deficient time perception (e.g., estimating passage of time processing time, and time discrimination).
- Findings relative to time perception in individuals with ADHD have been mixed, however, and studies are often characterized by methodological problems.

with ADHD is often lower than that of comparison children on IQ tests. However, this is not to say that some children with ADHD are not also gifted (sometimes referred to as "twice exceptional") (Budding & Chidekel, 2012). In fact, Antshel and colleagues (2007) studied 49 children with ADHD and an IQ of 120 or higher and 92 children without ADHD and an IQ of 120 or higher. Results indicated that the performance of children with ADHD who were "gifted" in terms of intelligence was similar on behavioral and academic measures to that of children of average intelligence. For example, both groups repeated more grades, required more academic supports, and were rated more poorly on parent rating scales compared to children without ADHD. Grizenko, Zhang, Polotskaia, and Joober (2012) found that children with Full-Scale IQs of 120 or higher had lower severity of ADHD symptoms compared to those with average (80–119) or borderline (70–79) IQs. Interestingly, Grizenko and colleagues found that all three groups of children responded equally to stimulant medication, with improvements on parent, teacher, and laboratory ratings.

In addition to composite score differences, researchers have explored whether children with ADHD perform differently than controls on specific subtests. This practice, known as "profile analysis," is controversial and largely criticized by psychometric theory (McDermott, Fantuzzo, & Glutting, 1990), yet it remains a common practice among clinicians, including school psychologists, clinical psychologists, and neuropsychologists (Pfeiffer, Reddy, Kletzel, Schmelzler, & Boyer, 2000). In 1980 and again in 1994, Kaufman suggested that the Freedom from Distractibility Factor (FFD) on the WISC-III, which comprised Coding, Arithmetic and Digit Span subtests and later was known as the Freedom from Distractibility Index (FDI) on the WISC-III, which comprised Arithmetic and Digit Span subtest scores, reflected attention problems. Subsequently, clinicians used the FDI as a diagnostic indicator for ADHD and researchers continue to explore its diagnostic utility. Collectively, these studies indicate that most children with ADHD do not show selective deficits on the FDI. For example, Egeland Sundberg, Andreassen, and Stensli (2006) studied a group of Norwegian children, with and without ADHD, and found no FDI difference between the groups. Anastopoulos, Spisto, and Maher (1994) reported similar findings with the WISC-III, as have others. It is important to note that lower FDI scores among children with ADHD are not unique to these children; in fact, nondisabled children and/or children with other disorders may perform poorly on the FDI. Likewise, as stated previously, many children with ADHD do not perform poorly on the FDI.

Additional IQ profiles have been studied and include comparisons using Processing Speed, Working Memory, Perceptual Organization, and Perceptual Reasoning Indices, as well as composite scores. Findings have been inconsistent across studies, with some reporting differences between children with and without ADHD, and others reporting no difference. For example, Ek, Westerlund, and Fernell (2013) compared 198 children classified as meeting full ADHD criteria and those who did not meet the criteria, and found that both groups scored higher on the General Cognitive Index than on Working Memory and Processing Speed. The groups' similar performance on the FDI is further evidence that the FDI is not a reliable indicator of ADHD. Alternatively, Mayes and Calhoun (2006b) compared the performance of children on the WISC-III and WISC-IV, and found that 100% of the children with ADHD in the sample scored lowest on the WISC-IV Working Memory Index or the Processing Speed Index. In 2004, Mayes and Calhoun reported that children with ADHD had lower Coding scores compared to children with mood disorders or brain injuries and that the "low FDI profile was two times more common in ADHD than other diagnoses" (p. 563). A score that is lower but still within the average range is not necessarily clinically meaningful, and certainly it is not diagnostic. The implication for clinicians from this body of work is that the FDI and other forms of profile analysis of IQ tests are neither reliable nor valid indicators for ADHD, and no configuration of subtests is diagnostic or specific to ADHD. Rather, clinicians should rely on a multimethod assessment approach involving objective, empirically supported techniques, as discussed in subsequent chapters.

Executive Functioning

Beyond intellectual functioning, a plethora of neuropsychological studies has been conducted with children with ADHD. These studies have included general neuropsychological tests batteries (e.g., Halstead–Reitan Battery, Luria Nebraska Neuropsychological Battery) and individual neuropsychological tasks. With regard to test batteries, Rajendran and colleagues (2013) recently explored whether severity of ADHD symptoms was associated with changes in neuropsychological

functioning in a group of preschoolers followed longitudinally using the Developmental Neuropsychological Assessment battery (NEPSY; Korkman, Kirk, & Kemp, 1998). Results indicated that baseline neuropsychological functioning was *not* associated with the slope of change of severity of ADHD symptoms. Similarly, Schaughency and colleagues (1989) failed to find support for the hypothesis that ADHD is associated with neuropsychological dysfunction on the Luria–Nebraska Neuropsychological Battery (Children's Revision). These findings, as well as others, led Gordon, Barkley, and Lovett (2006) to conclude that "in a review of the literature, we can establish no basis for suggesting routine administration of neuropsychological batteries within an ADHD evaluation" (p. 374). The take-away message for clinicians is that the use of neuropsychological test batteries with children for the purpose of an ADHD evaluation and diagnosis is unwarranted. Neuropsychological test batteries may be useful, of course, when a child has a suspected or known neurological history, or a more complicated medical history that may impact neuropsychological functioning.

Separate from test batteries, the performance of groups of children with ADHD on individual neuropsychological tasks has been studied extensively. Tasks that have received particular attention include those that measure verbal working memory, nonverbal working memory, self-regulation and inhibition, planning, perceptual motor speed, reaction time, perseveration, and sustained attention. Collectively, these cognitive processes are known as EFs. EF is a complex construct that encompasses a variety of cognitive abilities that allow for impulse control, strategic planning, cognitive flexibility, and goal-directed behavior (Barkley, 2012b). Approximately 25 years ago Welsh and Pennington (1988) defined EF as the ability to maintain an appropriate problem-solving set for attainment of future goals that may involve one or more of the following: "(1) an intention to inhibit a response or defer it to a later more appropriate time; (2) a strategic plan of action sequences; and (3) a mental representation of the task, including the relevant stimulus information encoded into memory and the desired future goal-state" (pp. 201–202).

The study of EFs and ADHD originated from research with primates that had undergone lesions to the frontal regions and neuropsychological studies of adults who sustained frontal lobe damage. In both primates and humans, injury to the frontal lobes was associated with deficits in planning ability, impulse control, and behavioral inhibition (Blau, 1936; Luria, 1966, 1972). Levin (1938) was among the first to note the striking similarity of these deficits and the symptoms associated with hyperactive children. Since that time, various perspectives concerning the role of EFs in ADHD have emerged. For example, Barkley (1997, 2012b), who perhaps has advanced the most comprehensive theory of ADHD to date, proposed that EFs are an integral component of a unifying theory of ADHD that stems from underlying deficits in behavioral inhibition and, more recently, working memory (Barkley, 2012b). Others (e.g., Brown, 2008) have also suggested that rather than being a behavioral disorder, due to the developmental impairment of EFs, ADHD is a cognitive disorder. Weyandt (2005, 2009; Weyandt et al., 2013) has emphasized that although EF deficits are characteristic of many individuals with ADHD, they are not characteristic of many if not most individuals with ADHD (Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005), at least as assessed by psychometric tests, and are present in other childhood disorders. This has led some reviewers to question the role of EF in ADHD (Weyandt, 2005, 2009) and others to conclude that in most cases ADHD is not a disorder of EF (Boonstra, Oosterlaan, Sergeant, & Buitelaar, 2005; Jonsdottir, Bouma, Sergeant, & Scherder, 2006; Marchetta, Hurks, Krabbendam, & Jolles, 2008; Nigg, Willcutt, Doyle, & Sonuga-Barke, 2005; Willcutt, et al., 2005). The veracity of this conclusion, however, is based on the premise that psychometric tests are the most valid measure for evaluating EF.

In contrast, on rating scales of EF, the vast majority of children with ADHD, children with ADHD followed to adulthood, and adults with ADHD are impaired across all dimensions typically captured by these scales (Barkley, 2012a, 2012b; Barkley & Fischer, 2011; Barkley & Murphy, 2010, 2011; Mahone & Hoffman, 2007; Reddy, Hale, & Brodzinsky, 2011; Thorell, Eninger, Brocki, & Bohlin, 2010; Weyandt et al., in press). Surprisingly, a meta-analysis of numerous studies of the issue found that EF tests and EF ratings do not correlate significantly with each other and therefore cannot be viewed as evaluating the same construct (Toplak, West, & Stanovich, 2013). The results of these studies typically reveal that any single EF task shares very little (0–10%) of its variance with EF ratings. Furthermore, the relationships among these tasks are frequently not statistically significant. Even the best

combination of EF tests shares approximately 12–20% of the variance with EF ratings or observations as reflected in these studies. If IQ is statistically removed from the results, the few significant relationships found in studies between EF tests and EF ratings often become nonsignificant (Mahone et al., 2002). Based on empirical evidence, Barkley (2012a, 2012b; Barkley & Fischer, 2011; Barkley & Murphy, 2011) has argued that EF rating scales are likely more valid indicators of EF because they are substantially more predictive of adaptive functioning and domains of impairment in daily life than are traditional EF tasks. Therefore, inferences and conclusions about the relationship between EF and ADHD will vary markedly depending on the types of methods used to evaluate EF.

The study of EFs in ADHD is critical because evidence suggests that children with EF deficits have lower achievement and are more likely to repeat a grade (Biederman et al., 2004). They are also at risk for various impairments in major life activities (Barkley & Fischer, 2011). Developmentally, research suggests that children with ADHD may demonstrate EF difficulties early in life. For example, Arnett, MacDonald, and Pennington (2013) reported that third-grade children with high versus low ADHD symptomology could be distinguished at age 15 months using behavioral and cognitive measures. Ghassabian and colleagues (2013) found an association between a smaller corpus callosum in infancy and impaired EF performance at age 4. Hutchinson, Mathias, and Banich (2008) also studied morphology of the corpus callosum and reported a relationship with ADHD in children and adolescents. Studies also suggest that EF problems in preschool may be predictive of EF deficits and ADHD in later childhood (Berlin, Bohlin, & Rydell, 2003; Friedman et al., 2007). With regard to long-term outcome, Fischer, Barkley, Smallish, and Fletcher (2005) found that children with ADHD continued to display EF difficulties into young adulthood. Biederman and colleagues (2007) reported that the majority (69%) of males with ADHD participating in a 7-year follow-up study maintained EF deficits into adulthood. Others (e.g., Hinshaw, Carte, Fan, Jassy, & Owens, 2007; Rinsky & Hinshaw, 2011) have conducted longitudinal studies of children with ADHD into adolescence and adulthood and have reported similar findings. Sciberras and colleagues (in press) have launched a community-based longitudinal study in Australia to study EFs (and other outcomes) of children with ADHD compared to those without the disorder. Collectively, these findings suggest that EF deficits are likely to emerge early in life in children with ADHD, and the impairments tend to persist into adolescence and young adulthood.

Although it is beyond the scope of this chapter to review the extensive literature concerning EF deficits and ADHD, core findings in the areas of planning, inhibition, and working memory are discussed. For more extensive discussions, readers should see the various meta-analyses of studies using EF tests with ADHD (Boonstra et al., 2005; Frazier et al., 2004; Willcutt et al., 2005).

Planning

The EF construct of planning has been conceived in a number of ways including visual–spatial and strategic planning. Although a variety of neuropsychological instruments has been used to assess planning, the Tower of London (TOL) test and its variants (e.g., Tower of Hanoi) are often used in the literature. In addition to the TOL, the Rey–Osterrieth Complex Figure/or Rey Complex Figure Test (ROCF/RCFT), and Trail Making tests are the most commonly used planning tasks reported in the literature according to a recent review of 141 studies employing EF tasks (Weyandt et al., 2013). In general, the findings across studies that compare planning task performance of children with and without ADHD are inconsistent, with some studies reporting poorer performance on these tasks in children with ADHD, while others have not found group differences. In 2005, Willcutt and colleagues conducted a meta-analysis of 83 EF studies and found that the majority of studies (59% of 27 studies) reported significant group differences on measures of planning. The most consistent differences were found with Tower of Hanoi and Porteus Maze tests rather than the TOL or ROCF. Similarly, Weyandt and colleagues (2013) also reported between-group differences among children with and without ADHD on planning tasks. However, they also found that children with other clinical disorders performed more poorly than control children on EF tasks. Although many studies do not differentiate between ADHD subtypes, Gau and Chiang (2013) recently found that children with ADHD combined subtype and ADHD inattentive subtype demonstrated poorer visual–spatial planning performance, as measured by the Stockings of Cambridge subtest of the Cambridge Neuropsychological Test Automated Battery, com-

pared to children with ADHD hyperactive–impulsive subtype and children without ADHD. Dolan and Lennox (2013) compared performance on the Stockings of Cambridge planning task in adolescents with comorbid conduct disorder (CD) and ADHD. Results revealed that children with ADHD performed more poorly on the planning task compared to controls and the CD-only group. In contrast, Skogli, Egeland, Andersen, Hovik, and Øie (2014) compared children with all three subtypes of ADHD to children without the disorder on a number of EF tasks and found no difference between groups in planning task performance.

Additional studies have used a variety of planning tasks, and the reader is referred to meta-analytic studies for additional information. It is important to remember, as noted earlier, that although meta-analytic studies and review studies have found group differences between children with and without ADHD, these differences are not found in all studies or in most cases of ADHD. In fact, nearly 30% of the studies reviewed by Willcutt and colleagues (2005) did not report significant differences between groups and, of those that did report differences, the effect sizes were not large. Similarly, Weyandt and colleagues (2013) found that planning task sensitivity to group differences ranged from 4% (TOL and variants) to 36% (Trail Making Test and variants). Collectively, these findings indicate that deficits in planning, at least as psychometrically assessed, are characteristic of some but not all children with ADHD. On rating scales of EF, in contrast, planning difficulties are nearly ubiquitous in children with ADHD (Barkley, 2012a) as well as adults (Barkley, 2011; Barkley & Murphy, 2010). Findings suggest that planning deficits are also found in children with other types of clinical disorders and are not unique to ADHD (Barkley, 2012a; Salcedo-Marin, Moreno-Grandos, Ruiz-Veguilla & Ferrin, 2013; Weyandt et al., 2013). The implication for clinicians is that planning tasks are useful in differentiating between children with and without planning difficulties, and many children with ADHD do exhibit planning deficits; however, these tasks are not diagnostic of the disorder.

Inhibition

Barkley (2006, p. 301) defined the construct of "behavioral inhibition" as (1) inhibiting the initial prepotent response to an event, (2) stopping an ongoing response or response pattern, thereby permitting a delay in the decision to respond or to continue responding, and (3) protecting this period of delay and the self-directed responses that occur within it from disruption by competing events and responses (interference control). Similarly, others, such as Nigg (2005), have argued that inhibition is a multidimensional construct and should be assessed accordingly. Over the years, a significant number of studies have reported differences in EF inhibition tasks between groups of children with and without ADHD (e.g., Barkley, Grodzinsky, & DuPaul, 1992; Ikeda, Okuzumi, & Kokubun, 2013; Metin et al., 2013; Pineda, Ardila, Rosselli, Cadavid, Mancheno, & Mejia, 1998; Thissen et al., 2013; Weyandt & Willis, 1994). It is important to note that a variety of EF tasks designed to measure behavioral inhibition have been used in the literature, and the psychometric properties of these tasks vary as well. In a recent review, Weyandt and colleagues (2013) found the most commonly used executive function tasks to assess inhibition included the Stroop Color–Word Test (and variants), the Wisconsin Card Sorting Test, the continuous-performance test, and the go/no-go task. Results revealed that these tasks varied in their sensitivity to group differences, and *all* of the tasks were better able to differentiate between children with and without ADHD compared to children with other clinical disorders (e.g., anxiety, depression). Research by Corbett and Constantine (2006) also indicated that inhibition deficits are found not only between children with and without ADHD but also in other clinical groups. Specifically, their findings revealed that children with ADHD performed poorly on an inhibition task (integrated visual and auditory (IVA) continuous-performance test; Sandford & Turner, 2000); however, children with autism performed even more poorly than children with ADHD on this task. Similarly, Schoemaker and colleagues (2012) found that preschool children with ADHD performed more poorly on inhibition measures (e.g., the go/no-go task) than children without the disorder; however, children with disruptive behavior disorders also showed inhibition deficits, comparable to those of children with ADHD. Interestingly, Skogli and colleagues (2014) in Norway recently reported that although they found differences between children with and without ADHD on a variety of EF measures, including inhibition measures, the tasks did not differentiate between children with different subtypes of ADHD. This finding was in contrast to studies that proposed distinctly different underlying pathologies for the DSM-IV subtypes of ADHD based on inhibitory function (e.g., Adams, Derefinko, Milich, & Fillmore, 2008; Randall, Brocki,

& Kerns, 2009). In 2005, Van Mourik, Oosterlaan, and Sergeant conducted a meta-analysis of 17 studies using the Stroop Color–Word Test, and concluded that "the results obtained with the Stroop Colour and Word Task do not provide strong evidence for a core deficit in interference control in AD/HD" (p. 162). The authors acknowledged, however, that the task itself might not be a valid measure of an inhibition deficit. In contrast, when EF rating scales contain subscales assessing inhibition, the vast majority of children, and perhaps young adults, with ADHD are impaired (Barkley, 2012a; Mahone & Hoffman, 2007; Reddy et al., 2011; Thorell et al., 2010; Weyandt et al., 2013). Theoretically, these findings are not surprising because children with ADHD are chosen to participate in research in part due to significantly elevated symptoms of hyperactivity–impulsivity, which index problems with behavioral inhibition.

What we can conclude from this body of work is that many, but not all, children with ADHD perform more poorly on psychometric or behavioral inhibition tasks than do children without the disorder. EF deficits in behavioral inhibition are not unique to ADHD, however; children with other types of clinical disorders have been found to perform poorly on these tasks. The clinical relevance is that although these tasks may be useful in elucidating the types of EF deficits a particular child may have, the tasks are not diagnostic and should be used as part of a larger assessment protocol. Moreover, recent findings suggest that different conclusions about the relationship between EF and ADHD may be reached if EF rating scales are employed along with traditional EF tasks.

Working Memory

"Working memory" has been defined by Becker and Morris (1999) as "a system of interacting components that maintain newly acquired and reactivated stored information, both verbal and nonverbal, and make it available for further information processing" (p. 1). Working memory has been studied rather extensively in children with ADHD. With regard to nonverbal working memory, Barkley (2006) subdivided nonverbal working memory into visual–spatial memory, sequential working memory, and sense of time. Visual–spatial memory tasks typically involve memory for location of designs or patterns of designs. Relative to verbal working memory, relatively few studies of nonverbal working memory have been conducted. Earlier studies (e.g., Douglas & Benezra, 1990; Mariani & Barkley, 1997; Reader, Harris, Schuerholz, & Denckla, 1994; Weyandt & Willis, 1994) produced conflicting results, with some, but not others, reporting visual–spatial working memory deficits in children with ADHD. Frazier and colleagues (2004) conducted a meta-analysis of six studies and did not find evidence of nonverbal working memory deficits in children with ADHD relative to control children. More recently, Martinussen and Tannock (2006) explored nonverbal working memory performance of children with ADHD compared to (1) children with ADHD and language disorder, (2) children with language disorders, and (3) control children. Results revealed that children with ADHD without comorbid language disorders exhibited deficits in visual–spatial storage and verbal and visual–spatial functions that were independent of comorbid psychiatric disorders. Children with language disorders, regardless of comorbidity with ADHD, exhibited impairments in both verbal and spatial storage. Symptoms of inattention, but not symptoms of hyperactivity–impulsivity, predicted performance on verbal and visual–spatial measures independent of age, verbal cognitive ability, and reading and language performance. Consistent with these findings were results by Gau and Chiang (2013), who found that inattention symptoms during early childhood (ages 6–8) were associated with impairments in nonverbal spatial working memory later in development. However, Thissen and colleagues (2013) recently reported that EF deficits, including nonverbal working memory, found in childhood were no longer evident during adolescence. In contrast, laboratory studies using very sensitive tasks of nonverbal and verbal working memory on repeated occasions do find that children with ADHD have substantial deficits in this domain and that the effect size (group difference) is nearly double that seen in the domain of verbal working memory and dramatically impaired relative to control children (Rapport et al., 2008), and that working memory deficits may adversely affect the social functioning of children with ADHD (Kofler et al., 2011). Thus, whether nonverbal working memory is impaired in children with ADHD is partly task- or test-related. Interestingly, preliminary findings suggest that stimulant medication may improve nonverbal working memory in children with ADHD (Shang & Gau, 2012) and alterations of the dopamine transporter gene (*DAT1*) may be associated with deficits in nonverbal working memory in children with ADHD (Shang & Gau, 2014).

Studies of verbal working memory in children with ADHD are plentiful and typically involve memory for verbally presented information (e.g., digits) and mental computation. Verbal working memory purportedly plays a critical role in reading and math achievement (Swanson, Jerman, & Zheng, 2008), and others have suggested that verbal working memory underlies more complex EFs (Rapport, Chung, Shore, & Isaacs, 2001). A number of studies indicate that children with ADHD perform more poorly than their nondisabled peers on tasks that require memory for digits forward and backward (Asberg, Kopp, & Gillberg, in press; Frazier et al., 2004; Rapport et al., 2008). In a recent longitudinal study of children with ADHD, Tillman, Brocki, Sorensen, and Lundervold (in press) found that deficits in working memory (for digits) during adolescence was predicted by inhibition deficits earlier in childhood. Differences between children with and without ADHD in working memory are even larger when tasks require more complex information and when this information must be held for longer periods of time (Seidman, Biederman, Faraone, Weber, & Oullette, 1997). Similar to other types of EF difficulties, however, research suggests that verbal working memory problems are not unique to ADHD. For example, Rhodes, Park, Seth, and Coghill (2012) recently reported that children with oppositional defiant disorder (ODD) and children with ADHD and comorbid ODD performed poorly on verbal working memory tasks; however, children with ADHD alone did not show impairment (all three groups performed poorly on visual–spatial working memory). Skogan and colleagues (in press) reported similar working memory findings in preschoolers with ADHD and ODD relative to preschoolers without these disorders. In addition, Willcutt and colleagues (2013) reported that children with reading disability and those with math disability both demonstrated weaknesses in working memory. What can be concluded from these studies is that children with ADHD often have difficulties with verbal working memory; however, children with other disorders often show similar deficits.

Sense of Time

With regard to sense of time, a substantial number of studies indicate that individuals with ADHD have alterations in time perception, for example, estimating passage of time, processing time, and time discrimination (Plummer & Humphrey, 2009; Smith et al., 2013; Walg, Oepen, & Prior, in press; Wilson, Heinrichs-Graham, White, Knott, & Wetzel, 2013). As Barkley (2006) noted, sense of time involves a number of dimensions, including time perception, motor timing, time estimation, time production–reproduction, and use of time in natural settings. Findings across these dimensions have been mixed, and studies are often characterized by methodological problems. Nevertheless, problems with time sense have been postulated to underlie the impulsivity difficulties characteristic of ADHD (e.g., Barkley, Koplowitz, Anderson, & McMurray, 1997; West et al., 2000). Factors that likely contribute to these, albeit inconsistent, alterations in time include impulsivity, difficulty sustaining attention, distractors, and perhaps, as more recently suggested, reduced activation in specific brain regions (anterior cingulate, prefrontal cortices, habenula, cerebellum) may underlie time-related deficits sometimes found in ADHD (Lee & Goto, 2013; Weyandt, 2005; Wilson et al., 2013). Perhaps most troublesome to parents and educators is the difficulty children with ADHD often have in completing tasks on time, as well as planning and organizational difficulties (Langberg, Dvorsky & Evans, 2013).

Likewise, studies using rating EF scales that include subscales related to time sense and time management find robust differences between ADHD groups and control children. Research has consistently found that the vast majority of children with ADHD, those followed to adulthood, and adults with ADHD fall in the impaired range on such scales (Barkley, 2012a; Barkley & Fischer, 2011; Barkley & Murphy, 2010, 2011; Barkley et al., 1997; Houghton, Durkin, Ang, Taylor, & Brandtman, 2011).

METHODOLOGICAL CONSIDERATIONS AND CONCLUSION

Several methodological issues should be considered relative to findings on developmental and neuropsychological deficits associated with ADHD. Many of the studies rely on small samples, and effect sizes, although rarely reported, are often small. This combination of small sample and effect sizes leads to low statistical power and reduced ability to detect differences that might exist between children with and without ADHD. Subtype information is also infrequently reported, and heterogeneity of symptoms may obfuscate differences. However, DSM-5 has eliminated the subtypes of

ADHD, and this may no longer be much of an issue. Also researchers are now looking more closely at sluggish cognitive tempo, a second attention disorder often lumped in with the old ADHD inattentive type, as the likely reason why ADHD inattentive types were sometimes noted to differ on various psychological tests (see Chapter 17). Demographic variables also likely play a role in the inconsistencies across studies. For example, Thissen and colleagues (2013) reported that age is an important moderator in the relationship between EFs and ADHD. Additionally, different criteria are used across studies to define a deficit (e.g., studies assessing language/learning difficulties) and can make overall conclusions or generalizations difficult to achieve. This issue is particularly salient regarding the definition of LDs, language disabilities, and EFs.

Perhaps a more serious methodological problem concerns the questionable psychometric properties of the EF tasks employed across studies. For example, tasks are referred to in the literature as "planning," "inhibition," or working memory tests; however, given the nature of the tasks, it is unlikely that these are "pure" measures of planning, inhibition, or working memory. The ROFC, for example, is often referred to as a planning task; however, aspects of working memory and perhaps inhibition are required to complete the task. Similarly, the types of tasks included vary widely across studies (e.g., multiple planning and/or working memory tasks are used), and it is presumptuous to assume the tasks are measuring the same construct. Indeed, confirmatory factor-analytic studies suggest that EFs are moderately correlated with one another, and "it is important to recognize both the unity and diversity of executive functions" (Miyake, Friedman, Emerson, Witzki, & Howerter, 2000, p. 49). In addition, despite their widespread usage, EF tests are not necessarily effective at discriminating between different clinical and control groups (Weyandt et al., 2013).

It is important to note, however, that the use of ratings scales designed to measure EF can often yield markedly different results than traditional EF tests; hence, the nature of EF and ADHD warrants further investigation. Notably, EF rating scales are better able to discriminate between cases of ADHD and other disorders, as well as typical control cases, and recent findings indicate that EF rating scales are better predictors of impairment in major life activities. Collectively, these findings suggest that a more comprehensive picture of the nature of EF will be elucidated if EF rating scales are used in conjunction with traditional EF tests.

Although the developmental and neuropsychological deficits reviewed herein appear frequently to co-occur with ADHD, it is critical that a causal relationship not be inferred because some children with ADHD do not have developmental or neuropsychological deficits. Likewise, children without ADHD have been found to have developmental and neuropsychological deficits; hence, deficits in these areas are not unique to ADHD and are in no way diagnostic of the disorder. Further longitudinal studies are needed to identify how ADHD manifests across the lifespan, and to identify variables that contribute to the heterogeneity of the disorder. Empirical studies are also needed to establish effective interventions to address the adaptive behavior and neuropsychological deficits often found in children with ADHD.

KEY CLINICAL POINTS

- ✓ Children with ADHD have significant deficits in self-care and adaptive functioning that are more disparate from their level of intelligence than do children with mild developmental delay.
- ✓ The deficits due to ADHD are primarily in the domains of communication, daily living, and socialization, and are closely associated with the degree of executive dysfunction.
- ✓ ADHD is also associated with significant delays in motor development and coordination, with up to half or more children qualifying for a diagnosis of DCD. Fine motor coordination, particularly for writing and drawing, may be the most impaired areas of motor performance. These difficulties may be lifelong.
- ✓ ADHD medications as well as physical therapy may serve to improve motor problems.
- ✓ A sizable minority of children with ADHD may experience problems in language development, primarily in expressive language, and especially the executive or pragmatic aspects of language expression and organization. These language problems can contribute additional risk for social problems beyond the risks posed by the primary symptoms of ADHD and comorbidity.
- ✓ Up to 45% or more of children with ADHD may have LDs (see Chapter 6).
- ✓ Although the evidence is somewhat mixed, ADHD is associated with a positive illusory bias in children's self-perception of competence in various domains of

task performance. It is not so much that children with ADHD report being significantly more competent than others but that they perceive themselves as doing as well as most others, when their actual performance in that domain is significantly worse than that of others.

- ✓ Expressions of low self-worth or low self-esteem are primarily a function of comorbidity with depression.
- ✓ ADHD is routinely found to be linked to a delay in the internationalization of language. This may account for the greater verbosity of children with ADHD compared to children of similar age who have already progressed to using private self-speech. And the self-speech they do employ is less organized, less efficient, and less likely to guide their task performance effectively.
- ✓ Children with ADHD, on average, are likely to score slightly lower in general intelligence than do typically developing children. Contrary to popular belief, ADHD is not more likely to be associated with intellectual giftedness.
- ✓ Substantial research has demonstrated that ADHD is associated with significant deficits in various EFs, including response inhibition, nonverbal and verbal working memory, and planning abilities. While these differences are commonly seen in group-level comparisons with controls, only a minority of children with ADHD score in the impaired range on traditional EF tests.
- ✓ In contrast, the majority of children and adults with ADHD score in the impaired range on rating scales of EF in everyday life. Since rating scales and EF tests are not significantly correlated with each other, and rating scales have greater utility in predicting impairment, clinical evaluations of EF should include rating scales of EF and not rely exclusively on EF tests to evaluate this domain of functioning.
- ✓ ADHD is associated with impairments in one's sense of time, particularly in time reproduction and on measures of the timing and timeliness of actions. These differences are even more evident on rating scales that measure sense of time and time management.

CHAPTER 5

Comorbid Psychiatric Disorders in Children with ADHD

Steven R. Pliszka

There is no doubt that a diagnosis of attention-deficit/hyperactive disorder (ADHD) conveys a significant risk for other, coexisting psychiatric disorders. Indeed, as many as 67–80% of clinic-referred children and 80% or more of clinic-referred adults with ADHD have at least one other disorder, and up to half have two other disorders (Barkley, Murphy, & Fischer, 2008). Such findings refute not only the naive claims that ADHD is a myth but also that ADHD is otherwise a benign condition about which one need not be concerned or seek treatment. This chapter focuses on each of the major comorbidities found with ADHD (disruptive behavior; mood, anxiety, and substance use, and tic disorders; intellectual disability; and autism spectrum disorders). There is a particular an emphasis on new paradigms from DSM 5 regarding mood dysregulation and bipolar disorder. This chapter has been further influenced by the growing awareness of the interrelatedness of many classic psychiatric disorders (Faraone, 2013). Angold, Costello, and Erkanli (1999) reviewed the reasons why disorders may coexist with each other. Common underlying etiologies (genetics, family environment, etc.) may lead to both disorders, or two disorders may be correlated with a third disorder that can account for their relationship. Apparent comorbidity also can be an artifact of methodological problems in research, such as referral bias, ascertainment bias, overlap in symptoms on diagnostic symptom lists, and other factors. Based on their meta-analysis of community samples in 21 studies, Angold and colleagues computed odds ratios (ORs) reflecting the likelihood that two disorders will coexist with each other. Use of community samples is important; clinic-referred samples can demonstrate an overlap of disorders that is based mainly, if not entirely, on referral biases in how those samples were obtained from those particular clinics. They found that, relative to the general population, patients with ADHD had greater than expected prevalence of oppositional defiant disorder (ODD)/conduct disorder (CD) (10 times), depression (5.5 times) and anxiety (3 times).

Yoshimasu and colleagues (2012) identified 379 ADHD cases in a large community sample of 5,718 children in a birth cohort (1976–1982) who were followed to age 19 years. Hazard ratios (HRs) estimated for a broad range of disorders revealed that ADHD was associated with a higher risk for adjustment disorders (HR = 3.88), ODD/CD (HR = 3.67), anxiety disorders (HR = 2.94), tic disorders (HR = 6.53), eating disorders (HR = 5.68), personality disorders (HR = 5.8), and substance-related disorders (HR = 4.03). Typically, comorbid disorders have an onset after that of the ADHD, indicating that the clinician must be alert to

the development of comorbidity over the course of the patient's life.

ODD AND CD

Studies suggest that from 45 to 84% of children and adolescents with ADHD will meet full diagnostic criteria for ODD, either alone or with CD (Barkley, DuPaul, & McMurray, 1990; Fischer, Barkley, Edelbrock, & Smallish, 1990; Pfiffner et al., 1999; Pliszka, Carlson, & Swanson, 1999; Wilens et al., 2002). The Multimodal Treatment Study of ADHD (MTA) found that 40% of children with ADHD met criteria for ODD, while 14.3% met criteria for CD (Swanson et al., 2008). Wilens and colleagues (2002) reported that 62% of their preschool-age children with ADHD and 59% of their school-age sample also had ODD. These same studies indicate that among those with ADHD, as many as 15–56% of children and 44–50% of adolescents will be diagnosed with CD (Szatmari, Boyle, & Offord, 1989; Wilens et al., 2002). In their meta-analysis, Angold and colleagues (1999) reported a median OR of 10.7 (range 7.7 to 14.8) between ADHD and CD/ODD, making it the most likely comorbidity between ADHD and any other set of disorders. This relationship does not appear to be an artifact of the coexistence of a third type of disorder with these two. As Barkley (2010) has argued (Chapter 3), this comorbidity may be partly or largely a function of the difficulties with emotional dysregulation in ADHD that make such cases highly likely to progress into ODD.

A review (Pliszka, 2009) and a meta-analysis (Waschbusch, 2002) have examined the following differences between children with ADHD and those with CD/ODD.

Family Environment and History

Children with ADHD and ODD/CD have parents with far greater rates of psychopathology than do children with ADHD alone. This higher rate of mental illness in families includes not only antisocial problems but also depressive and anxiety disorders as well (Biederman et al., 1992; Faraone, Biederman, Jetton, & Tsuang, 1997; Faraone, Biederman, Keenan, & Tsuang, 1991; Goldstein, Harvey, & Friedman-Weieneth, 2007; Lahey et al., 1988; Pfiffner, McBurnett, Rathouz, & Judice, 2005). Pfiffner and colleagues (2005) demonstrated that the family histories of children with ADHD and CD were significantly more likely to include maternal depression and paternal antisocial behavior than those of children with ADHD alone, or those with only ADHD and ODD. Parents of 3-year olds with both hyperactivity and oppositional behavior had significantly more antisocial behavior (fathers only), depression, and anxiety than those parents of preschoolers who were only hyperactive (Goldstein, Harvey, Friedman-Weieneth, Pierce, et al., 2007). In contrast, they found that adult ADHD was equally elevated in the parents of both hyperactive and hyperactive–oppositional preschoolers. Parents of hyperactive–oppositional preschoolers were in conflict with each other significantly more than parents of control or hyperactive-only children.

Compared to children with ADHD alone, children with ADHD and ODD/CD are more likely to experience divorce (August & Stewart, 1983) or be placed in foster care (Reeves, Werry, Elkind, & Zametkin, 1987). Mothers of hyperactive–oppositional preschoolers experienced more parental distress, had more dysfunctional interactions with their child, and rated the child as being more difficult than did parents of hyperactive-only preschoolers (Goldstein, Harvey, & Friedman-Weieneth, 2007). In a study of older children with ADHD, this pattern of negative parent–child interactions in those with ODD/CD was even more apparent. Pfiffner and colleagues (2005) obtained measures of parenting in three groups of children with ADHD: ADHD only (n = 66), ADHD/ODD (n = 48) and ADHD/CD (n = 35). Both ODD and CD were associated with maternal negative/ineffective discipline, while only CD was associated with lack of maternal warmth, ineffective parental discipline, and parental antisocial personality. In the MTA, a codiagnosis of ODD/CD was associated with more deviant scores on the Wells Parenting Index and more negative parent–child interactions (Jensen et al., 2001).

Cognition

Children with ADHD and comorbid CD (or delinquency) were far more likely than those with ADHD alone to have reading and learning disabilities (McGee, Williams, & Silva, 1984; Moffitt & Silva, 1988). Children with ADHD and CD had lower reading scores than did children with CD alone (who were not different from controls) (Schachar & Tannock, 1995). Moffitt (1990) followed an epidemiological sample of children with ADHD and controls from ages 3 to 13 years. Children with lower Verbal IQ, ADHD, *and* high family adver-

sity at age 3 were more likely to become delinquent later in life. Compared to children with ADHD alone, those with comorbid ODD/CD showed more severe hyperactive–impulsive symptoms on both parent and teacher ratings (Jensen et al., 2001; Newcorn et al., 2001). The comorbid group also made more impulsive errors on a laboratory measure of impulsivity (Newcorn et al., 2001).

Long-Term Outcome

Children with ADHD and comorbid disruptive behavior disorders (particularly CD) have a much higher likelihood of developing antisocial behaviors as adults than do those with ADHD alone. Both hyperactivity and aggression independently contribute to the prediction of criminal behavior in childhood and adolescence. Satterfield and colleagues (2007) examined the criminal histories of 179 children with ADHD and 75 controls over a 30-year period. Almost 30% of the children with ADHD were convicted of an offense (17% for a felony); the comparable rates in controls were 8.0 and 2.7%, respectively. Felony convictions, in particular, were much higher among the subjects with ADHD who had higher CD ratings in childhood. Kindergartners who are rated high in hyperactivity, antisocial behavior, and fearlessness are far more likely to be involved in deviant peer activities 12 years later than kindergartners who are only hyperactive (Lacourse et al., 2006).

The path to substance abuse for children with ADHD is mediated by CD. Adolescent drug use outcomes were compared between ADHD-only (n = 27), ADHD externalizing (mostly ODD) (n = 82), and normal control (n = 91) groups; only the externalizing group had a higher rate of substance and alcohol use disorders than the ADHD-only group or controls (August et al., 2006). Conduct, not attentional problems, predicted drug abuse in a 25-year follow-up of 1,265 adolescents in New Zealand. Any association between early attentional problems and later substance abuse was mediated by the association between conduct and attentional problems (Fergusson, Horwood, & Ridder, 2007).

Response to Pharmacological Treatment

Early studies showed that the ADHD core symptoms in children with ADHD and ODD/CD respond as well to psychopharmacological treatment as those in children with ADHD alone (Barkley, McMurray, Edelbrock, & Robbins, 1989; Pliszka, 1989). In addition, stimulants have been shown to reduce oppositional behavior, as well as covert and overt antisocial behavior (Hinshaw, Heller, & McHale, 1992; Klein et al., 1997). In the MTA, the stimulant response of children with ADHD and ODD/CD was just as good as that of the noncomorbid ADHD group (Jensen et al., 2001). Recent studies of both long-acting stimulants and atomoxetine have robust effects on symptoms of ODD (Newcorn, Spencer, Biederman, Milton, & Michelson, 2005; Spencer et al., 2006).

Genetics

Biederman and colleagues (1992) first showed that ADHD/CD "breeds true" in families; that is, children with ADHD without CD do not have higher than expected rates of relatives with CD. The increase is confined to relatives of children with the combined condition. Examining a genetic isolate of families, Jain and colleagues (2007) found genetic markers that cosegregated with ADHD/ODD and ADHD/CD, suggesting that these are distinct genetic subtypes. Silberg, Maes and Eaves (2012) used an extended children-of-twins design to test whether genetic and/or family environmental factors accounted for the association between parental antisocial behavior and children's behavioral problems. The relationship between parental antisocial personality and childhood depression was solely environmental, whereas genetic and family environmental factors accounted for the resemblance between parents' antisocial personality and children's conduct disturbance. The association between parental antisocial personality and ADHD was entirely genetic. Polygenetic risk (greater number of ADHD risk alleles) was significantly higher in subjects with ADHD and CD than in those without CD (Hamshere et al., 2013).

Catecholamine-O-methyltransferase (COMT) degrades dopamine and norepinephrine. The human COMT gene is located on chromosome 22q11 and contains a valine/methionine (Val/Met) polymorphism at codon 158. The Met allele is associated with a 40% reduction in enzymatic activity in the prefrontal cortex (PFC) and possibly a higher level of PFC dopamine (Chen et al., 2004). Multiple studies have shown that persons with ADHD who carry the Met allele have higher rates of antisocial, disruptive, and aggressive behavior than Val/Val carriers (Caspi et al., 2008; DeYoung et al., 2010; Langley, Heron, O'Donovan, Owen, & Thapar, 2010; Monuteaux, Biederman, Doyle, Mick,

& Faraone, 2009; Thapar et al., 2005). There is an interaction between being a Met allele carrier with a history of child abuse and future antisocial behavior (Kim-Cohen et al., 2006).

Neuroimaging

Rubia (2011) reviewed neuroimaging studies that compared children with ADHD to those with CD. The review was limited by the fact that, in most of the studies, the CD sample was highly comorbid with ADHD. The review highlighted four functional magnetic resonance imaging (fMRI) studies (Rubia et al., 2008, 2010; Rubia, Halari, et al., 2009; Rubia, Smith, et al., 2009) that compared children with ADHD to those with CD without ADHD. They found that relative to pure CD, children with ADHD alone showed underactivation in the inferior frontal cortex and overactivation of the cerebellum during tasks of motor inhibition and attention. In contrast, underactivation of limbic regions was noted in children with pure CD relative to those with ADHD alone during reward tasks. Rubia hypothesized that "direct comparisons in functional imaging show that these associations of cool inferior fronto-striato-cerebellar dysfunction in ADHD and of hot orbitofrontal-paralimbic dysfunction in CD are disorder-specific" (p. e69). There is, however, growing evidence that dysfunction in such "hot" ventromedial orbitofrontal–limbic circuits is present in ADHD even without comorbid aggression or CD.

EMOTIONAL IMPULSIVITY

Highly relevant to my discussion of comorbidity of ADHD and mood disorders is the concept of emotional impulsivity (EI), which is expanded on at length elsewhere (Barkley, 2010; see also Chapter 3). EI comprises impatience, low frustration tolerance, hot temper, irritability, anger, and emotional overreactivity. Difficulties with emotional regulation, not surprisingly, affect children with ADHD and comorbid disruptive behavior much more than they affect those with ADHD alone. Melnick and Hinshaw (2000) placed children with ADHD who scored high or low in aggression (as well as controls) in a playroom with their parents. The family had to build a Lego model that had two pieces missing. The children's emotional reactions were assessed by observers blind to the children's diagnostic status. Relative to children with ADHD alone, ADHD/aggressive boys vented more loudly, showed less overall emotional regulation, accommodated less, and had more negative responses. All the groups were then observed in a naturalistic summer camp. Controlling for core ADHD symptomatology, Melnick and Hinshaw found that noncompliance in the naturalistic setting was predicted by boys' overall emotion regulation and three specific strategies (emotional accommodation, problem solving, negative responses) during the task. Over the long term, EI is found at much higher rates in adults with ADHD than in controls and adults who had childhood ADHD but do not currently meet criteria for the disorder. EI also predicts impairments in a variety of activities (driving, finances, dating, marriage) beyond the ADHD symptoms themselves (Barkley & Fischer, 2010).

fMRI was used to assess neural activity in adolescents with and without ADHD while they performed a task involving the subliminal presentation of fearful faces (Posner et al., 2011). Adolescents with ADHD had greater right amygdala activation in response to fearful faces than controls, as well as increased connectivity between the amygdala and the lateral prefrontal cortex (LPFC). Intriguingly, in controls, presentation of the faces appeared to inhibit the amygdala–LPFC connections, whereas they enhanced the connections in the subjects with ADHD. Stimulant treatment normalized these findings in those with ADHD, both reducing amygdala activation and decreasing amygdala and LPFC connectivity. Presence or absence of ODD did not affect the imaging findings. As this discussion proceeds, a key question will relate to the difference between the "irritability" of EI and that of a major depressive or manic episode based on the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013).

AGGRESSION AND IRRITABILITY

Children with ADHD who meet criteria for ODD appear to come in two "subtypes": irritable and defiant (Kuny et al., 2013). There are those with ADHD who talk back, argue, and tease their siblings and peers yet rarely lose their temper (for any length of time) or do spiteful things. Others with ADHD/ODD throw prolonged tantrums (yelling, screaming, saying "I hate you!") yet do not become physically aggressive. More problematic individuals with ADHD do indeed engage in verbal ("I'm gonna kill you") or physical aggres-

sion (hitting people, putting holes in walls) and may or may not engage in other CD behaviors. Which of these children has a comorbid mood disorder? Parents often do not distinguish between this array of symptoms when they come for their child's evaluation ("He's just mad!"), and even experienced clinicians may lump all of these symptoms into a heterogeneous category of mood disorder. It is best to begin by carefully parsing the symptom clusters of aggression, irritability, depression, and mania.

Mick, Spencer, Wozniak, and Biederman (2005) looked at the specific questions that assess irritability in the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS). For depression, the KSADS asks, "Has there ever been a period of 2 weeks or longer in which you were feeling mad (or cranky) most of the day, nearly every day?" In contrast, in the mania section, the irritability question is phrased differently: "Have you ever had a period of 1 week or longer when you felt super-angry, grouchy (or cranky) all of the time?" Mick and colleagues noted that in DSM-IV, items about depression and mania followed a "two-tier" format. That is, the question about irritability was asked first. Only if the abnormal mood was present 50% of the time did the clinician query the parent or patient about other symptoms of either depression or mania. Manic irritability was characterized by extreme ("super-angry") and pervasiveness ("all the time"), while depressive irritability was characterized by primarily negative mood and attitude, which may be punctuated by some good days. Explosive outbursts were far less likely to be a part of the picture in depression, but they were in mania. In contrast, ODD followed a one-tier format in that the parent or patient was queried about all nine symptoms. While there was no specific "irritability" item, three of the symptoms of ODD clearly tapped into this construct: "Do you often lose your temper?"; "Are you often angry or resentful?"; and "Is it easy to make you mad or to annoy you?" In the case of ODD, the symptoms had to be present "more often than not" for a period of 6 months or more.

Mick and colleagues (2005) next examined data from 274 children with ADHD, ages 6–17 years, who were studied using the K-SADS. Many (n = 144) had no mood disorder diagnosis, while 100 had unipolar depression and 30 had bipolar disorder. ODD-only-type irritability (easily annoyed, loses one's temper, angry or resentful) was highly prevalent in all three groups. In contrast, children with ADHD and comorbid depression were more likely to endorse the mad–cranky item than those without a mood disorder. Those with bipolar disorder endorsed the "super-mad" criteria in addition to the "mad–cranky" item in the depressive module. Even if the angry mood was extreme, this was not sufficient to diagnose a mood disorder. Only 46% of the children met criteria for bipolar disorder because it was also necessary that they show other symptoms: inflated self-esteem, decreased need for sleep, pressured speech, and flight of ideas or excessive involvement in pleasurable/dangerous activities.

It is clear from this that disentangling irritability and aggression is not straightforward. Aggression itself was subdivided between "reactive" and "proactive," with the former having a strong irritable/angry component and the latter perceived as "instrumental" (i.e., coldly grabbing a purse from a victim solely to obtain the contents) (Dodge, 1991). Studies of aggression in ADHD have not always clearly distinguished the two subtypes, although it is clear from a review of these studies that reactive aggression is more often the focus (King & Waschbusch, 2010). Other reviews indicated that children with ADHD show elevated levels of aggressive behavior even when researchers control for cooccurring ODD/CD. Dodge, Harnish, Lochman, and Bates (1997) found that children with high levels of reactive aggression also tend to have more inattention and impulsivity–hyperactivity problems. Children with ADHD, ODD/CD, *and* reactive aggression are more impaired in terms of peer relationships and classroom behavior than children with ADHD + ODD/CD who are not aggressive (Waschbusch, Willoughby, & Pelham, 1998). Jensen and colleagues (2007) reexamined data from the MTA and found that 267 of the original sample of 579 children (46%) exhibited clinically significant aggression. Of even greater concern, 44% of the aggressive subgroup remained so even after medication treatment of ADHD.

Social information-processing theory (Dodge, 2006; Dodge & Schwartz, 1997) provides a mechanism to better understand how aggressive children think. Dodge and Schwartz reviewed the stages of Dodge's social information-processing model: encoding, interpretation of social cues, goal selection, response access and construction, and response decision. When looking at social situations, aggressive children encode fewer relevant cues and do not seek out additional information when the situation is ambiguous. They are more likely to interpret ambiguous cues as hostile. Dodge (2006) suggested that recognizing hostile intent may be a "hardwired" function of the amygdala, while at-

tributing benign intent to an ambiguous situation is a learned process. As for goal selection, aggressive children seek dominance and control, and generate fewer potential responses to a problematic social situation. There is a negative correlation between the number of responses and the child's rate of aggression. In terms of response decision, aggressive children view aggression as producing more desirable outcomes. They are more likely to see aggression as leading to tangible rewards and peer group approval, and they do not see their victims as suffering any real harm. The encoding and the response decision phases differ in children with different subtypes of aggression (Dodge et al., 1997). Children with ADHD as a whole make more social information-processing errors than do controls (King & Waschbusch, 2010). However, children with ADHD and aggression, relative to controls and nonaggressive children with ADHD, utilize social cues poorly (Milich & Dodge, 1984), have more difficulty anticipating the consequences of their aggressive actions (Bloomquist, August, Cohen, Doyle, & Everhart, 1997), and generate aggressive solutions to problems (Matthys, Cuperus, & van Engeland, 1999).

Both pharmacological and psychosocial methods have been utilized in the treatment of ADHD and aggression. Two large-scale reviews of the effects of stimulant medication on aggression have been undertaken. Connor, Glatt, Lopez, Jackson, and Melloni (2002) reviewed 28 published studies from 1970 to 2001 that measured stimulant effect on aggression; mean effect sizes were 0.84 for overt aggression and 0.69 for covert aggression. Similarly, Pappadopoulos and colleagues (2006) reviewed 19 stimulant studies involving over 1,000 subjects and found stimulants to have an effect size of 0.78 in the treatment of aggression. These effect sizes are equivalent to those of stimulants on the core symptoms of ADHD. There has been a long-standing belief that stimulants *cause* aggression, so much so that the U.S. Food and Drug Administration convened a special panel to study this issue (Mosholder, 2006). No significant difference was found between placebo and stimulant in the prevalence of psychotic, manic, and suicidal events or aggression. Only very rarely do patients have an idiosyncratic reaction of this sort to stimulant. Elliott, Malecki, and Demaray (2001) reviewed social skills interventions for children and noted that they are most effective for withdrawn children and tend to be less effective for aggressive children, while parent training is effective for children with ADHD and comorbid ODD/CD (Fabiano et al., 2009; Patterson, Chamberlain, & Reid, 1982). Combining psychosocial treatment with pharmacological treatment of the child's ADHD is a desirable first-line intervention before moving to more aggressive psychopharmacology (i.e., mood stabilizers, antipsychotics) (Pliszka, 2009).

How much of a benefit is provided in terms of reducing aggression by adding an antipsychotic to a stimulant? Children with ADHD and aggressive behavior were treated with stimulants and parent training for 3 weeks, then either placebo or risperidone was added in a randomized, double-blind fashion (Aman et al., 2014). Disruptive behavior scores declined from a mean of 45 at baseline to 25 at Week 3 (before addition of risperidone). At Week 9, the risperidone group was showed a further mean drop of 14 in disruptive behavior ratings, compared to an 8.1 mean drop in the placebo group ($p = .0143$, effect size = 0.5). There were no differences between the groups at Week 9 in terms of clinician ratings of overall improvement. Thus, while adding risperidone was beneficial in reducing severe disruptive behavior, the effect was modest when combined psychosocial and stimulant treatment of ADHD were implemented first.

DISRUPTIVE MOOD DYSREGULATION DISORDER

In DSM-5, the American Psychiatric Association (2013) has added the diagnosis of disruptive mood dysregulation disorder (DMDD; see Table 5.1). This change in name illustrates a fundamental dilemma: Is this severely problematic mix of mood lability and aggression a "disruptive" or a "mood" disorder? The need for such a new category was driven in large part by the debate as to whether bipolar disorder (BP) in youth exists in either a classic episodic form or a chronic irritable form (Biederman, 1998; Carlson, 2007; Klein, Pine, & Klein, 1998). Furthermore, in the last decade there has been a 40-fold increase in outpatient visits (Moreno et al., 2007) and a sixfold increase in hospital admissions for youth diagnosed with BP (Blader & Carlson, 2007). During the same period, there has been a marked increase in the use of mood stabilizers and antipsychotics in children and youth (Moreno et al., 2007; Olfson, Blanco, Liu, Moreno, & Laje, 2006), often for predominant symptoms of aggression. The debate has moved beyond the scientific literature into the lay media, where the approach to the topic is often ambivalent: a great deal of sympathy for children with

TABLE 5.1. DSM-5 Diagnostic Criteria for Disruptive Mood Dysregulation Disorder (DMDD)

A. Severe recurrent temper outbursts manifested verbally (e.g., verbal rages) and/or behaviorally (e.g., physical aggression toward people or property) that are grossly out of proportion in intensity or duration to the situation or provocation.

B. The temper outbursts are inconsistent with developmental level.

C. The temper outbursts occur, on average, three or more times per week

D. The mood between temper outbursts is persistently irritable or angry most of the day, nearly every day, and is observable by others (e.g., parents, teachers, peers).

E. Criteria A–D have been present for 12 or more months. Throughout that time, the individual has not had a period lasting 3 or more consecutive months without all of the symptoms in Criteria A–D.

F. Criteria A and D are present in at least two of three settings (i.e., at home, at school, with peers) and are severe in at least one of these.

G. The diagnosis should not be made for the first time before age 6 years or after age 18 years. Age of onset by 10 years.

H. By history or observation, the age at onset of Criteria A–E is before 10 years.

I. There has never been a distinct period lasting more than 1 day during which the full symptom criteria, except duration, for a manic or hypomanic episode have been met. **Note:** Developmentally appropriate mood elevation, such as occurs in the context of a highly positive event or its anticipation, should not be considered as a symptom of mania or hypomania.

J. The behaviors do not occur exclusively during an episode of major depressive disorder and are not better explained by another mental disorder (e.g., autism spectrum disorder, posttraumatic stress disorder, separation anxiety disorder, persistent depressive disorder [dysthymia]). **Note**: This diagnosis cannot coexist with oppositional defiant disorder, intermittent explosive disorder, or bipolar disorder, though it can coexist with others, including major depressive disorder, attention deficit/hyperactivity disorder, conduct disorder, and substance use disorders. Individuals whose symptoms meet criteria for both disruptive mood dysregulation disorder and oppositional defiant disorder should only be given the diagnosis of disruptive mood dysregulation disorder. If an individual has ever experienced a manic or hypomanic episode, the diagnosis of disruptive mood dysregulation disorder should not be assigned.

K. The symptoms are not attributable to the physiological effects of a substance or to another medical or neurological condition.

BP or severe mood issues (Egan, 2008) versus skepticism regarding the psychopharmacology of the disorder (Carey, 2007).

The debate began when Wozniak and colleagues (1995) identified 43 children in a psychiatric outpatient clinic who met their criteria (K-SADS) for mania; all but one of these children also met criteria for ADHD. They were compared to 164 nonmanic children with ADHD and 84 controls. The total of 206 (42 manic and 164 nonmanic) subjects with ADHD yielded a 20% prevalence of mania of 20% in the ADHD sample in this study. There were only two children with euphoric mania, while 77% showed "extreme and persistent mania." That is, they did not cycle or have any prolonged periods of euthymia. Eighty-four percent showed "mixed mania," in which symptoms of mania and depression co-occurred. Biederman and colleagues (1995) studied a second sample of 120 children with ADHD and found 29 children (21%) who met criteria for BP. Child Behavior Checklist (CBCL) scores of the children with ADHD/mania were elevated compared to those of children with ADHD only on nearly all of the subscales. Of note, it was the Aggression subscale that most differentiated the manic/ADHD group from the ADHD-only group (Biederman et al., 1995).

At the time, Biederman and colleagues (1998) and Klein and colleagues (1998) had an extensive debate in the *Journal of the American Academy of Child and Ado-*

lescent Psychiatry regarding the validity of the broader diagnosis. In particular, Klein and colleagues pointed to the fact that the concept of chronic irritable mania violated the DSM-IV requirement for a "distinct period" of abnormal mood. That is, there is a period of euthymic mood and a specific point at which the manic or depressive episode can be said to begin. However, given that virtually all studies indicated that children with BP have very high rates (40–90%) of comorbid ADHD (Kowatch, Youngstrom, Danielyan, & Findling, 2005; Singh, DelBello, Kowatch, & Strakowski, 2006), how does one mark the beginning or end of a manic episode when the child is chronically hyperactive and talkative? For instance, B. Geller and colleagues (1995) noted that one child in a study had 104 episodes in a year, lasting from as short as 4 hours to a whole day. Findling and colleagues (2001) followed 90 youth with BP using prospective life charting and found that only two subjects ever showed "interepisode recovery," defined as being euthymic for a 2-month period.

In 2003, Leibenluft, Charney, Towbin, Bhangoo, and Pine (2003) published a very influential article that proposed a research strategy for resolving these issues. They suggested that the diagnosis of BP be limited to those youth who show elation as the mood change and whose abnormal mood state was clearly distinct from baseline. These youth also would have to meet the other first-rank symptoms of mania (pressured speech, grandiosity, etc.) and for the required periods of time. They proposed severe mood dysregulation (SMD) as an alternative diagnosis for those with chronic irritability. SMD formed the template for DMDD, but there are significant differences. In DSM-5, both entities require persistent abnormal mood (anger/sadness but *not* elation) and temper outbursts, with severe temper problems in at least one setting. SMD permits the presence of manic symptoms in the hyperarousal category (insomnia, agitation, pressured speech, etc.) as long as the youth does not have elevated mood, grandiosity, or inflated self-esteem. In contrast, in DSM-5, DMDD specifically excludes children with hyperarousal (see Table 5.1). A substantial body of data has emerged with respect to SMD, but the reader should bear in mind that it might not apply entirely to DMDD due to this important difference in their criteria.

Brotman and colleagues (2006) examined data from the Great Smoky Mountains epidemiology study and used items from the structured interview in that project to diagnose SMD retrospectively; about 3% of the cohort met criteria for this diagnosis. Not surprisingly, there was a high degree of comorbidity in members of this sample: ADHD (27%), ODD (50%), anxiety disorder (15%), and depression (13.4%). The rate of BP in this study was extremely low and did not differ between those with and without SMD. Recently, data from three large epidemiological studies were combined to examine the prevalence of DMDD based on constructing the criteria from the specific questions asked in structured interviews (Copeland, Angold, Costello, & Egger, 2013). The prevalence rates ranged from 0.8 to 3.3%, with the highest rate in preschoolers (who may not be given the DMDD diagnosis). The highest level of comorbidity were with depressive disorders (ORs 9.9–23.5) and ODD (ORs 52.9–103.0). DMDD *cannot* be comorbid with ODD, however, so if these two exclusionary criteria are applied, the prevalence falls to about 1% (Axelson, 2013). Axelson further points out that the diagnosis of DMDD requires children and parents to recall the frequency, persistence, and duration of aggressive outbursts and irritability, which can be very difficult and perhaps lead to instability of the diagnosis and its poor test–retest reliability (kappa = 0.25; Regier et al., 2013).

Does DMDD belong in the bipolar or unipolar spectrum? Stringaris and colleagues (2010) followed 93 youth with narrow phenotype ("classic") BP and 84 youth with SMD. At follow-up (median = 28.7 months), 63% of youth with BP had a full manic episode, compared to only a handful of such episodes in youth with SMD, who were more likely to have depressive episodes, though not dramatically so. A number of long-term follow-up studies suggest that youth with chronic irritability (although these subjects were not necessarily diagnosed with SMD) are more likely to show depression rather than BP on follow-up (Sobanski et al., 2010; Stringaris, Cohen, Pine, & Leibenluft, 2009; Stringaris & Goodman, 2009). This underlies the DSM-5 decision to include this disorder in the depressive disorders category (American Psychiatric Association, 2013, p. 157).

As noted, Biederman and colleagues (1995) published a report of a distinct behavioral profile of children with BP, as measured by the CBCL, with marked elevations on the Attention, Aggression, and Anxious/Depression subscales. This profile was found in about 0.8% of a large twin population and had a different pattern of inheritance from those with ADHD alone (Hudziak, Althoff, Derks, Faraone, & Boomsma, 2005). Thus, there is evidence that this dysregulated group is a distinct genetic subpopulation. Althoff,

Verhulst, Rettew, Hudziak, and van der Ende (2010) followed over 2,000 children who had CBCL's conducted at baseline and subjected to latent class analysis (LCA). LCA clearly identified a subgroup of children who showed the "BP profile" on the CBCL. However, when they were followed up 14 years later, none had developed BP. Rather, this dysregulated profile was a risk factor for a wide range of psychiatric disorders. It should be noted, however, that in this entire sample of over 1,500 subjects who were followed, there were only six cases of BP. This does raise some concerns that the interview procedures either underidentified BP or the sample was not completely representative of the general population. Nonetheless, it certainly showed that elevations on the Attention, Aggression, and Anxiety/Depression subscales of the CBCL are not diagnostic or predictive of BP.

Imaging studies have shown differences between youth with BP (narrowly defined) and those with SMD (Brotman et al., 2010). Children with ADHD alone, BP, SMD, and typically developing controls observed faces while undergoing fMRI. The participants had to rate either the fearfulness of the faces or the nose width of the individual (the latter was a control condition for contrast). Surprisingly, youth with BP did not differ from controls on these measures. Children with ADHD alone showed a marked increase in left amygdala activation relative to controls, while those with SMD showed deactivation of the amygdala compared to both controls and those with ADHD alone. This does suggests that the SMD and narrow BP groups are physiologically distinct, as was implied by an earlier event-related potential study (Rich et al., 2010). The picture remains unclear, however. In contrast to Brotman and colleagues (2010), a recent study from the same group found that children with BP and SMD both had reduced amygdala activation to angry faces relative to healthy controls (Thomas et al., 2012). Relative to healthy controls, children with SMD show decreased activation of the left posterior cingulate and precuneus during negative feedback (losing money in a game) but no differences during positive feedback (Deveney et al., 2013). No differences were found in the amygdala or prefrontal areas that were predicted to differentiate these groups.

What are the pharmacological treatment implications for DMDD? A diagnosis of BP is an indication for treatment with mood stabilizers and second-generation antipsychotics (SGAs; Kowatch, Fristad, et al., 2005). Given that these agents also are effective for aggression (Pappadopulos et al., 2003, 2006; Schur et al., 2003), it not surprising that that there has been a marked increase in the clinical use of these agents in children and adolescents (Patel et al., 2005; Patel, Crismon, & Shafer, 2006). This too has been a source of controversy in the lay media (Harris, Carey, & Roberts, 2007), and pharmaceutical companies have paid large fines for off-label marketing for use of these agents in children and older adults. SGAs are associated with significant weight gain and change in lipid metabolism (Correll et al., 2009). Will the addition of DMDD to DSM-5 lead to changes in prescribing practices? If the chronically irritable and aggressive child currently diagnosed as "BP not otherwise specified (NOS)" has his or her diagnosis changed to DMDD, will the physician be less likely to prescribe less medication? At present this does not seem likely. Brotman and colleagues (2010) found that equal numbers of the BP and SMD groups were taking mood stabilizers and SGAs. One study suggests that it is possible to avoid placing some aggressive children on SGAs. Blader, Schooler, Jensen, Pliszka, and Kafantaris (2009) treated 74 children with ADHD and significant aggression (though not necessarily diagnosed with SMD) with stimulants and a behavior management program; the aggression remitted in 31 of the participants. Thirty subjects were randomized to either placebo or valproate for 6 weeks; those subjects on valproate had a significant decrease in aggression. Although this group of children with ADHD had high levels of reactive aggression, they were not formally diagnosed with SMD or DMDD. Dickstein and colleagues (2009) admitted 45 youth with SMD to an inpatient unit; 20 of these had reduced aggression after a week on placebo and were excluded. The remaining 25 subjects whose mood dysregulation remained problematic were randomized to either lithium or placebo for 6 weeks. There was not even a trend for lithium to be effective relative to placebo, and there were few responders in either group, suggesting that SMD is very difficult to treat. A study of citalopram in SMD is under way (Dickstein et al., 2009). The results of such a study will be informative. If SMD is indeed part of the BP spectrum, one would expect high rates of "switching" to mania. If this does not occur, then this would be evidence that SMD is not related to BP.

The addition of DMDD provides a challenge for the clinician. It will need to be considered whenever a child with ADHD and aggression *also* exhibits chronic irritability between aggressive episodes. This is likely to encompass a large group of children who often

have been diagnosed with "mood disorder, not otherwise specified." Thus, the differential diagnosis will be among mania, DMDD, and ADHD + ODD. Note in Table 5.1 that DMDD *cannot* be comorbid with ODD or a manic episode, while it *can* be comorbid with ADHD or a major depressive episode.

MANIA

DSM-5 (American Psychiatric Association, 2013, p. 157) mentions "some researchers" (no citation) who "view severe, non-episodic irritability as characteristic of bipolar disorder." This may be an oblique reference to the Massachusetts General group's earlier work, although it should be noted that the full mania criteria (not just chronic irritability) were used in their studies (Biederman et al., 1995; Wozniak et al., 1995). It is further stated in DSM-5 that "the term bipolar disorder is explicitly reserved for episodic presentations of bipolar symptoms" (p. 157). Thus, DSM-5 has "doubled-down" on the 19th-century definition of Emil Kraepelin of the manic episode. But what is an "episode?" A patient must have an elevated, expansive or irritable mood (1 week for mania, 4 days for hypomania) with three or more of the associated symptoms (grandiosity, decreased need for sleep, increased talkativeness, flight of ideas, increased goal-directed activity or risky behaviors). Rather than diagnose children and adolescents with ADHD who have chronic irritability/aggression alone with BP, clinicians should begin using DMDD for this group. This section focuses on those with ADHD who meet the classic criteria for a manic episode, although we must accept the word of the researchers that their samples contain patients who have distinct cycles of mood disturbance as identified by structured interviews, such as the K-SADS.

Pataki and Carlson (2013) reviewed a number of major issues concerning the comorbidity of ADHD and BP. They noted that community samples show very low rates of BP in children with ADHD (0–2%), while studies in tertiary-care clinics show comorbidity rates of 11–30%. In contrast, preadolescent children with BP have ADHD at rates of 75–95%. In the Longitudinal Assessment of Manic Symptoms (LAMS; Arnold et al., 2011) study, a Mania Screening scale was administered to over 2,600 parents of patients (ages 6–12) presenting to several academic child psychiatry clinics; 1,124 screened high for mania, while about 1,500 did not. Children from the high (n = 621) and low (n = 86) mania screening groups underwent an in-depth psychiatric interview, and BP was diagnosed only if the manic episodes were episodic. The authors found that 60% of the sample met criteria for ADHD without BP, only 6.3% met criteria for BP without ADHD, 16.5% had both ADHD and BP, and the remaining 17.5% did not meet criteria for either diagnosis. Parent K-SADS established the diagnosis in this study; it was interesting that teacher ratings of mania were elevated only in the two ADHD groups and that the ADHD + BP and ADHD – BP groups did not differ from each other. More striking, the BP-only group had lower mania ratings than the ADHD-only group. Pataki and Carlson asked how mania could only present at home. This shows the lack of clear research or clinical consensus on how to aggregate data from different sources to make a diagnosis.

Table 5.2 suggests ways for the clinician to distinguish between the various comorbid mood diagnoses that can present with ADHD. As Carlson (2007) pointed out, the differential diagnosis is not *between* ADHD and BP; the question is whether the aggression and mood lability meet the criteria for BP. As shown in Table 5.2, severe ADHD, ADHD with ODD/ intermittent explosive disorder (IED), and ADHD/BP are all characterized by increases in motor activity, distractibility, and excessive talking, so these factors cannot be used to distinguish the conditions. Caretakers often view ADHD (combined type) children as energetic, but those with ADHD/BP show marked increased in energy ("They never wear out," "Everyone else in the family is exhausted"). In DSM-5, it is now imperative to separate the chronic irritability of DMDD from the episodic manic episodes of BP. Sleep can be disturbed in all children with ADHD (trouble going to bed and a tendency to sleep late), but only those with ADHD/BP show a true *decreased need* for sleep. It is the core symptoms of mania that truly distinguish BP from ODD or mood dysregulation (B. Geller, Tillman, Craney, & Bolhofner, 2004; B. Geller, Warner, Williams, & Zimmerman, 1998; B. Geller, Williams, et al., 1998). What is the difference between excessive talking and pressured speech? Children with ADHD often engage in more random speech at inappropriate times (talking in class or in church). Yet when they must engage in goal-directed speech, they often are less talkative (e.g., during the clinician interview). In contrast, children with BP talk over the examiner, use more words, and clearly have an increased *rate and volume* of speech. Patients with ADHD/ODD/IED are often perceived as

TABLE 5.2. Differential Diagnosis of Mood Lability and Aggression in ADHD

	"Severe" ADHD	ADHD + IED or ODD/CD	ADHD + DMDD	ADHD and BP
Motor activity	Increased	Increased	Increased	Increased
Distractibility	Increased	Increased	Increased	Increased
Excessive talking	Increased	Increased	Increased	Increased
Energy	Increased	Increased	Increased	Markedly Increased
Anger outbursts	None	Intense, but time limited, interoutburst mood within normal limits	Severe outbursts at least three times a week in at least two settings	Prolonged, affective storms, "walking on egg shells"
General mood	Euthymic	Irritable only when frustrated	Chronic irritability/ sadness	Pervasive abnormal mood over weeks, but distinct episodes
Sleep	Erratic bedtime and wake up time, sleeps 8-10 hours	"Night owl"—particularly in adolescents; sleeps 8–10 hours	"Night owl"—particularly in adolescents; sleeps 8–10 hours	Sleeps 6 hours a night or less
Core mania symptoms				
Pressured speech	Absent	Absent	Absent	Present
Flight of ideas	Absent	Absent	Absent	Present
Grandiosity	Absent	Absent	Absent	"Full of self"
Sexuality	Absent	Early sexual activity	Early sexual activity	Abnormal sex acts
Judgment/risks	Immature	Antisocial risks	Absent	Dangerous acts
Elation/silliness	Limited	Limited	Limited	Present
Psychosis	Absent	Absent	Absent	Often present

arrogant and as lacking remorse, but the patient with BP lacks any realistic awareness of his or her capabilities. Although frank delusions of grandeur are rare in children and teens, beliefs that one can do whatever one wants are often a key symptom. A child with ODD knows he or she will fail a test (and does not care), whereas a child with BP may be fully convinced that he or she will make an "A" even without having studied or going to class. Children and teens with BP often hold completely unrealistic fantasies about what will happen in the future and plan their lives around them. Children with ADHD often tend to initiate sexual activity earlier than non-ADHD peers, but there is nothing hypersexual about their behavior. Children with BP engage in age-inappropriate sex play and obsession with pornography (especially on the Internet). Psychosis, particularly if the delusions or hallucinations have a grandiose character, strongly suggests mania. Psychosis is absent in ODD, CD, and DMDD.

A major concern for many clinicians is that treatment of ADHD will make a child with BP worse. Will stimulant treatment of ADHD in a child at risk for BP (due to either family history of mood disorder or the presence of mood dysregulation) induce a manic episode? Galanter and colleagues (2003) examined the stimulant response of children in the MTA who showed high levels of manic-like symptoms (but were not diagnosed with BP). They found that in this subgroup, the response of ADHD symptoms to stimulants was just as robust as that in the "euthymic" children with ADHD, with no evidence of mood destabilization. After reviewing four studies that showed no evidence of emerging manic symptoms in children with ADHD treated with stimulants, Goldsmith, Singh, and Chang (2011) concluded, "Collectively, these findings suggest that psychostimulant exposure is not instrumental in the development of BD. Moreover, ADHD symptom severity at the time of presentation may be the pri-

mary predictor of psychostimulant treatment, which also does not predict a greater chance of BD outcome" (p. 228). There is widespread consensus that a patient with acute mania should undergo mood stabilization treatment before attempting treatment of ADHD (Pataki & Carlson, 2013; Pliszka, 2009). Three placebo-controlled studies (Findling et al., 2007; Scheffer, Kowatch, Carmody, & Rush, 2005; Zeni, Tramontina, Ketzer, Pheula, & Rohde, 2009) found that once mood is stable, stimulants can be combined with mood stabilizers without causing relapse of mania.

DEPRESSION

Regarding the comorbidity of depression and ADHD, in this review I move beyond irritability and aggression to focus on those individuals who have ADHD and full DSM-5 criteria for major depressive disorder (MDD) or persistent depressive disorder (as dysthymia has been renamed). DSM-5 continues to allow clinicians to diagnose MDD in youth using irritable mood as well as depression as criteria; the abnormal mood must be persistent and associated with four of these other criteria (loss of interest, weight loss, sleep disturbance, agitation/retardation, fatigue, low self-esteem, diminished concentration, suicidal ideation/attempts). When a patient has ADHD, the concentration problems related to depression must be above and beyond those attributable to the ADHD. Up to one-third of children with ADHD may meet criteria for depression, while one-fourth to one-half of children with depression have ADHD (Angold & Costello, 1993; Pliszka et al., 1999). On the other hand, some studies show no overlap at all between ADHD and depression (McGee et al., 1990). This variation in prevalence is related to sample type (community vs. clinical), different methods of eliciting depressive symptoms, and type of informant (parent vs. child).

Daviss (2008) reviewed the literature regarding the comorbidity of depression and ADHD. Compared to those with depression alone, youth with comorbid ADHD and depression show greater impairments in social functioning, earlier age of onset of depression (in females), and higher rates of suicidality and reoccurrence of depression. Adolescents with ADHD and depression have higher levels of family conflict, more negative life events, and more trauma exposure than do those with ADHD and no depression. Blackman, Ostrander, and Herman (2005) compared their sample of depressed and nondepressed children with ADHD to healthy controls on a variety of measures. Depressed children with ADHD were not different from nondepressed subjects in terms of hyperactivity, conduct problems, or aggression, but they did have greater problems with social competence. The relationship between ADHD, depression, and suicidality is complex. Youth with ADHD do have higher rates of suicidal ideation and deliberate self-harm than controls, even after researchers control for gender, substance abuse, and behavioral problems (Hurtig, Taanila, Moilanen, Nordstrom, & Ebeling, 2012). However, the depressed youth with both ADHD and disruptive behavior disorder remains at the highest risk for suicide (James, Lai, & Dahl, 2004; also see Chapter 11).

Is there any etiological relationship between ADHD and depression? Many children with ADHD in fact have positive illusory biases that "protect" their self-esteem from the consequences of their behavior and predict poor response to psychosocial intervention (Mikami, Calhoun, & Abikoff, 2010; see Chapter 4). Thus, it is unlikely that the high rate of depression in ADHD is related to the "demoralization" of living with ADHD (Biederman et al., 1998). Family studies reveal a pattern in which patients with ADHD alone have a higher than expected rate of depressive disorders in their relatives; conversely, patients with depression alone have a higher than expected rate of ADHD (Faraone & Biederman, 1997). This suggests that the disorders share genetic factors.

There have been only limited post hoc analyses of antidepressant clinical trial data as to whether the presence of ADHD affects treatment outcome, and the results are contradictory (Daviss, 2008). In contrast, there is no evidence that early treatment of ADHD with stimulants predisposes a patient to future depressive episodes (Daviss, Birmaher, Diler, & Mintz, 2008; Staikova, Marks, Miller, Newcorn, & Halperin, 2010). Studies of the treatment of comorbid depression and ADHD are also very limited. Findling (1996) found that a combination of stimulants and specific serotonin reuptake inhibitors were well tolerated in seven patients, ages 10–16 years, with comorbid ADHD and MDD. An open-label study of bupropion in 24 adolescents with comorbid ADHD and MDD revealed an 88% response rate for depression and a 63% response rate for ADHD (Daviss et al., 2001). Kratochvil and colleagues (2005) randomized 173 youth with comorbid ADHD and depression to either placebo or fluoxetine for 8 weeks, with both groups receiving atomoxetine during the final 5 weeks of the study. Depression and ADHD symptoms were reduced in both groups, with no clinically mean-

ingful differences between them at endpoint. A large group (n = 142) of adolescents with ADHD and MDD were randomized to either placebo or atomoxetine for 9 weeks in a double-blind design. Symptoms of ADHD were significantly improved on atomoxetine relative to placebo at endpoint, but both groups improved over the study in terms of depression (Bangs et al., 2007). It has become standard clinical practice to combine stimulants and antidepressants in the treatment of comorbid ADHD and MDD, with the more severe disorder being treated first (Pliszka et al., 2006).

ANXIETY DISORDER AND POSTTRAUMATIC STRESS DISORDERS

Estimates of the prevalence of anxiety disorders in children with ADHD have ranged from 25 to 50%, compared to the prevalence of about 6–20% in the general pediatric population (Costello, Egger, & Angold, 2004). Thus, the OR of having an anxiety disorder is 2.1–4.3 greater in children with ADHD relative to the general population (Angold et al., 1999). Children with anxiety disorder also have higher than expected rates of ADHD (Last, Hersen, Kazdin, Finkelstein, & Strauss, 1987), as do adults with panic disorder (Fones, Pollack, Susswein, & Otto, 2000; Safren, Lanka, Otto, & Pollack, 2001). Adults with ADHD also show high rates of anxiety disorders relative to the general population (Biederman et al., 1993).

When children with ADHD and anxiety disorders are compared to those with anxiety disorder alone, no differences emerge in subtype or severity of the anxiety itself. That is, ADHD does not have any moderating effect on the anxiety disorders (Hammerness et al., 2010). Sleep disorders are increased in people with ADHD and anxiety relative to those with ADHD without anxiety; the latter in turn have more sleep problems than do controls (Accardo et al., 2012; Hansen, Skirbekk, Oerbeck, Richter, & Kristensen, 2011). Studies have been inconsistent as to whether ADHD with and without anxiety differs in terms of the presence of other disruptive behavior disorders. One study found a lower rate of CD (Pliszka, 1989), while most studies have found no difference in the rate of ODD or CD (Becker, Luebbe, Stoppelbein, Greening, & Fite, 2012; Biederman, Faraone, Keenan, Steingard, & Tsuang, 1991; Pliszka, 1992; Vloet, Konrad, Herpertz-Dahlmann, Polier, & Gunther, 2010). Still other studies have shown increased rates of ODD/CD in the ADHD with anxiety group relative to those with ADHD alone (Humphreys, Aguirre, & Lee, 2012; Newcorn et al., 2001; Tannock, 2000). Differences in these studies may relate to both sample source (community vs. clinical) and interview method. In highly structured interviews, parents of those with ADHD and ODD/CD may interpret irritability as anxiety, whereas clinical interview methods that include child self-report rule out the anxiety disorder in ODD/CD because the child denies anxiety having when asked directly.

How anxiety affects the cognitive and behavioral aspects of ADHD may well depend on whether the child has an additional comorbid disruptive behavior disorder. Newcorn and colleagues (2001) examined continuous performance test errors in children with ADHD in the MTA, stratified by comorbidity. The ADHD/anxiety group showed decreased impulsivity and dyscontrol errors relative to the other ADHD groups. This effect was moderated by gender: Only girls with ADHD/anxiety showed this pattern. Cases with ADHD/anxiety *and* ODD/CD were as impulsive on this measure as those with ADHD alone. Teachers also rated children with ADHD/anxiety as less impulsive than either the ADHD-only or dual-comorbid group. On the other hand, parents rated children with ADHD/anxiety + ODD/CD as *more* impulsive and hyperactive than those with ADHD alone. One recent study has shown that anxiety aggravates behavioral dysregulation as assessed by parent report (Sørensen, Plessen, Nicholas, & Lundervold, 2011), while another showed no effect of anxiety on a computerized measure of impulse control in children with ADHD (Vloet et al., 2010) Vloet and colleagues (2010) also found, however, that performance on attentional measures was *improved* in those with ADHD and anxiety relative to the ADHD only group. Both of these studies included both ADHD/anxiety and ADHD/anxiety/ODD/CD groups and did not examine the triple-comorbid groups separately.

Stimulant treatment does not worsen anxiety in the comorbid group (Pliszka, 1989), and one study in adults with ADHD indicates that it may actually reduce anxiety (Gabriel, 2010). Children with ADHD and anxiety were more likely to have a placebo response (Pliszka, 1989). This was not confirmed by the MTA (MTA Cooperative Group, 1999b), in which children with ADHD/anxiety showed a positive response to methylphenidate, as did those without anxiety. Interestingly, those subjects with ADHD/anxiety (but not ODD/CD) had a more robust response to the behavioral intervention by itself relative to nonanxious children with ADHD. The subgroup with triple comorbidity (ADHD + ODD/CD + anxiety) was more likely to benefit from the combination treatment of the behavioral

intervention and medication relative to the children with ADHD alone. In a further analysis of the MTA treatment outcome data, March and colleagues (2000) found that parent-reported anxiety alone was a moderator; there was no relationship between the children's self-report of anxiety and treatment outcome. Parent-reported anxiety was strongly related to the comorbidity of ODD/CD and to the phenomena of "negative affectivity," rather than fears and phobia. Thus, March and colleagues hypothesized that the strong behavioral management focus of the MTA psychosocial intervention was helpful for children with ADHD/anxiety and ODD/CD because it helped the parent manage such negativity.

How and when should anxiety in the presence of ADHD be treated pharmacologically? Numerous studies have established the efficacy of specific serotonin reuptake inhibitors in the treatment of a variety of child and adolescent anxiety disorders (Pliszka, 2011). But since these agents do not treat ADHD, they must be combined with a stimulant. Abikoff and colleagues (2005) treated 32 children with ADHD/anxiety with methylphenidate and found that 26 (81%) responded with respect to ADHD but remained anxious. Twenty-five children were then randomized to either placebo or fluvoxamine (while remaining on methylphenidate) for 8 weeks. At the end of the study period, there was no difference between the treatment groups in terms of anxiety. Thus, the efficacy of this approach remains to be established. Alternatively, atomoxetine may treat both ADHD and anxiety. A large sample (n = 162) of children with ADHD/anxiety were randomized to receive either atomoxetine or placebo for 12 weeks in a double-blind, placebo-controlled, parallel-groups design (D. A. Geller et al., 2007). An ADHD rating scale and an anxiety scale were used to assess the different comorbid symptoms over the course of the trial. *Both* ADHD and anxiety symptoms were reduced significantly on atomoxetine relative to placebo; clinicians also rated those children on atomoxetine as showing greater global improvement. Cognitive-behavioral therapy is a highly effective treatment for a variety of childhood anxiety disorders (Pliszka, 2011), so it also may be combined with pharmacological treatment of ADHD in order to address both problems.

The relationship between ADHD and posttraumatic stress disorder (PTSD) is complex. Wozniak and colleagues (1999) found no statistically significant difference in the rate of trauma exposure between an ADHD sample (12%) and controls (7%). While MDD was associated with exposure to trauma, ADHD was not, and exposure to trauma was rare in this sample. Ford and colleagues (Ford et al., 1999, 2000) examined the problem from a different angle, looking at a large sample of children treated in an outpatient clinic for trauma exposure. Once they controlled for a variety of family factors associated with trauma (parental psychopathology, social adversity, poor parenting), they found PTSD to be associated primarily with ODD rather than with ADHD itself. Only 6% of the children with ADHD alone had PTSD, compared to 22% of the children with ADHD and ODD. Nonetheless, recent studies have shown an increased risk of PTSD in adults with ADHD (Adler, Kunz, Chua, Rotrosen, & Resnick, 2004; Kessler et al., 2006). Biederman and colleagues (2013) obtained a large battery of psychiatric and neuropsychological measures on 271 youth with ADHD and 230 controls and their siblings both at baseline and at follow up 4–11 years later. Rates of PTSD were significantly higher in those with ADHD (5.2%) than in controls (1.7%). Comorbidity of PTSD did not affect the age of onset, severity, or nature of symptoms of ADHD; mean age of onset of PTSD was significantly later than that of the ADHD symptoms. Those with ADHD and PTSD also had higher rates of other disruptive, anxiety, and mood disorders. PTSD was not elevated in the siblings of those with ADHD alone, whereas ADHD was increased in the siblings of those with both ADHD and ADHD + PTSD. The latter finding (together with the age of onset of PTSD vs. ADHD) indicates that it is unlikely that ADHD is in fact an underlying or masked form of PTSD. ADHD is a risk factor for PTSD, however, and the two disorders may share familial etiological factors.

TIC DISORDER AND OBSESSIVE–COMPULSIVE DISORDER

There is a genetic link between tic disorder and obsessive–compulsive disorder (OCD) because individuals with OCD have a higher than expected number of relatives with tic disorder and vice versa (Pauls et al., 1995; Pauls, Leckman, & Cohen, 1993). Roughly 13–26% of patients with OCD have tic disorders (D. A. Geller, 2006), while up to 50% of patients with full-blown Tourette syndrome have symptoms of OCD (Swain, Scahill, Lombroso, King, & Leckman, 2007). Simple and transient tics are quite common in the pediatric population, affecting 6–20% of all children (Khalifa & von Knorring, 2005), while prevalence of chronic motor tics and Tourette syndrome combined is 1.2% (Kraft et al., 2012). Onset of tic disorder is gener-

ally between ages 3 and 5 years, with peak prevalence at 9–12 years. Only about 20% of children continue to experience tics in adulthood (Bloch et al., 2006; Swain et al., 2007). Whereas 50 to 60% of children with tic disorders have ADHD (Rothenberger, Roessner, Banaschewski, & Leckman, 2007), only about 10% of children with ADHD have a tic disorder (MTA Cooperative Group, 1999a).

Reviewing the extensive clinical and neuropsychological literature on the overlap of ADHD and tic disorders, Rothenberger and colleagues (2007) concluded the following:

- Tic disorders and ADHD are not alternative phenotypes of a single underlying genetic cause; ADHD with tic disorder may be a separate etiological entity.
- In comorbid ADHD and tic disorder, ADHD is associated not with tic severity but with learning problems, disruptive behavior disorders, and social dysfunction.
- The presence of tic disorder does not have any impact on the symptoms or severity of the ADHD itself. Greimel, Herpertz-Dahlmann, Gunther, Vitt, and Konrad (2008) did not find any differences between children with ADHD with and without tics on several laboratory measures of impulsivity, executive function, and sustained attention.

The natural course of tic disorder parallels the time that children with ADHD are likely to start and stop stimulant treatment, and this may have led to the false belief that stimulants "unmask" or "cause" tics. Ninety-one children with ADHD, with and without comorbid tics (but who did not have a formal tic disorder), were randomly assigned to receive stimulant or placebo in a 1-year prospective study (Law & Schachar, 1999). New tics developed in 19.6% of the children without preexisting tics who received methylphendiate and in 16.7% of those receiving placebo. Deterioration of tics was observed in 33% of children with preexisting tics who received methylphenidate and in 33% of those who received placebo. Thus, contrary to common clinical lore, stimulant treatment did not lead to an increase in tics. Perhaps even more surprising, multiple controlled studies of patients with comorbid ADHD and tic disorders have failed to show any increase of tics when on stimulant relative to placebo (Bloch, Panza, Landeros-Weisenberger, & Leckman, 2009). Tricyclic antidepressants and atomoxetine reduced tics relative to placebo (Allen et al., 2005; Spencer, Biederman, Kerman, Steingard, & Wilens, 1993). In a multicenter, randomized, double-blind clinical trial, 136 children with ADHD and chronic tic disorder were randomly administered clonidine alone, methylphenidate alone, a combination of the two, or placebo in a 2×2 factorial design for 16 weeks (Tourette's Syndrome Study Group, 2002). For the primary outcome measure of ADHD, significant improvement occurred for subjects assigned to clonidine and those assigned to methylphenidate. Compared with placebo, the greatest benefit occurred with the combination of clonidine and methylphenidate. Worsening of tics was no higher in those treated with methylphenidate (20%) than in those administered clonidine alone (26%) or placebo (22%). Remarkably, when compared with placebo, measured tic severity lessened in all active treatment groups, with the greatest reduction of tics found in those treated with the combination of clonidine and methylphenidate. In those patients whose tics remain problematic when the ADHD is treated with stimulant, adding an alpha agonist such as clonidine or guanfacine is an effective strategy.

While OCD is not found at elevated rates in patients with ADHD, 51% of children and 36% of adolescents with OCD also meet criteria for ADHD. The ADHD in these cases is not accounted for as an epiphenomena of the OCD itself (i.e., as obsessions distracting the patient) (D. Geller et al., 1998; D. A. Geller, 2006; D. A. Geller et al., 2002). Examining the triple comorbidity of ADHD, tic disorder, and OCD adds a layer of complexity. Using a worldwide database on patients with tic disorders, Freeman (2007) found that 21% of children with ADHD and Tourette syndrome also had OCD relative to 16% of those with Tourette syndrome who did not have ADHD. Masi and colleagues (2006) compared children with ADHD, ADHD/OCD, and controls in terms of OCD symptoms, psychiatric diagnoses, and social functioning. Children with and without ADHD did not differ in prevalence of ordering, aggressive, contamination, or hoarding obsessions. Those with ADHD/OCD had generally poorer social functioning compared to those with OCD only; they also had a higher prevalence of bipolar, tic, and oppositional disorders, but a lower prevalence of depression. Similarly, Sukhodolsky and colleagues (2005) found that children with ADHD/OCD have poorer social skills both at home and school, less family cohesion, and higher ratings of internalizing symptoms than children with OCD only (who in turn were more impaired on these measures than controls). As with tic disorders, the greater impairment of the ADHD/OCD

was driven primarily by the presence of the ADHD and other externalizing diagnoses associated with it, rather than any unique interaction of the ADHD and OCD symptomatology. Family studies have looked at the rate of both OCD and ADHD in the relatives of children with OCD alone, ADHD alone, and those with ADHD/OCD compared to controls (D. Geller et al., 2007a, 2007b). Again, as with tics, the rate of ADHD is elevated in the relatives of patients with ADHD, and OCD is elevated in the relatives of patients with OCD, but ADHD/OCD combined is only found in relatives of those patients with ADHD/OCD (cosegregation).

SUBSTANCE ABUSE

A more complete discussion of substance use and abuse in ADHD can be found in Chapter 11. A meta-analysis of longitudinal studies shows clearly that ADHD is a risk factor for future nicotine (OR = 2.36), alcohol (OR = 1.35), and cannabis (OR = 1.51) abuse, with less precise but still elevated risk of abuse of the other psychoactive substances (Charach, Yeung, Climans, & Lillie, 2011). As noted in Chapter 11, the comorbidity of CD in childhood is the strongest predictor of future substance use/abuse. Of interest, a number of other clinical features (family history of substance use disorder, executive function defects) have not been found to predict substance use (Wilens et al., 2011; Wilens & Morrison, 2011). Exposure to maternal substance abuse increases a youth's later risk for substance abuse, but ADHD does not further increase this risk (Yule, Wilens, Martelon, Simon, & Biederman, 2013). Prenatal exposure to nicotine increases the risk for neurodevelopmental disorders and future substance abuse (Ernst, Moolchan, & Robinson, 2001). In a large community sample in Europe (which excluded subjects with any psychiatric disorder, including ADHD), smoking during pregnancy was associated with greater inattention and increased smoking in the adolescent. During a reward task, subjects exposed to prenatal nicotine had reduced activation of the ventral striatum on fMRI (Muller et al., 2013), a pattern also seen in adolescents with ADHD (Scheres, Milham, Knutson, & Castellanos, 2007).

A meta-analysis indicated that treatment of ADHD with stimulants in childhood does not increase the risk of later substance use, though it also may not provide a protective factor (Humphreys, Eng, & Lee, 2013). What about the acute treatment of youth who have comorbid ADHD and substance abuse? Riggs, Hall, Mikulich-Gilbertson, Lohman, and Kayser (2004) randomized 69 adolescents with CD, substance use, and ADHD to a 12-week clinical trial of pemoline (n = 35) or placebo (n = 34). Pemoline was more effective than placebo for ADHD symptoms, but it had no effect on substance use. Over 300 youth with ADHD and substance use were randomized to either placebo or osmotic, controlled-release oral delivery system (OROS) methylphenidate; all subjects received cognitive-behavioral therapy aimed at the substance use. The stimulant reduced parent- but not youth-rated ADHD symptoms relative to placebo, but both groups showed similar declines in substance use. Similar results were found in a placebo-controlled trial of atomoxetine for comorbid ADHD and substance use (Thurstone, Riggs, Salomonsen-Sautel, & Mikulich-Gilbertson, 2010). Thus, ADHD that is comorbid with substance abuse can be treated pharmacologically without further increasing or decreasing substance use.

INTELLECTUAL DISABILITY

ADHD occurs in children with intellectual disability (ID) at prevalence rates of 18–40%, compared to 7–10% in the general population (Epstein, Cullinan, & Polloway, 1986; Koller, Richardson, Katz, & McLaren, 1983; Pearson & Aman, 1994). Several large-scale studies that examined the prevalence of ADHD symptoms in those with ID have concluded that the increased rate cannot be accounted for by rater bias or by confounding associations with other psychiatric conditions (Hastings, Beck, Daley, & Hill, 2005; Simonoff, Pickles, Wood, Gringras, & Chadwick, 2007). The presence or absence of ADHD is not related to the underlying etiology of the ID (Pliszka, 2009).

Over the last 15 years, at least 20 randomized controlled trials have examined the effects of methylphenidate in children with ADHD who have comorbid ID (see Handen & Gilchrist, 2006, for a review). The response rate to methylphenidate (45–66%) significantly exceeds that of placebo and is only slightly below the response rate for typically developing children with ADHD. Some studies have shown that an IQ above 50 predicts a better response to stimulant medication (Aman, Kern, McGhee, & Arnold, 1993; Aman, Marks, Turbott, Wilsher, & Merry, 1991) and that very low IQ levels (severe, profound) predict a poorer response (Aman, Buican, & Arnold, 2003). There is evidence that children with ADHD and ID are at a higher risk for both tics and social withdrawal than are typically developing children (Handen, Feldman, Gosling,

Breaux, & McAuliffe, 1991). While somewhat more conservative dose titration would be wise in this population, ADHD should not be left untreated in the child with ID; clinicians and families should never dismiss the symptoms of ADHD as "normal" for a child with ID because of a reduced mental age.

AUTISM SPECTRUM DISORDERS

DSM-5 combines autistic disorder, Asperger's syndrome, and pervasive developmental disorder into the single category autism spectrum disorder (ASD). It also removed ASD as an exclusionary criterion for the diagnosis of ADHD—a criterion that both clinicians and researchers have long ignored. Reviews of prevalence studies have shown that 30–80% of individuals with ASD meet criteria for ADHD, and those with ADHD have ASD traits above the levels in the general population (Rommelse, Franke, Geurts, Hartman, & Buitelaar, 2010). The study of ADHD and ASD is of particular interest because these two disorders, once thought exclusionary of each other, are increasingly thought to share clinical and etiological factors (Rommelse, Geurts, Franke, Buitelaar, & Hartman, 2011). This review notes that ADHD and ASD both have early onset (though the onset of ADHD is earlier), high heritability, comorbidity with learning/language problems, and shared genes. In twin studies, ADHD and ASD traits can be assessed dimensionally; the latter is typically done with an instrument such as the Social Communication Questionnaire (SCQ). In children, correlations between ASD and ADHD traits are .54 for parent ratings and .51 for teacher ratings, with estimates of genetic correlations of greater than .5 (Constantino, Hudziak, & Todd, 2003). In young adult twins, the genetic correlation between ADHD and ASD traits on self-report scales was .72 (Reiersen & Todd, 2008). Some caution is required, however, since some items on social questionnaire scales (e.g., "Does not understand others' feelings") may be rated higher in children with ADHD due to the comorbidity of ODD or CD rather than to autistic lack of empathy.

The relationship between ASD and ADHD was explored by performing LCA on data from the Conners Parent Rating Scale—Revised, Long version (CPRS-R:L) and the SCQ obtained from a community sample of 644 participants ages 6–17 years (van der Meer et al., 2012). The participants did not undergo a clinical interview to formally make either diagnosis. The LCA study can show that different symptom ratings group together to form identifiable subsets of diagnoses. About 65% of the sample fell into the normal range on both scales. Sixteen percent of the sample had scores on the CPRS-R:L in the clinical range for ADHD but minimal ASD symptoms. *No* class of children that emerged had only ASD symptoms without ADHD symptoms. Those with elevated ASD symptoms fell into two classes: those with predominately ADHD symptoms with significant ASD problems (ADHD + ASD, 9.2%) and those with more prominent ASD symptoms with problematic ADHD symptoms (ASD + ADHD, 9.0%). Many of these children were unlikely to meet criteria for a formal diagnosis of ADHD or ASD (i.e., the study should *not* be interpreted to mean that 35% of the population meet criteria for either ASD or ADHD!). The study does show that many children have significant levels of both traits. Membership in each class was related to performance on neurocognitive tasks. The ADHD class was impaired only on tasks of motor inhibition and working memory; those with ADHD/ASD were also impaired on a measure of facial emotion recognition.

Over the last several decades, multiple candidate gene, linkage, and genomewide association studies have been performed on thousands of subjects in an attempt to discover genes for both ADHD and ASD. These studies increasingly show an overlap of ADHD and ASD (Nijmeijer et al., 2009). Nijmeijer and colleagues (2009) obtained the SQCs for over 1,000 children with ADHD and their siblings (none of the subjects met formal criteria for ASD). DNA was obtained from the subjects and their parents, and multivariate quantitative trait locus (QTL) linkage was examined for ADHD and ASD symptoms to identify loci in the genome related to ADHD, ASD-like traits, or both. While none of the loci identified reached genomewide significance, the study suggested separate loci underlying ASD symptoms on chromosomes 7q, 12q, 15q, 16p, and 18p. The loci on chromosome 12, 16, and 18 were also related to ADHD, suggesting a possible genetic cause for the comorbidity. In an extensive review, Rommelse and colleagues (2010) identified 16 single-nucleotide polymorphisms (SNPs) from ADHD studies that might be involved in ASD, as well as 25 SNPs from ASD studies that could be related to ADHD.

The pharmacological treatment of ADHD in those with ASD is becoming increasingly well established. A large-scale stimulant trial has established the efficacy and safety of methylphenidate in this population (Research Units on Pediatric Psychopharmacology [RUPP]

Autism Network, 2005). Children with ASD (n = 72) received a test dose of methylphenidate; 66 of those who tolerated it were enrolled in a 4-week, double-blind crossover study of placebo and three different doses of methylphenidate. Adverse events (though none were serious or life-threatening) led to discontinuation of medication in 18% of the participants. Overall, 49% of the subjects were considered methylphenidate responders. Thus, while stimulants are helpful in reducing inattention and hyperactivity in children with ASD, one must expect more treatment failures in these children than in more typically developing children with ADHD. In an 8-week, double-blind, placebo-controlled trial of atomoxetine in 97 patients with ADHD/ASD, 21% were judged "very much improved" on active drug, compared to only 9% on placebo (p = .014) (Harfterkamp et al., 2012). Adverse events were typical of atomoxetine, but none were serious. Guanfacine significantly reduced symptoms of ADHD in patients with ASD in an open trial (Scahill et al., 2006) and was superior to placebo in a small (n = 11) controlled crossover study (Handen, Sahl, & Hardan, 2008). ADHD in the patient with ASD should be treated just as it is in the patient without ASD, with the caveat that there are likely to be more nonresponders. However, there is no evidence that severe, adverse psychiatric events are to be anticipated.

THE END OF COMORBIDITY?

Pliszka (2009) reviewed the diagnoses of 1,035 patients ages 3–18 years in a university-based child and adolescent psychiatry clinic (see Figure 5.1). Whereas only 27% had no comorbidity, many children had more than one comorbid diagnosis. Figure 5.1 shows only those with up to three diagnoses. Pliszka also noted the presence of about 40 children who had four or more diagnoses. This challenges the view of examining co-

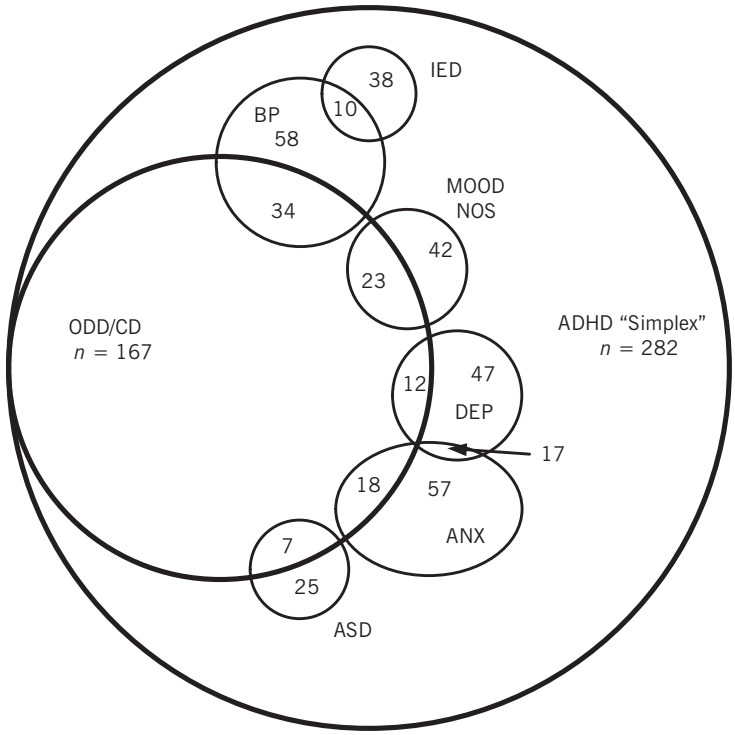

FIGURE 5.1. Overlap of diagnoses in children and adolescents with ADHD with more than one comorbid diagnosis. From Pliszka (2009). Copyright 2009 by The Guilford Press. Reprinted by permission.

morbidity from the standpoint of just one other comorbid diagnosis (i.e., ADHD + ODD or ADHD + BP). Genetic and imaging studies increasingly challenge the categorical approach to the problem of comorbidity (Faraone, 2013). Larsson and colleagues (2013) studied over 60,000 persons with ADHD and their first- and second-degree relatives, who were matched with a control group of people without ADHD and their relatives. Conditional logistic regression was used to determine the risks of bipolar disorder and schizophrenia in the relatives of the two groups. First-degree relatives of the ADHD group were at increased risk of both BP and schizophrenia. The authors suggested that the co-occurrence of ADHD and BP, as well as ADHD and schizophrenia, is due to shared genetic factors. Another large-scale study found four genetic markers that surpassed the statistical cutoff for genomewide significance for *all* five disorders: ADHD, ASD, BP, MDD, and schizophrenia (Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013). It is no longer a matter of one gene–one disorder or even separate genes for separate disorders. It would be tempting to believe that comorbidity emerges when an individual has both "ADHD genes" and "bipolar genes," but this is not case. Rather, there are risk genes that affect underlying neurodevelopment from which any of the major psychiatric disorders may emerge. Dimensional measures of ADHD are as heritable as the categorical diagnosis (70–90%) (Sherman, Iacono, & McGue, 1997). Disorders that share behavioral or cognitive features (impulsivity, working memory deficits) also may show similar abnormalities on neuroimaging studies (Pliszka, 2012). A new paradigm is needed that focuses on the principal dimensional impairments, such as inattention, impulsivity, mood regulation, social reciprocity, anxiety, negative cognitions and learning/language deficits. Each patient may vary along each dimension, with the "comorbid" individuals being impaired on multiple dimensions. These dimensions are also more likely to be related to underlying "endophenotypes," that is, neurobiological substrates which in turn are more directly related to genetic and environmental etiological factors.

KEY CLINICAL POINTS

- ✓ Between 67 and 80% or more of children and adults with ADHD have a second disorder, and many have a third disorder that coexists with their ADHD (comorbidity).
- ✓ The presence of the comorbid disorder(s) can impact current functioning, life course risks, and treatment planning, among other important clinical concerns.
- ✓ Among the most common comorbidities are ODD (45–84%) followed by CD (15–56%) and related substance use disorders, anxiety (25–50%), depression (up to 30%), disruptive mood dysregulation disorder, and to a much lesser extent BP (0–30%), PTSD (5–6%), tic disorders (10%), and OCDs.
- ✓ Among other factors, the component of dysregulation of emotion in ADHD may be a predisposing factor to and shared trait of comorbidity with ODD, anxiety, depression, and BP, among others.
- ✓ Likewise, irritability may also be a substantial risk factor for mood and anxiety disorders, as well as reactive aggression. The new diagnosis of disruptive mood disorder appears to capture this propensity for irritability and aggression, and is designed for children who previously were thought to have BP without mania. Little is known about the overlap of DMDD with ADHD and its impact on impairments, life course, and treatment planning.
- ✓ By adolescence or adulthood, some personality disorders are also more likely to be linked to ADHD.
- ✓ Children with comorbid ADHD + ODD/CD often have families with greater psychopathology and social adversity, and these children are at increased risk for antisocial activities, drug use, peer rejection, and school failure, among other adverse outcomes. They are also more likely to develop depression and anxiety disorders by adolescence.
- ✓ Children with ADHD in community samples have no higher risk for BP (0–2%) than the base rate in the population, which may also be the case for clinic-referred children with ADHD followed to adulthood. But some studies of clinic-referred children with ADHD show significantly higher risks (11–30%). Among children with BP, however, the risk for comorbid ADHD is quite high (60%+).
- ✓ The presence of BP with ADHD warrants management of the mood disorder first, before enacting ADHD-specific treatments, such as ADHD medications.
- ✓ Evidence is mixed on whether ADHD is associated with a higher risk for depression, with such risk being mediated more by comorbidity with ODD/CD, adverse life events, and parental history of depression. But 25–50% of depressed children and teens may have

comorbid ADHD, which increases their risk for suicide attempts.

- ✓ Children with ADHD and anxiety disorders may have a somewhat lower level of impulsivity, although results are mixed. Some research suggests that this comorbidity may increase positive responding to psychosocial interventions and may not be related to a reduced ADHD medication response, as was earlier believed. Nonetheless, stimulants are unlikely to manage comorbid anxiety; nonstimulants, such as atomoxetine, may be beneficial in managing anxiety in such cases. The addition of cognitive-behavioral therapy to target the anxiety symptoms might also be beneficial.
- ✓ While only a small percentage of children with ADHD have tic disorders or OCD, 50–60% of those with tic disorders and 36–51% of those with OCD may have ADHD. In this comorbidity, it is typically the ADHD that creates most of the impairments in major life activities.
- ✓ ADHD alone is a risk factor for future nicotine, alcohol, and cannabis use, while the presence of ODD/CD may further increase the risk for use and abuse of other substances. Treatment with ADHD medications does not predispose children to any risks for later substance use or abuse.
- ✓ Although children with ADHD have only a slightly greater risk for ID, cases of the latter do show elevated rates of ADHD (18–40%). The response rate of these comorbid individuals to ADHD medications is only slightly lower than that of individuals with ADHD only, unless IQ is below 50, in which case even a lower response rate may be expected.
- ✓ About 20–30% of children with ADHD may show elevated rates of ASD symptoms, while up to 30–50% of ASD cases may have comorbid ADHD. Comorbid individuals are somewhat less likely than individuals with ADHD only to respond positively to ADHD medications.

CHAPTER 6

Educational Impairments in Children with ADHD

George J. DuPaul and Joshua M. Langberg

Children and adolescents with attention-deficit/hyperactivity disorder (ADHD) frequently exhibit clinically significant educational impairment. Prevalence rates reported for learning and/or achievement problems in samples of youth with ADHD range from 50 to 80%, depending on the definition of the problem (DuPaul & Stoner, 2014). The educational impairment of children with ADHD persists into adolescence and adulthood in the vast majority of cases (e.g., 75%; Hechtman, 2000; see also Barkley, Murphy, & Fischer, 2008, Chapter 12) and is one of the main reasons individuals with ADHD are referred for assessment and treatment (Loe & Feldman, 2007). Furthermore, the long-term connection between ADHD symptoms and delinquency is largely mediated by low academic achievement (Defoe, Farrington, & Loeber, 2013), thus highlighting the critical importance of educational impairment as an assessment and intervention target for this population. As a group, children and adolescents with ADHD experience significantly lower standardized achievement scores and school grades, and higher rates of grade retention and school dropout in comparison to their same-age peers (DuPaul & Stoner, 2014). Longitudinal research demonstrates that the educational impairments of youth with ADHD are best attributed to core characteristics of the disorder, such as deficits in executive function (EF) and symptoms of inattention, rather than to comorbid conditions such as oppositional defiant disorder (ODD) or conduct disorder (CD) (Langberg, Molina, et al., 2011; Massetti et al., 2008; Miller, Nevado-Montenegro, & Hinshaw, 2012).

Although a majority of youth with ADHD experience educational impairment, there is significant variability in the presentation, severity, and causes of this impairment. For some youth with ADHD, educational impairment is largely rooted in behavioral issues, such as inattention, distractibility, and restlessness, that interfere with the ability to be productive with work completion. Youth with ADHD may also exhibit specific skills deficits that interfere with learning, such as deficits in reading or mathematics ability. Many youth with ADHD also exhibit deficits in aspects of EF, such as self-regulation, decision making, and engaging in planned sequences of goal-directed behaviors (see Chapter 4). Youth with ADHD and EF deficits often experience problems with the normal behaviors that facilitate learning and performance, such as organization of school materials and time management (Langberg, Epstein, & Graham, 2008). Each of these problems alone, or in combination, can lead to the occurrence of negative educational outcomes. Importantly, the presentation of these problems is linked to development; the

behaviors that are most salient and impairing vary with the child's age/grade and contextual demands. Given the diversity of educational impairments experienced by youth with ADHD, and the fact that they manifest differently across development, evidence-based assessment and treatment can be complex.

Accordingly, the primary goals of this chapter are to (1) identify the main educational impairments experienced by youth with ADHD; (2) describe how to measure/assess each distinct aspect of impairment; and (3) briefly review the evidence for interventions that target educational impairment (see Chapter 24 for more details regarding school-based interventions). For our purposes in this chapter, "educational impairment" is defined as *a failure to learn, progress, or perform academically at a level that could reasonably be expected given the child's age, intellectual ability, and family–school context*. Importantly, this definition takes an idiographic perspective to defining impairment, whereby if full academic potential is not being realized, then educational impairment is considered to be present, regardless of the child's standing relative to peers. This definition also limits educational impairment to the realm of academic functioning rather than broadly defining educational impairment as difficulties in school. For this reason, we do not review the assessment/treatment of problems with school-based peer relationships or interpersonal functioning except as directly related to academics (e.g., see the section "Educational Impairment Exhibited by Preschoolers").

In this chapter, we use the terms "skills deficit," "performance deficit," and "academic enablers" to describe factors related to educational impairment. The term "skills deficit" refers to a lack or absence of specific skills/abilities, such as reading or mathematics skills, at a point in time when mastery of those skills would be expected. Skills deficits are often characterized as learning disabilities (LD). In contrast, the term "performance deficit" refers to problems in demonstrating already acquired knowledge or attained skills. Specifically, the child understands the material and has the necessary skills but has difficulty demonstrating this knowledge on tests, through homework, or verbally. Finally, the term "academic enabler" encompasses a range of behaviors that facilitate the process of learning and performance, such as managing and organizing homework assignments and studying effectively (DiPerna & Elliott, 2000). It is worth noting that the distinction between performance and enabler behaviors is not always clear, and some behaviors may fit into both categories. For example, making careless mistakes is covered under performance deficits in this chapter (i.e., careless mistakes prevent the student from demonstrating knowledge) but it may also be considered an enabler (i.e., test taking skills/strategies to review and check work for accuracy). Nevertheless, when describing educational impairments in this chapter, we differentiate among skills, performance, and enablers because each may require a different assessment tool and intervention approach. Furthermore, given that educational impairments often manifest differently across development, information is presented by grade in school (i.e., preschool, elementary school, and secondary school). Impairments, assessment, and intervention for elementary and secondary school students with ADHD are discussed separately for academic skills, performance, and enablers.

DEFICITS IN EDUCATIONAL FUNCTIONING ASSOCIATED WITH ADHD

Educational Impairment Exhibited by Preschoolers

Despite the many difficulties associated with clinically significant ADHD symptoms in young children, the vast majority of research studies on this disorder have been conducted with elementary school-age children. Although issues such as rapid developmental changes between ages 2 and 6 years make diagnosis of preschool-age children appear somewhat tenuous (Lahey et al., 1998), there is ample evidence that symptoms of ADHD emerge at a very young age (e.g., Egger, Kondo, & Angold, 2006; Sterba, Egger, & Angold, 2007; Strickland et al., 2011) in many, though by no means all, cases and are associated with significant deviations in brain structure (Mahone et al., 2011). Furthermore, ADHD-related characteristics observed in young children mirror those of older children with respect to prevalence, subtypes, and gender differences, offering support for an accurate nosology.

ADHD in preschool-age children is associated with significant impairment in behavioral, social, and preacademic functioning, with affected children approximately two standard deviations below their typically developing peers in all three areas (DuPaul, McGoey, Eckert, & VanBrakle, 2001). Because ADHD tends to be chronic, at least 70–80% of preschool-age children with this disorder continue to exhibit significant ADHD symptoms during elementary school (Lahey et

al., 2004; Riddle et al., 2013). Children exhibiting high levels of hyperactive and impulsive behaviors (i.e., combined or predominantly hyperactive–impulsive presentations of ADHD) are at higher than average risk for developing other disruptive behavior disorders (i.e., ODD and CD, along with academic and social deficits; Campbell & Ewing, 1990). In addition, 59–67% of children with ADHD whose difficulties are persistent at school entry continue to show significant disruptive behavior disorder symptoms during middle childhood and early adolescence (Pierce, Ewing, & Campbell, 1999) and nearly 90% will fall short of being considered well adjusted as adolescents (Lee, Lahey, Owens, & Hinshaw, 2008).

Children's early experiences with literacy and numeracy have a significant influence on later academic skills. Specifically, children's experience with early literacy activities, such as those that increase phonemic awareness (Snow, Burns, & Griffin, 1998) and early numeracy activities (Gersten, Jordan, & Flojo, 2005), make a significant difference in their later language and literacy skills and mathematics achievement. Unfortunately, preschoolers with ADHD experience significant difficulties with early literacy and numeracy skills. For example, DuPaul and colleagues (2001) found that young children meeting diagnostic criteria for ADHD obtained significantly lower scores on a test of cognitive, developmental, and academic functioning compared to a sample of typically developing peers. On average, relative to mean scores obtained by typically developing peers, children with ADHD received scores one standard deviation below the expected mean for their age. This academic achievement gap is similar to that found for older children and adolescents with ADHD (Frazier, Youngstrom, Glutting, & Watkins, 2007) and suggests that many young children with ADHD enter kindergarten significantly behind their typically developing classmates in basic math and prereading skills (Spira & Fischel, 2005). Not surprisingly, 3- and 4-year-old children with ADHD are significantly more likely to receive special education services than their peers without ADHD (Marks et al., 2009). In fact, Marks and colleagues (2009) found that approximately 25% of their sample of children with ADHD received special education services relative to about 5% of control sample children. Of greatest concern, the educational impairments exhibited by young children with ADHD are associated with chronic underachievement in reading, math, and spelling throughout the school years (Massetti et al., 2008).

Although very few research studies have examined deficits in specific preacademic skills among preschoolers with ADHD, there appear to be at least three areas of educational functioning that may be affected: early literacy skills, early numeracy skills, and school-readiness skills and behaviors (DuPaul & Kern, 2011). Early or emergent literacy skills include three factors correlated with later reading achievement: oral language, phonological awareness and processing, and knowledge of print (Whitehurst & Lonigan, 1998). The latter two factors are particularly important in the development of early reading skills such as decoding (Lonigan et al., 1999). Several studies have shown statistically significant relationships between ADHD symptoms and emergent literacy skills (e.g., phonological sensitivity, print knowledge) in young children such that higher severity/frequency of ADHD symptoms is associated with lower performance on measures of early literacy (e.g., Lonigan et al., 1999; Sims & Lonigan, 2013). This relationship appears to be primarily accounted for by inattention symptoms as statistically significant correlations of low to moderate magnitude are typically found for measures of inattention, whereas correlations of early literacy with impulsivity (Sims & Lonigan, 2013) or hyperactivity (Lonigan et al., 1999) are near zero and not statistically significant.

Early numeracy skills include quantity comparison, oral counting, one-to-one correspondence, and number naming (Floyd, Hojnoski, & Key, 2006), as well as early geometry skills (e.g., shape naming) (Polignano & Hojnoski, 2012). The development of preschool math abilities has received much less attention relative to emergent literacy skills. In fact, we were unable to locate any studies examining the degree to which young children with ADHD exhibited deficits in specific numeracy or geometry skills beyond aforementioned lags in general math achievement scores. Based on research regarding early literacy skills, we presume that ADHD symptoms are associated with deficits in all areas of early numeracy development and that this association is particularly more pronounced in children with inattention rather than impulsivity and hyperactivity symptoms. Of course, this assumption requires greater empirical scrutiny.

The concept of school readiness includes the development of age-appropriate early academic skills (e.g., letter, number, and color recognition) as described previously, as well as self-regulatory behaviors including self- and social awareness (Bracken, 1998). Self-regulatory behaviors are very similar to academic en-

ablers (e.g., executive and organizational functioning) discussed later in this chapter in reference to elementary- and secondary-level students. Kindergarten teachers expect children to be able to follow directives, comply with rules, pay attention to instruction and assigned work, and organize classroom materials. Research studies have consistently demonstrated that young children with ADHD are approximately one standard deviation below their typically developing peers with respect to school readiness skills and behaviors (e.g., DuPaul et al., 2001). This is not surprising because ADHD symptoms, particularly in the inattention domain, overlap considerably with school readiness behaviors.

Educational Impairment Exhibited by Elementary School Students

Academic Skills

Elementary-age children with ADHD sometimes exhibit deficits in specific academic skills, such as reading or math. Meta-analyses, which combine information from all available studies, suggest that, on average, children with ADHD perform significantly below their peers in reading, math, and spelling (Frazier et al., 2007). Meta-analyses use effect sizes to quantify the magnitude of differences between groups. An effect size below 0.30 is considered a small difference, one in the 0.50 range is considered a medium difference, and an effect size around 0.80 is be considered a large effect/difference between groups (Cohen, 1988). In comparison to their peers, children with ADHD score on average 0.71 standard deviation units (i.e., a medium to large effect) lower on standardized achievements tests, which measure academic skills (Frazier et al., 2007). The largest differences appear to be associated with reading skills (d = 0.73), with moderate effect sizes reported for math (d = 0.67) and spelling (d = 0.55). There is also accumulating evidence to suggest that many youth with ADHD have significant difficulties with written expression, perhaps even to a greater extent than with reading (Mayes, Calhoun, & Crowell, 2000). Deficits in reading, math, spelling, and writing have been documented on standardized achievement tests, as well as assessed through the use of parent and teacher rating scales (Frazier et al., 2007).

It is important to note that meta-analytic studies report group-level differences, and not all elementary-age children with ADHD exhibit academic skills deficits. Furthermore, the Frazier and colleagues (2007) meta-analysis did not exclude youth with LD. Approximately, 1 in 3 children with ADHD also meet criteria for an LD (DuPaul & Stoner, 2014), with some studies reporting higher rates of overlap when problems with written expression are also considered (DuPaul, Gormley, & Laracy, 2013; Mayes et al., 2000). This relatively high comorbidity rate is important because it may be that group-level differences in academic skills are primarily driven by the one-third of the sample with ADHD that also has a comorbid LD (i.e., rather than skills deficits inherent to ADHD).

The relationship between ADHD and LD is complex, and the directionality is not entirely clear. Specifically, it may be that youth with ADHD do not acquire academic skills, such as reading and math, at the expected rate because their symptoms of inattention and distractibility interfere with learning (i.e., ADHD causes LD). Alternatively, it could be that an LD leads to a diagnosis of ADHD because children who cannot understand the subject matter being presented are likely to appear inattentive and distracted. Indeed, in samples of youth with LD, approximately 38% also meet criteria for ADHD (DuPaul et al., 2013). Likely, both scenarios occur because youth with ADHD and LD appear to share a common biological etiology and a genetic predisposition to both disorders (Willcut, Pennington, Olson, Chhabildas, & Hulslander, 2005). Regardless of the directionality of the relationship, it is clear that with 30– 45% of youth with ADHD also exhibiting sufficient skills deficits to warrant being classified as having an LD, clinicians need to be prepared to assess for skills deficits when seeking to identify causes of educational impairment.

In terms of development, early indicators of a skills deficit often include delays in speech and language development, and other prerequisites to academic achievement. For example, a young child might have a limited expressive vocabulary, "talk late," and be slow with naming objects or colors (Swanson, Harris, & Graham, 2013). In early elementary school, children with ADHD and skills deficits are often identified because they are struggling to learn to read. Specifically, children may display difficulty with phonemic awareness and other phonological processing skills, such as sound–symbol relationships or "phonics." Elementary-age children may also have difficulty with other aspects of phonological awareness, such as rhyming or syllable blending (Shanahan & Lonigan, 2010). As children progress with reading, they must learn to apply phonological and decoding skills fluently and automati-

cally. Children who are not able to apply these skills fluently often exhibit deficits with reading comprehension by middle to late elementary school (Swanson et al., 2013). In early to middle elementary school, children may also begin to exhibit difficulties acquiring math skills, such as learning math facts (e.g., addition and subtraction) and understanding concepts such as measurement (Anderson, 2010). For all academic skills (reading, math, and written language), it is important to acknowledge that students learn at different paces, and it can take some children more time than others to be able to apply skills fluently.

Academic Performance

Elementary-age children with ADHD frequently experience difficulties with accurately and efficiently completing classwork, homework, and tests. Specifically, when provided with an academic task such as a worksheet or a quiz to complete independently in a set amount of time, on average, youth with ADHD complete fewer problems and fewer problems correctly than do their peers (e.g., Atkins, Pelham, & Licht, 1985). Problems with productivity can largely be attributed to the core symptoms of ADHD, including high rates of off-task behaviors. Research has consistently demonstrated that students with ADHD exhibit significantly lower rates of on-task behavior relative to their elementary school peers (for meta-analytic review, see Kofler, Rapport, & Alderson, 2008). Differences in frequency and length of on-task behavior are evident across classroom activities (e.g., higher during small-group instruction relative to individual seatwork) and academic content (e.g., higher during less academic subjects like art and music relative to core academic subjects) (Imeraj et al., 2013). Presumably, because children with ADHD are easily distracted and frequently off-task, they are less efficient with work completion (Cantwell & Baker, 1991). Furthermore, a core symptom of ADHD is "fails to give close attention to details or makes careless mistakes in schoolwork" (American Psychiatric Association, 2013, p. 59). As such, even when children with ADHD are able to stay on-task, they often fail to pay attention to instructions, rush through assignments, and fail to check the accuracy of their work.

In terms of the relationship between ADHD symptoms and educational impairment, it is largely symptoms of inattention that drive problems with academic outcomes (i.e., as opposed to symptoms of hyperactivity and impulsivity). Multiple longitudinal studies have demonstrated that symptoms of inattention in early childhood predict academic performance throughout elementary school and into middle and high school (e.g., Langberg, Molina, et al., 2011; Massetti et al., 2008; Rapport, Scanlan, & Denney, 1999). Furthermore, the negative influence of inattention appears to increase (i.e., become more powerful) as youth move through elementary school and into middle school (Rowe & Rowe, 1992). It is also important to consider that approximately 60% of elementary-age children with ADHD meet criteria for ODD. ODD is characterized by the presence of noncompliant and defiant behaviors that can compound problems with academic productivity. Children with ADHD and ODD may actively defy parents and teachers, and refuse to start or to complete assignments.

Increasing evidence suggests that dysfunction in motivation and reward processing may also play a significant role in problems with academic productivity (e.g., Volkow et al., 2010). Specifically, children with ADHD appear to be particularly sensitive to immediate rewards and to have a difficult time getting motivated to work for rewards available in the future, even if those rewards are larger than those that are immediately available (Barkley, 1997; Sonuga-Barke, 2003). This has significant implications both for academic productivity and for engaging in academic enabler behaviors (see the next section). In terms of academic productivity, elementary-age children with ADHD frequently choose to engage in immediately rewarding behaviors (e.g., drawing, daydreaming, and talking with friends) over work completion, which is associated with delayed reward (i.e., later receiving a good grade). Stated differently, youth with ADHD seem to lack the motivation to devote sufficient time and effort to being productive with assignment/test completion because doing so is not immediately reinforcing (Barkley, 1997). The tendency of youth with ADHD to choose immediately available rewards over larger, long-term rewards has significant implications for interventions targeting educational impairment.

Academic Enablers

Even when academic skills and performance are not problematic, youth with ADHD may still experience educational impairment because of problems with academic enablers. As noted earlier, many youth with ADHD exhibit deficits in aspects of EF and have significant difficulty engaging in goal-directed behaviors

over prolonged periods of time (i.e., organization and planning behaviors). Academically, EF deficits in children with ADHD manifest as lost or misplaced homework assignments; disorganized desks and book bags; failure to record homework assignments accurately, if at all; and inefficient planning ahead to complete work (Langberg, Epstein, & Graham, 2008). The ability to organize behaviors and school materials effectively across time (i.e., plan out steps necessary to complete work) appears be particularly important for academic functioning (Abikoff & Gallagher, 2008; Langberg, Dvorsky, & Evans, 2013). Specifically, difficulties with organization of homework materials have been shown to predict the academic outcomes of youth with ADHD, above and beyond the traditional symptoms of ADHD (e.g., Langberg, Epstein, et al., 2011; Langberg, Molina, et al., 2011).

For youth with ADHD, the prominence of difficulties with academic enablers varies considerably across development, primarily as a function of changes in academic demands (e.g., workload) and in the types tasks the child is expected to manage independently. Often, by the time children reach third or fourth grade, they are expected to take some responsibility for organizing and managing their own school materials and for recording homework assignments accurately (Abikoff & Gallagher, 2008). Specifically, teachers provide fewer prompts about homework recording and are less likely to help students organize desks and book bags. Furthermore, around the same time, parents may begin to encourage their children to be more autonomous with homework management and completion. Typically, problems with materials organization and homework management (i.e., losing materials and assignments) become apparent and impairing in middle to late elementary school, whereas problems with planning, time management, note taking, and studying become more apparent in middle and high school, in which long-term assignments and cumulative exams are common (Evans, Serpell, & White, 2005).

Educational Impairment Exhibited by Secondary School Students

Academic Skills

Adolescents with ADHD continue to display significant deficits in reading, math, and spelling in comparison to their peers (d = 0.60; Frazier et al., 2007). In the Frazier and colleagues (2007) meta-analysis, the magnitude of skills deficits appeared to decrease from childhood (d = 0.75) to adolescence (d = 0.60). However, there were only seven studies of adolescents included in the meta-analysis. More recent longitudinal work confirms that skills deficits persist into adolescence and suggests that the magnitude of these deficits may actually increase. In the Multimodal Treatment Study of Children with ADHD (MTA), 436 children diagnosed with ADHD were followed into adolescence (M age = 16.6 at 8-year follow-up; Molina et al., 2009). Participants with ADHD performed significantly lower on math (d = 0.50) and reading (d = 0.65) standardized achievement tests in adolescence than did a group of matched peers without ADHD (N = 232). The magnitude of these differences is similar to what was reported in the Frazier and colleagues (2007) meta-analysis. In comparison, Massetti and colleagues (2008) compared the academic achievement of 125 children with ADHD, followed into adolescence, and 130 demographically matched comparison children, and examined the impact of ADHD subtype. Participants diagnosed with ADHD inattentive subtype (ADHD-I) in childhood exhibited significant skills deficits in adolescence in comparison to the control group, and the magnitude of the effect was large (d = 1.16 for reading; d = 1.30 for math). In contrast, comparisons between children diagnosed with ADHD combined subtype (ADHD-C) or ADHD hyperactive–impulsive subtype (ADHD-HI) and controls revealed small or nonexistent differences in academic skills in adolescence. These findings suggest that ADHD presentation/type may play an important role in predicting the persistence of skills deficits into adolescence.

In summary, academic skills deficits persist into adolescence, as measured by performance on standardized achievement tests, and these deficits are clinically significant and moderate to large in magnitude. Furthermore, inattentive symptoms appear to be the driving force in terms of predicting the maintenance of skills deficits over time (Massetti et al., 2008). It is important to note that in the longitudinal studies reviewed previously, only a small percentage of the samples continued to meet full diagnostic criteria for ADHD in adolescence (e.g., MTA = 30%; Molina et al., 2009). Therefore, it is clear that a childhood diagnosis of ADHD confers significant risk for the presence of academic skills deficits in adolescence regardless of whether the child continues to meet full diagnostic criteria for ADHD. This has also been found to be the case when these children with ADHD continue to be followed

into adulthood (Barkley et al., 2008; also see Chapter 12).

Academic Performance

Although symptoms of hyperactivity and impulsivity often decline–improve during adolescence, symptoms of inattention remain relatively stable (Hart, Lahey, Loeber, Applegate, & Frick, 1995; Martel, von Eye, & Nigg, 2012) and may actually worsen during developmental transitions (Langberg, Epstein, Altaye, et al., 2008). As such, it is not surprising that adolescents with ADHD continue to experience difficulties completing school work efficiently and effectively. In elementary school, difficulties with productivity are primarily seen in children's classwork and homework, such as while completing a math worksheet. Following the transition to middle school, grades become more heavily influenced by writing assignments, quizzes, and a few large exams, spaced-out across the academic semester (e.g., midterms/finals). Furthermore, teachers are more likely to "lecture" during class (Evans, Pelham, & Grudberg, 1995). Accordingly, adolescents with ADHD frequently exhibit problems with academic performance across a wider range of activities, including examination completion, studying for tests, homework completion, and note taking in the classroom (Evans et al., 2001). For example, an adolescent with ADHD may know how to study for tests (i.e., have the knowledge/skills set) but have significant difficulty independently remaining on-task and studying in an efficient manner. Clinically, this often presents as parents expressing concern that their adolescent is spending 2 or 3 hours per night studying and completing homework when it should take no longer than 1 hour. Similarly, adolescents with ADHD may not be productive with note taking during class and may fail to retain material from lectures adequately (Evans et al., 1995). In summary, the academic performance difficulties exhibited by children with ADHD frequently persist into middle school and high school, and become apparent across broader range of tasks.

Academic Enablers

As noted in the section "Educational Impairment Exhibited by Elementary School Students," many youth with ADHD exhibit deficits in EF, and these deficits are associated with educational impairment (Biederman et al., 2004; Miller et al., 2012). The period of early adolescence is thought to be when development of more complex EF skills, such as planning, organization, and self-regulation of these actions, takes place (Best, Miller, & Naglieri, 2011). At the same time that these skills are developing, they are becoming increasingly important for academic success. Specifically, surrounding the elementary to middle school transition, academic demands significantly increase as students are expected manage classwork, homework, and test preparation for multiple teachers (Eccles, 2004; Jacobson, Williford, & Pianta, 2011). Furthermore, students are asked to complete more long-term projects and homework assignments (e.g., book reports). These changes increase the importance of EF abilities such as goal-setting, organizing, and planning out actions in advance over extended periods of time. At the same time, parental and teacher support decline, and students are forced to self-regulate their own goal-directed organization and planning behaviors (Steinberg, 2005). Accordingly, during the period of adolescence, the EF deficits exhibited by students with ADHD often lead to significant problems with academic enablers and to additional educational impairment (Jacobson et al., 2011). In fact, academic enablers, such as homework management abilities, have been shown to mediate the relationship between ADHD symptoms of inattention and educational impairment (Langberg, Molina, et al., 2011). The meditational role for academic enablers is important because it suggests that interventions that improve ADHD symptoms will not necessarily impact educational impairment unless academic enabler behaviors also improve, thus possibly necessitating direct targeting of enablers (e.g., homework support strategies).

Academic Outcomes

Given that children diagnosed with ADHD continue to exhibit significant difficulties with academic skills, performance, and enablers into adolescence, it is not surprising that a diagnosis of ADHD is associated with numerous negative educational outcomes in adolescence and young adulthood. For example, in comparison to their peers, high school students with ADHD experience significantly higher rates of course failure, lower overall levels of class placement (Kent et al., 2011), and are more likely to drop out of school (Barkley et al., 2006). Adolescents with ADHD are also far less likely than their peers to enroll in a 4-year college (29.5% of the ADHD sample and 76.8% of the comparison sample; Kuriyan et al., 2013), and instead

are more likely to enroll in junior/community colleges (55% of the ADHD sample and 18% of the comparison sample; Kuriyan et al., 2013). Furthermore, recent research demonstrates that problems with educational impairment continue at the college level; college students with ADHD frequently struggle academically and fail to graduate (Weyandt & DuPaul, 2013; also see Chapter 12). Importantly, academic problems identified as early as elementary school have been shown to predict educational outcomes in late adolescence (Langberg, Molina, et al., 2011). As such, clinicians need to assess for problems with academic skills, productivity, and enablers accurately and comprehensively, so that interventions can be implemented and the occurrence of these negative outcomes is reduced.

MEASUREMENT OF EDUCATIONAL FUNCTIONING

Given the ubiquitous and potentially chronic educational impairment experienced by many children and adolescents with ADHD, clinicians must use psychometrically sound measures both to assess academic functioning as part of the diagnostic process and to document changes as a function of intervention. These measures and methods vary according to the purpose and focus of assessment. For example, measures used to establish impairment for the purpose of diagnosis differ from those used to assess progress with treatment. Also, assessments vary based on whether academic skills or enablers are being targeted. Finally, assessment types and content differ across age groups (preschool, elementary, and secondary). For a more general discussion of assessment of ADHD in children, see Chapter 16.

Measurement of Educational Functioning in Preschoolers

Direct assessment of early educational functioning involves both norm-referenced tests of academic achievement and school readiness, and criterion-referenced (curriculum-based) measurement of early literacy and numeracy skills (DuPaul & Kern, 2011). With respect to norm-referenced assessment, one option is to use standardized achievement tests that include normative data from preschool through high school and beyond. For example, the Woodcock–Johnson Tests of Achievement, Third Edition (WJ-III; Woodcock, McGrew, & Mather, 2001) includes 12 subtests that assess reading, math, and written expression for individuals ranging in age from 2 to 90 years. Of course, the primary limitation of the WJ-III and similar achievement tests for assessing young children is the high probability of floor effects given that most skills assessed by these measures are advanced for the preschool age group. A more developmentally appropriate option is to use norm-referenced tests of early language, math, and reading abilities such as the Bracken Basic Concepts Scale, Third Edition: Receptive (BBCS-3:R; Bracken, 2006b) and the Bracken Basic Concept Scale, Third Edition: Expressive (BBCS-3:E; Bracken, 2006a). These tests provide age-appropriate information about early academic skills, including school readiness. Furthermore, these measures provide specific assessment of school readiness, and receptive and expressive skills with normative data for children from age 3 years to age 6 years, 11 months.

Criterion-referenced tests specific to early academic skills may be of even greater value than norm-referenced achievement tests given that obtained data may translate more directly to instructional strategies and directly assess progress toward individual academic goals with treatment. For reading and language, Phonological Awareness Literacy Screening (Invernizzi, Sullivan, & Meier,, 2001) and Dynamic Indicators of Basic Early Literacy Skills (DIBELS; Kaminski & Good, 1996) have good psychometric properties with the early childhood population. Fewer measures are available for early math skills, but instruments include the Early Numeracy Skills Assessment (ENSA; Sokol, 2002) and the Preschool Numeracy Indicators (Floyd, Hojnoski, & Key, 2006; Hojnoski, Silberglitt, & Floyd, 2009).

Measurement of Educational Functioning in Elementary School Students

Assessment of educational functioning in elementary school students with ADHD may include norm-referenced achievement tests (i.e., for diagnostic purposes, to measure academic impairment relative to typically developing peers) and curriculum-based measurement (CBM) probes (i.e., for assessing treatment effects on academic skills). In addition, several methods and measures can be used to assess academic enablers and productivity, including behavior rating scales and collection of permanent products.

Norm-Referenced Achievement Tests

As described previously, on average, students with ADHD score about 0.71 standard deviation units below their typically developing peers on standardized achievement tests (Frazier et al., 2007). Thus, one way to establish whether there is educational impairment secondary to ADHD symptoms is to use a published, norm-referenced achievement test covering the basic skills areas of reading, math, and writing. Some of the more prominent standardized achievement tests include the aforementioned WJ-III (Woodcock et al., 2001), the Wechsler Individual Achievement Test, Second Edition (WIAT-II; Wechsler, 2001), and the Kaufman Test of Educational Achievement, Second Edition (K-TEA-II; Kaufman & Kaufman, 2004). All of these tests provide normative data across a wide age range with respect to reading, math, and writing skills. As such, they provide reliable and valid data regarding how a student's achievement in these areas compares with others of the same age or grade level. Specifically, clinicians can examine obtained standard scores to determine the degree to which a child is exhibiting academic impairment relative to grade-level expectations. The primary disadvantages of norm-referenced achievement tests is that they require more time and resources to administer than do other academic indices (e.g., report card grades, CBM probes) and typically are insensitive to treatment effects, at least over short periods of time, such as several weeks or months (Shapiro, 2011).

CBM Probes for Math, Reading, and Writing

Brief probes of a child's acquisition of skills being taught in the curriculum can be very helpful in several ways (Shinn, 1998). First, CBM data can pinpoint the instructional level of a child within a given subject area. In fact, one of the reasons that CBM methods were developed was to aid teachers in making instructional decisions. Thus, CBM can help determine how individual students are performing relative to expected benchmarks within the curriculum. Second, for exploring the possible diagnosis of ADHD for a given child, CBM data can help a clinician to ascertain whether a child's attention and behavior difficulties may result from the frustration of being asked to do academic work that is beyond his or her capabilities. Stated differently, it is possible that the child is being instructed at a *frustrational* rather than at an *instructional* level. It may be that a child is consistently being asked to complete work that is too easy (e.g., mastery-level material), resulting in attention problems due to boredom. This information can be very helpful in deciding whether inattention and/or hyperactivity–impulsivity difficulties are due to ADHD or are secondary to inappropriate educational placement and instruction (DuPaul & Stoner, 2014).

A third assessment purpose is to use CBM probes on a repeated basis over time to determine whether changes in instruction or implementation of intervention strategies lead to concomitant improvements in academic skills acquisition. Because CBM probes are relatively brief (2–3 minutes), it is feasible to collect these data periodically prior to and following implementation of academic or behavioral interventions, or even following initiation of pharmacotherapy. The primary index used to evaluate skills acquisition (i.e., growth) is slope; therefore, multiple data points are necessary to calculate slope reliably in each intervention phase (Shapiro, 2011). Typically, CBM data are collected two to three times per week over several weeks in order to establish slope under specific treatment conditions.

Measures of Academic Enablers and Productivity

Academic enablers and productivity are most commonly measured through parent- and teacher-completed rating scales and the collection of permanent products; best-practice procedures include a combination of these methods. Parent and teacher rating scales have been developed to evaluate a wide range of academic enabler behaviors, including homework management, homework completion, organization of materials, time management and planning, and study skills. Collection of rating scales from parents and teachers is considered best-practice because perspectives can vary considerably across informants–settings (Pelham, Fabiano, & Massetti, 2005). For example, a parent should be able to rate problems accurately during homework completion (e.g., distractibility and off-task behaviors while completing work at home), specific behaviors related to organization of materials (bringing the necessary books/materials home), and procrastination (waiting until the last minute to complete homework). In contrast, teachers may be less aware of these behaviors because they do not have the opportunity to observe the home setting (Pendergast, Watkins, & Canivez, in press),

but may be better equipped than the parent to identify problems with desk organization, being prepared for class (materials and homework), and work productivity in the classroom.

Two brief measures that focus on the ability to manage and complete homework include the Homework Problems Checklist (HPC; Anesko, Schoiock, Ramirez, & Levine, 1987) and the Homework Performance Questionnaire (HPQ; Mautone, Marshall, Costigan, Clarke, & Power, 2012; Power et al., 2006). Both of these measures include items related to the organization, management, and completion of homework materials, and have been shown to have adequate psychometric properties. Notably, only the HPQ has both parent and teacher versions (i.e., HPC is for parents only). The Children's Organizational Skills Scale (COSS; Abikoff & Gallagher, 2009) is a measure of organization, planning, and time-management skills that has parent, teacher, and child versions. Scoring the COSS yields three subscale scores that have been validated through factor analysis: Task Planning, Organized Actions, and Memory and Materials Management. Normative data are available for the COSS, and psychometric properties are adequate. The Classroom Performance Survey (CPS) is 22-item, teacher-completed measure that assesses problem behaviors commonly exhibited in the classroom by students with ADHD, including difficulties with being prepared for class, with materials organization, interacting effectively with teachers, and turning in homework assignments. A recent study of the CPS with an adolescent sample validated psychometric properties and provided normative data (Brady et al., 2012). Finally, the Academic Competence Evaluation Scales (ACES; DiPerna & Elliot, 2000) is a norm-referenced measure with student and teacher versions that measure a wide range of academic enabler behaviors, including academic motivation, study skills, and classroom engagement. The ACES has been used in multiple studies evaluating the impact of educational interventions and has good psychometric properties.

Regardless of the specific rating scales administered, permanent products should also be collected. Specifically, clinicians are encouraged to supplement rating scales with objective data, such as the percentage of homework assignments turned in daily/weekly, the percentage of classwork completed and/or completed accurately, school grades earned each semester and overall grade point average (GPA), and objective measures of binder/locker organization. The collection of these permanent products is especially important in the context of establishing treatment goals/targets and evaluating response to intervention. This is because permanent products, such as the percentage of assignments turned in daily, are going to be more sensitive to change/improvement and easier to collect repeatedly. Furthermore, permanent products, such as grades on examinations, tend to be more meaningful to stakeholders (i.e., parents and teachers).

Measurement of Educational Functioning in Secondary School Students

As was the case for elementary school students, assessment of educational functioning in secondary school students includes norm-referenced achievement tests, measures of academic enablers and productivity, and, possibly, CBM probes of academic skills.

Norm-Referenced Achievement Tests

Norm-referenced academic achievement tests can be used to assess the degree to which ADHD symptoms in adolescents are associated with academic impairment. Given the wide age and grade range for these instruments, clinicians can use the same tests that were recommended for younger children (i.e., WJ-III, WIAT, K-TEA). Obtained standard scores in reading, math, and writing can then be compared with age and grade norms to ascertain whether or not students are meeting expectations (i.e., possible impairment in academic achievement). The disadvantages of these measures are the same as for younger students, in that individual achievement testing requires time and resources. Furthermore, scores on these measures may not be sensitive to short-term treatment effects.

Other Measures of Academic Skill and Progress

Although CBM probes for secondary schools are available (e.g., Espin, Wallace, Lembke, Campbell, & Long, 2010), these measures are more limited at the secondary level because most students have progressed beyond basic skills acquisition in reading and math. Thus, other assessment techniques are necessary, particularly when documenting academic progress following intervention. One relatively crude measure of educational functioning is report card grades. Although grades have substantial face validity and are used to make high-stakes decisions (e.g., whether students pass a par-

ticular course), they are limited as measures of intervention effects because grades are typically issued on a quarterly (i.e., infrequent) basis. Another possibility is to obtain ratings of academic progress from teachers in a student's primary classes (e.g., English, math, science, and social studies). For example, the CPS was designed to assess the unique academic performance demands of secondary schools (Children and Adults with Attention Deficit Disorders [CHADD], 1996). The original CPS was a 20-item, Likert-type response measure that asked teachers to rate students' classroom behaviors pertaining to areas of strengths and weakness. A 15-item revised version of the CPS is available that comprises two factors: Academic Skills and Interpersonal Skills (Brady, Evans, Berlin, Bunford, & Kern, 2012). Both factors have been shown to have adequate reliability and validity. In particular, the Academic Skills factor can be helpful in obtaining teacher judgments regarding student educational functioning over a specific period of time.

Measures of Academic Enablers and Productivity

Each of the measures described in the previous section (e.g., HPQ, ACES) can also be utilized with secondary school students. However, as noted previously, additional enablers (e.g., time management, note-taking skills) become more relevant in middle and high school, and may need to be assessed. Furthermore, the aspects of materials organization that are most relevant often shift from organization of desks and book bags in elementary school to organization of lockers and binders in secondary school. Objective skills checklists that measure organization of binder, book bag, and locker, and time-management and planning skills have been developed and used in multiple outcome studies (e.g., Evans, Schultz, DeMars, & Davis, 2011), and are publically available (Langberg, 2011). Tools designed to evaluate the productivity and accuracy of note taking from lectures have also been developed for adolescents with ADHD (Evans et al., 1995).

In addition to the rating scales described in the previous section, the Learning and Study Strategies Inventory (LASSI; Weinstein & Palmer, 2002) is a student-completed rating scale that assesses multiple academic enablers, including time-management and study skills, use of study aids, and academic motivation. The LASSI is commonly used to evaluate academic enablers at the college level. Rating scales designed to measure EF can also be used to evaluate the academic enablers of adolescents with ADHD. For example, the Behavior Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy 2000) comprises 86 items rated on a 3-point scale (*never*, *sometimes*, *often*), with higher ratings indicating greater EF impairment. Several subscales on the BRIEF measure academic enabler behaviors, including the Planning and Organization and the Organization of Materials subscales. The BRIEF is psychometrically valid, and the Planning and Organization and Organization of Materials subscales have been shown to predict the school grades and homework problems of adolescents with ADHD (Langberg et al., 2013). As with the assessment of elementary-age students, permanent products, such as the percentage of homework turned in on time and/or hours spent completing homework, should also be collected.

INTERVENTIONS TARGETING EDUCATIONAL IMPAIRMENT

Because educational impairment is one of the most common and chronic difficulties associated with ADHD, children and adolescents with this disorder typically require early and ongoing academic support and intervention. At the very least, the effects of treatments used to address ADHD symptoms (e.g., stimulant medication, behavioral intervention) on academic skills and enablers should be assessed, so that the data can be used to make appropriate treatment decisions. Although methods commonly used to treat the educational impairments of youth ADHD are described briefly below, additional details regarding these treatment strategies are provided in other chapters (e.g., Chapter 24). Because very few research studies have specifically examined academic intervention effects for students with ADHD, we sometimes draw on empirical findings from other at-risk populations (e.g., students with LD).

Interventions to Support Development of Preacademic Skills in Preschoolers

Given the importance of reading for short-term and long-term academic achievement, many intervention approaches have been developed to enhance skills fundamental to reading development. It is important to note that no extant studies have directly assessed the effects of academic intervention strategies specifically for young children with ADHD. Thus, we have iden-

tified strategies that have been examined empirically with at-risk groups (e.g., children from low socioeconomic status [SES] families) or with the general population of preschoolers. A universal intervention that benefits all young children is for parents and teachers to embed strategies that promote early literacy into household and preschool routines and activities, respectively. For example, *Ladders to Literacy: A Preschool Activity Book* (Notari-Syverson, O'Connor, & Vadasy, 1998), can be used in preschool settings. The program offers multiple activity choices and opportunities for practice, which makes it appropriate for children at a variety of developmental levels. Activities and experiences contained in *Ladders to Literacy* fall into three broad areas that have been identified to influence children's literacy development, including print/book awareness, metalinguistic awareness, and oral language. *Ladders to Literacy* contains simple activities that are also feasible for parents and can be completed in the context of other activities (e.g., while washing the dishes or driving the car). An example of an activity is for parents to ask children to predict what will happen next when reading a familiar story.

For young children with ADHD who exhibit severe or refractory literacy deficits, more intensive early reading intervention strategies may be used, such as shared book reading (Justice, Kaderavek, Xitao, Sofka, & Hunt, 2009), phonological awareness training (Koutsoftas, Harmon, & Gray, 2009), explicit emergent literacy intervention (Justice, Chow, Capellini, Flanigan, & Colton, 2003), and computer-assisted instruction for phonological sensitivity (Lonigan et al., 2003).

One of the simplest yet most effective methods for building early reading skills is for parents and other adults to read books to children. In fact, shared book reading, without directly targeting oral language abilities, has been found to improve children's vocabulary, grammar skills, and letter-sound awareness (van Kleeck, 2008). The value of shared book reading is further enhanced when adults and children discuss story content in an interactive way. This is sometimes referred to as "dialogic reading" (Zevenbergen & Whitehurst, 2003). With interactive dialogue, shared book reading can address both decoding and comprehension skills. Comprehension skills are directly targeted by having adults ask literal (e.g., "What did the main character do?") and inferential (e.g., "How do you think the main character feels?") questions about stories and embedding scripted questions in storybooks before sharing them. Scripted questions are particularly important for adults who are less comfortable or experienced in reading to children and can structure the interaction in a way that best addresses comprehension skills. Family literacy workshops can be used to encourage parents to engage in effective book sharing techniques. In fact, Primavera (2000) found that book-sharing workshops led to significant increases in parents of low-income preschoolers reading to their children, as well as significant enhancement of children's language skills and interest in reading. Similar findings were obtained for a sample of Head Start preschoolers with language impairments, exposed to a book-sharing with embedded questions intervention twice per week over 8 weeks (van Kleeck, Vander Woude, & Hammett, 2006). In fact, moderate to large effect sizes in literal and inferential comprehension skills were found between the intervention and control groups in this study.

Comparatively little research has examined specific early intervention strategies for the development of mathematics skills, and no studies have focused specifically on effects for preschoolers with ADHD. Thus, recommended approaches have limited empirical support. The Number Worlds program (Griffin, 2007) is a promising intervention protocol that addresses early mathematics skills through direct instruction from prekindergarten through sixth grade. Mathematics is viewed as comprising three "worlds," including the world of real quantities that exist in space and time, the world of counting numbers and iconic symbols (e.g., spoken language), and the world of formal symbols (e.g., written numerals and operation signs). Number Worlds leads children through a developmental sequence that is consistent with the putative natural progression of math knowledge. The Number Worlds program has been evaluated longitudinally with several samples of children. Significant improvements in various math skills (e.g., number knowledge, computational skills) have been observed in children receiving instruction in the Number Worlds program relative to control participants (Griffin, 2007).

The early intervention for ADHD program described by DuPaul and Kern (2011) takes a similar approach to the Number Worlds program in promoting early numeracy skills. One session of group-based parent education is devoted to promoting numeracy skills, wherein parents are urged to take an active approach to incorporating numeracy learning into everyday activities. Furthermore, activities require children to manipulate objects in real-world tasks in order to make math concepts as concrete as possible. The primary

objective of home-based activities is for children to develop number sense. A child who has a well-developed number sense (1) is able to think about numbers in a variety of ways, (2) has a sense of what numbers mean, (3) is able to make comparisons, and (4) has the ability to perform mental math. Nine related number sense skills are addressed, including rote counting, quantity concepts, counting using one-to-one correspondence, representations, number identification, number naming, number writing, adding and subtracting, and fractions. In the final portion of the parent education session, parents pair up to generate ideas about possible activities for each math concept, then share these ideas with the larger group. Parents are given a homework assignment to write down four different ways that they will teach number sense skills to their children before the next parent education session. They are also asked to note how these activities worked, so that they can report back to the group at the beginning of the next session. Again, the specific effects of this strategy await controlled empirical evaluation.

Direct Interventions for Skills Deficits

As reviewed in the next section, most classroom interventions for elementary school students with ADHD have used behavioral strategies to improve academic performance and/or enablers. Over the past two decades, interventions directly targeting academic skills and abilities have been increasingly evaluated with ADHD samples. Exemplifying this point, DuPaul and Eckert (1997) conducted a meta-analysis of the school-based intervention for ADHD literature from 1971 to 1995, and found only eight studies of academic interventions over that time period (representing 12.7% of the intervention studies located for that meta-analytic review). Conversely, a meta-analysis of the more recent school-based ADHD intervention literature found 15 studies of academic intervention over the period 1996–2010, representing 25% of the available studies (DuPaul, Eckert, & Vilardo, 2012). In both meta-analyses, interventions directly targeting academic skills (e.g., peer tutoring, computer-assisted instruction) were associated with moderate to large effects on academic enabling behaviors (e.g., staying on-task, assignment completion). In fact, effect sizes associated with academic interventions were of similar magnitude to those obtained for behavioral interventions (e.g., contingent reinforcement). Academic interventions were associated with relatively small effects on reading and math skills in the earlier meta-analysis (DuPaul & Eckert, 1997), but with effect sizes of moderate magnitude in the more recent meta-analytic review (DuPaul et al., 2012). Alternatively, effects of behavioral interventions on academic skills were small in magnitude in both meta-analyses. Thus, it appears that academic interventions are valuable in terms of not only directly improving achievement but also impacting classroom behavior, perhaps to the same degree as more traditional behavioral strategies.

Academic interventions that have successfully improved reading, math, and other subject area skills of students with ADHD and related behavior disorders include peer tutoring (e.g., DuPaul, Ervin, Hook, & McGoey, 1998), computer-assisted instruction (e.g., Clarfield & Stoner, 2005), a self-regulated strategy for written expression (e.g., Lienemann & Reid, 2008), and explicit instruction (Nelson, Benner, & Boharty, 2014). These interventions are discussed in greater detail in Chapter 24.

We discuss two academic interventions in detail to illustrate the use of skills-oriented strategies in treating students with ADHD, and because these interventions provide a great example of using resources other than the classroom teacher to deliver treatment. Classwide peer tutoring (CWPT; Greenwood, Maheady, & Delquadri, 2002) involves splitting a classroom of students into two teams, then into tutoring pairs. Students in each pair take turns in the tutor and tutee roles. The tutor presents specified material (e.g., math problems), monitors tutee responses, provides praise and points for correct answers, corrects incorrect responses, and arranges for additional practice on missed items. During the 20-minute CWPT session, the teacher monitors pairs and provides bonus points for adherence to prescribed procedures and cooperative behavior. After the session is complete, students record their progress; the scores for each team are tallied, and one team is declared the winner. The CWPT procedure has been shown to enhance academic performance and reduce behavioral difficulties among students with ADHD, as well as their typically developing classmates (e.g., DuPaul et al., 1998).

Computer-assisted instruction (CAI) includes several features that may be helpful to students with ADHD. CAI can provide clear instructions, breaking measurable objectives into manageable goals that lead to immediate performance feedback. CAI can also present material with an interesting, interactive, game-like display using both visual and auditory stimuli

that highlight key information and limits distraction. CAI is particularly valuable in providing students with ADHD the opportunity to practice learned skills. Specifically, CAI has been found to increase time on-task, completion of coursework, and higher accuracy on assignments relative to typical paper-and-pencil classwork (e.g., Mautone et al., 2005). These effects have also been observed in children with comorbid ADHD and LD (Ota & DuPaul, 2002), suggesting that CAI may be helpful for students with ADHD and academic skills deficits.

Behavioral Interventions Targeting Academic Performance and Enablers

Behavior therapy/modification is the most commonly utilized evidence-based psychosocial approach for treating problems with academic performance and enablers (Pelham & Fabiano, 2008). Interventions grounded in behavior theory apply operant procedures, such as the manipulation of antecedents and consequences, to increase the occurrence of desired behaviors (Fabiano et al., 2009). Behavior modification has been used to treat children with ADHD for many years. Initially, behavior modification primarily addressed problems such as noncompliance, defiance, and off-task/productivity behaviors. Evidence-based interventions targeting these behaviors include behavioral parent training and classroom contingency management (Pelham & Fabiano, 2008). More recently, the principles of behavior modification have also been applied to problems with academic enablers, such as organization and time-management skills (see Storer, Evans, & Langberg, 2013, for a review). In general, the impact of behavior modification is large and significant for improving behavioral targets (e.g., disruptive behaviors; Fabiano et al., 2009) and small to moderate for addressing specific academic behaviors (e.g., assignment completion or reading fluency; DuPaul et al., 2012). Below, we review a few interventions that use the principles of behavior modification to address problems with work productivity and enablers (see also Chapter 24).

One of the most widely used behavior modification interventions is a Daily Report Card (DRC), which is designed to address the fact that specific, immediate, and frequent feedback is needed to facilitate behavior change in youth with ADHD. A DRC typically comprises three or four specifically defined target behaviors that a teacher monitors and tracks during the school day. Ideally, the teacher provides frequent feedback regarding the student's performance (e.g., praise and/or redirection) and sends the DRC home to parents each day after school for additional rewards/consequences to be applied (e.g., increased television time for meeting a DRC target). Disruptive classroom behaviors and academic productivity are common targets on DRCs. For example, a DRC target might be that the student completes all of the assigned classwork within the designated time and with at least 80% accuracy. Academic enabler behaviors can also be targeted on the DRC. For example, the DRC might involve the student coming prepared to class with all of the necessary materials, including a writing utensil, school binder, and completed homework. The efficacy of DRCs has been evaluated for children with ADHD as part of large, multimodal interventions (e.g., MTA; Arnold et al., 1997), as a stand-alone intervention (Owens et al., 2012), and as implemented through individualized education plans (IEPs; Fabiano et al., 2010). DRCs have been shown to improve the academic productivity and reduce disruptive classroom behaviors of children with ADHD (Fabiano et al., 2010; Owens et al., 2012), and they require minimal time and effort to implement.

The principles of behavior modification can also be used to teach and encourage students to apply academic enabler behaviors consistently. Most interventions that target academic enablers begin with a period of skills training, in which the student is taught specific strategies for note taking, organization, time management, and study skills, or some combination of these (e.g., Abikoff et al., 2013; Evans et al., 1995, 2011; Langberg, Epstein, Becker, Girio-Herrera, & Vaughn, 2012; Pfiffner, Villodas, Kaiser, Rooney, & McBurnett, 2013; Power et al., 2012). For example, a student might be taught a specific and structured way to organize a school binder. Similar to a DRC, specific targets/goals are set relative to implementation of skills, and monitoring/tracking is frequent. For example, an academic enabler target might include the following: The student brings his or her school binder to class at least 4 out of 5 days and all worksheets/papers are be filed in the appropriate section of the binder. Rewards and consequences are then applied as frequently and immediately as possible (often though the use of a point system) based the child's progress toward achieving the goal. Behavioral interventions targeting academic enablers have been shown to lead to large improvements in both parent and teacher ratings of academic impairment and

in more objective measures, such as school grades (e.g., Pfiffner et al., 2013).

Strategies to Prevent High School Dropout

Adolescents with ADHD are at higher than average risk for dropping out of school and not completing their high school education (Barkley et al., 2008; also see Chapter 12). Presumably, risk for dropout may be reduced when evidence-based treatments for ADHD are used on a consistent basis. Alternatively, rather than assuming that ADHD treatment will lessen educational risk, clinicians are advised to consider the use of dropout prevention strategies. A prominent example of an effective dropout prevention program is Check and Connect (Anderson et al., 2004). This program includes two components: (1) *Check*: systematically evaluate the student's engagement and functioning in school by monitoring classroom performance, behavior and attendance, and (2) *Connect*: establish a constructive mentoring relationship between the student and school-based coach (e.g., teacher, counselor, or administrator). Studies have demonstrated that the quality of staff–student relationships involved in *Check and Connect* predicts increased attendance, homework completion and interest in school for students with learning disabilities and behavior disorders (Anderson, Christenson, Sinclair, & Lehr, 2004). In *Check and Connect*, the coach regularly collects data related to key school functioning behaviors (e.g., attendance, tardiness, assignment completion) and records this information on tracking sheets. If behaviors exceed the established Check and Connect thresholds indicating risk, then the coach and student use problem-solving techniques to generate and implement a solution. For this strategy to be successful, it is critical that coaches establish a relationship with the students to keep the latter engaged and motivated to achieve at school.

IMPLICATIONS FOR FUTURE RESEARCH

Although increased clinical and research attention has been paid to the identification, assessment, and treatment of educational impairment in children and adolescents with ADHD, the empirical literature in this area is still in its infancy compared to the abundant research focused on ADHD symptoms, associated behaviors, and comorbid disorders. Given the ubiquitous, chronic impact of ADHD on school and academic outcomes, there is a critical need to increase the number and complexity of empirical studies focused on educational impairment. Three major directions are recommended for research in this area include comprehensive longitudinal investigations of educational impairment, identification of predictors of educational impairment, and further development of intervention targeting educational functioning.

Comprehensive Longitudinal Investigations of Educational Impairment

Most studies examining educational functioning in children and adolescents with ADHD have been cross-sectional (i.e., academic performance or achievement data collected on one occasion) (Frazier et al., 2007). This is problematic because the functional impairments associated with ADHD are chronic and dynamic, not static. Thus, cross-sectional studies provide a limited snapshot of the challenges that students with ADHD encounter across their school years. Another limitation of the extant literature is a relative preponderance of studies with elementary school-age children and scant empirical evaluation of academic difficulties experienced by preschoolers and adolescents with ADHD. Even when academic achievement is examined in longitudinal investigations, currently available studies typically employ relatively limited measurement of educational functioning. Most often, studies only use one or two measures, and many investigations rely exclusively on a single, norm-referenced achievement test. As discussed in this chapter, educational functioning is multifaceted and comprises skills and performance components. Therefore, a more comprehensive approach to outcome measurement is needed.

To address these important limitations, longitudinal investigations of educational functioning in children with ADHD should begin in preschool and extend through at least high school, if not postsecondary schooling. Furthermore, outcomes should be assessed using multiple methods, including norm-referenced achievement tests, criterion-referenced or CBMs, teacher ratings of academic skills and enablers, report card grades, and perhaps permanent products and/or direct observations of academic-related behaviors. Stated differently, educational functioning should receive the same emphasis as has been accorded ADHD symptoms, behavioral functioning, and psychological/psychiatric

comorbidities in prior longitudinal studies. The recommended longitudinal approach should yield data that will be critical in helping clinicians and researchers to advance our understanding of (1) the nature of educational impairments associated with ADHD, (2) the dynamic changes that may occur with respect to scholastic functioning, and (3) the critical time periods when intervention may be most needed (e.g., entry to elementary school, transition to middle school).

Identification of Predictors of Educational Impairment

Similar to the study of educational functioning in general, very few studies have sought to identify variables that may moderate or predict academic and school outcomes in children and adolescents with ADHD. Those studies that have been conducted have focused on generic, demographic characteristics such as gender, SES, and IQ or on broad ADHD symptom dimensions as predictors. As reviewed previously, there is ample evidence that inattention symptoms rather than hyperactivity–impulsivity are statistically significant predictors of educational outcome in this population (e.g., Massetti et al., 2008). Although such findings certainly advance our understanding of factors related to educational impairment, future studies should take a more comprehensive, multivariate approach to identifying predictors. The examination of a varied set of predictors, along with multiple measures of educational functioning, may not only increase the number of known moderators of outcome but may also indicate more specific predictor–outcome relationships. For example, it is possible that variables that predict outcomes for academic enablers may be different from factors that predict achievement in specific academic areas (e.g., Langberg, Molina, et al., 2011). The identification of predictors is critically important, particularly if these variables are malleable because these findings may help clinicians and researchers identify possible targets for prevention and early intervention programs.

Further Development of Interventions Targeting Educational Impairment

Rapid progress has been made over the last 10 years with respect to the development of interventions targeting educational impairment; however, a number of notable limitations remain. In comparison to research with elementary-age students with ADHD, there has been minimal research on psychosocial interventions that address the educational impairment of secondary-age students with ADHD (DuPaul et al., 2012). In particular, there has been almost no research evaluating educational interventions for high school and college students with ADHD. This is important because the types of interventions applied to elementary-age students with ADHD are unlikely to be effective with high school and college-age students. One reason for this is that high school and college-age students are expected to operate autonomously and receive minimal support from parents and teachers. Behavioral interventions for elementary-age students rely heavily on parents and teachers to provide structure, monitoring, and rewards. This is unlikely to be feasible or acceptable as a major component of interventions for high school and college age students, and alternate strategies will need to be developed and evaluated (Fleming & McMahon, 2012). These interventions are clearly needed; although the number of college students with ADHD is rapidly increasing, many are struggling academically and may fail to graduate (Weyandt & DuPaul, 2013).

Another limitation is the relative lack of interventions targeting educational impairment that are truly feasible for schools to implement. Delivering such interventions in school settings is associated with improved outcomes and greater prospects for generalization (DuPaul et al., 2012, Evans, Langberg, & Williams, 2003). However, many of the interventions that have been developed for youth with ADHD are multicomponent interventions that are staff- and resource-intensive. Even if these interventions are highly effective, it is not clear that schools have the expertise or resources needed to carry them out. Additional research is needed on interventions such as DRCs that can be implemented with minimal staff effort and resources. Research is also needed to understand better the efficacy of services currently provided in schools for youth with ADHD. For example, academic accommodations are commonly used by schools to address educational impairment even though very little is known about their efficacy (Harrison, Bunford, Evans, & Owens, in press). Furthermore, research is needed to evaluate different strategies for deploying and disseminating ADHD interventions into school settings and factors that predict schools adoption of evidence-based interventions. Without an increased focus on feasibility, acceptability, and deployment/dissemination, it is unlikely that the interventions being developed for educational impairment will reach the youth for whom they were designed.

CONCLUSIONS

The majority of children and adolescents with ADHD exhibit clinically significant impairment in educational functioning that is multifaceted and chronic. In particular, students with this disorder are at higher than average risk for underachievement, grade retention, referral for special education services, failing report card grades, school dropout, and lower completion of postsecondary education. Impairment can be experienced in the development of academic skills, performance, and/or enablers. Deficits in one or more of these areas not only hinder scholastic progress but also have important implications for individuals' eventual financial status and psychological well-being. Academic deficits can be identified at an early age (i.e., prior to school entry) and require multimodal, ongoing assessment throughout a student's educational career. Intervention strategies can be directed towards skills acquisition and fluency, consistent scholastic performance, improved academic achievement, and enhanced academic enablers. Ultimately, multiple areas of functioning may require intervention in order to optimize both short- and long-term progress. It is hoped that the next wave of empirical research will prioritize comprehensive assessment and treatment of educational functioning, preferably in the context of longitudinal designs that include multiple measures of outcome. Anything short of a more comprehensive approach to research, assessment, and intervention of academic functioning will limit our ability to promote successful outcomes for students with ADHD.

KEY CLINICAL POINTS

- ✓ The vast majority of children and teens with ADHD experience impairment in the educational setting.
- ✓ They manifest lower preschool academic readiness skills, lower academic achievement skills in formal school settings, skills deficits, performance deficits, and poor academic enabler behaviors. These are in addition to their ADHD symptoms, EF deficits, peer relationship problems, comorbid psychiatric disorders, and health problems, as identified in other chapters in this section.
- ✓ In academic skills, children and teens with ADHD show significant deficits in reading, math, spelling, and handwriting competencies, as well as a higher probability of qualifying for a learning disability (33–45%+).
- ✓ Performance deficits include high rates of off-task behavior, variable on-task behavior, less efficient approaches to work performance, careless work behavior, inability to sustain motivation to work as long as typically developing children, and reduced self-monitoring and self-correction of work.
- ✓ Poorer competencies in academic enablers include deficits in EF in daily life, such as time management, self-organization, problem solving, self-motivation, and emotional self-regulation, all of which further contribute to risk for academic failure.
- ✓ Deficits in academic functioning are more a function of the degree of ADHD inattention symptoms than of the hyperactive–impulsive symptom dimension.
- ✓ Significant transitions in academic settings over the course of development, such as the shift from elementary to middle school or from the latter to high school, may be associated with a worsening of symptoms and further impairments due in part to a reduction in external structure and increased emphasis on self-regulation associated with such transitions.
- ✓ Follow-up studies also show higher than typical rates of adverse academic outcomes, such as grade retention and failure to complete compulsory education, among others.
- ✓ Assessing the educational problems of children and teens with ADHD is complex and should include not only tests of basic achievement skills but also rating scales of academic performance and school enablers, and curriculum-based assessment and direct observations of in-school functioning, among other, more ethological approaches to documenting difficulties.
- ✓ Interventions for the educational impairments of children and teens with ADHD need to target not only the modification of ADHD symptoms and related problematic behaviors but also academic skills, performance-related behavior, and academic enablers, if improvements in more than just behavior are to be achieved. Additional interventions may be needed to target directly the increased risk for dropping out of school.

CHAPTER 7

Families and ADHD

Charlotte Johnston and Andrea Chronis-Tuscano

Despite recognition that genetics and biological characteristics such as brain structure and function are central to the etiology of attention-deficit/hyperactivity disorder (ADHD) (Scassellati, Bonvicini, Faraone, & Gennarelli, 2010; also see Chapter 14), research convincingly indicates that parenting and parental psychopathology play an important role in determining the developmental course of ADHD and the occurrence of comorbid conditions (e.g., Faraone et al., 2005; Nigg, Hinshaw, & Huang-Pollock, 2006). We argue in this chapter that the family context that surrounds children with ADHD is crucial for both a complete understanding of the disorder at a nomothetic level and the idiographic understanding necessary to guide treatment planning for an individual child and his or her family. Family factors are seen as contributing to ADHD partly in a direct etiological fashion, and partly as important moderators and mediators of child outcomes and treatment effects. We place parent–child interactions at the nexus of the many family factors that impinge on and interact with child ADHD, recognizing the proximal nature of these interactions to the child and their potential as either powerful protective or risk factors. Our understanding of this central place of parent–child interactions in families of children with ADHD is grounded in a developmental–transactional framework, which recognizes that parents and children each contribute to the quality of family interactions, and that individual characteristics and relationship properties evolve dynamically over time.

We begin the chapter with an outline of this developmental–transactional framework and its implications for understanding, assessing, and treating ADHD within the family context. Using this framework as our reference point, we then review current knowledge regarding the centerpiece of the framework, parent–child interactions. In the following sections, we consider evidence addressing the impact of parent and family characteristics, including parent psychopathologies and marital and sibling relationships, on parent–child interactions and child ADHD. Although our theoretical model incorporates important extrafamilial influences, such as the school environment, cultural perspectives, and the impact of social disadvantage, we focus on the family context, and this precludes extensive consideration of these broader contextual factors. We conclude with a discussion of emerging directions and challenges in our understanding of the families of children with ADHD. Throughout the chapter, we strive to highlight research findings that may have par-

ticular relevance within the clinical context and hold promise for improving the lives and outcomes of these children and their families.

THE DEVELOPMENTAL–TRANSACTIONAL MODEL OF ADHD AND FAMILY FUNCTIONING

We believe that the most useful framework for understanding families of children with ADHD is one that acknowledges biological and social influences, recognizes the dynamic and interactive nature of influences among family members, and incorporates contextual factors both within and outside of the family (Johnston & Mash, 2001; Sonuga-Barke & Halperin, 2010). A simplified schematic representation of such a model is provided in Figure 7.1. Unpacking the model, we first highlight the strong heritability of ADHD symptoms (e.g., Nikolas & Burt, 2010; Waldman & Gizer, 2006) and the resultant recognition that an individual, typically a child diagnosed with ADHD, may well reside within a family in which other members also show high levels of ADHD symptomatology. We provide a more complete discussion of this possibility in the following section on parental psychopathology, including ADHD. In addition to the biological links in ADHD symptomatology among family members, research also suggests genetic overlap of ADHD with other disorders (e.g., oppositional defiant disorder [ODD] or conduct disorder [CD], referred to collectively as disruptive behavior disorders in this chapter; learning disorders, autism spectrum disorders, depression, substance use disorders, bipolar disorder) and with personality or temperament dimensions of neuroticism and low conscientiousness (e.g., Faraone, Biederman, & Wozniak, 2012; Lichtenstein, Carlström, Råstam, Gillberg, & Anckarsäter, 2010; Martel, Nikolas, Jernigan, Friderici, & Nigg, 2010; Taylor, Allan, Mikolajewski, & Hart, 2013; see Child Characteristics in Figure 7.1). An awareness of these possible shared biological underpinnings informs a more comprehensive understanding of the difficulties families of children with ADHD may be facing.

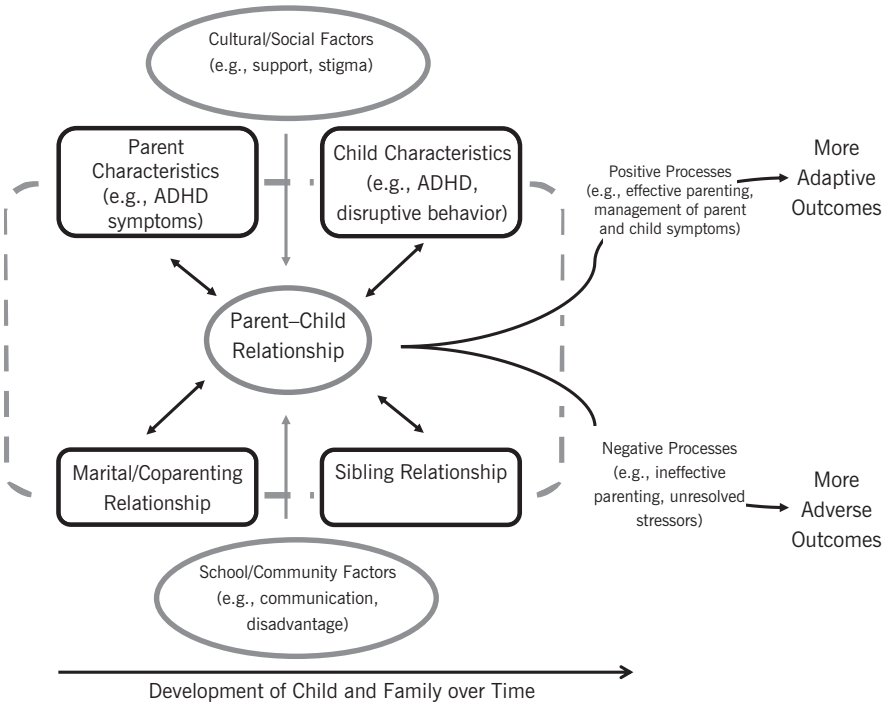

FIGURE 7.1. Developmental–transactional model of ADHD within the family context.

Sharing influence and often interacting with the child's genetic vulnerabilities to ADHD are the important and proximal impacts of functioning within the parent–child dyad (the Parent–Child Relationship at the center of Figure 7.1). We use the term "parent–child" to encompass the child's relationships with any and all relevant parenting figures in the family. Not only does parenting interact with the child's genetic endowment to modulate risk, but environmental factors such as parenting also appear to have epigenetic functions, whereby these environmental factors alter the functioning of genes in a way that contributes to stable changes in the expression of the child's genetic makeup (Nigg, 2012). Although direct effects on the child are acknowledged, other family variables, including parents' cognitions and characteristics and marital and sibling relationships, are seen as exerting their influence on the trajectory of child functioning primarily through the filter of parent–child interactions (e.g., Li & Lee, 2013; Nikolas, Friderici, Waldman, Jernigan, & Nigg, 2010; Pennington et al., 2009; see Parent Characteristics, Marital/Coparenting Relationship, and Sibling Relationship in Figure 7.1). Critically, within the developmental–transactional model, the characteristics and behaviors of family members and family subsystems are reciprocally influential, with each acting to change the other over the course of time and development (these influences are partially captured by the numerous recursive and continuous arrows in Figure 7.1). This fact necessitates an understanding of family functioning that resists a focus on unilateral effects (e.g., parent or child blaming) and places current functioning within the family's own historical context. Finally, related to the dynamic, ever-changing nature of the influences among family members is a recognition that patterns of functioning are tied to the developmental stage of the child, or of the family, and that a true understanding of the child only arises from knowledge of the developmental pathway that has led to the current picture of functioning.

In summary, at the center of understanding child ADHD is recognition of the constant flow of influences from child to parent and back again. Interacting with a child with ADHD is a stress-generating experience that can negatively alter parental cognitive, emotional, and behavioral functioning, especially if ADHD is comorbid with ODD (e.g., Fischer, 1990; Theule, Wiener, Tannock, & Jenkins, 2013). At the same time, parent factors, such as depression or poor self-regulation, serve to influence the quality of parenting and parent–child interactions, and ultimately adjustment and outcomes for children with ADHD (e.g., Johnston, Mash, Miller, & Ninowski, 2012). Both parent and child functioning are intertwined with other aspects of the family, such as functioning within sibling or interparental systems. Finally, consideration must be given to not only the mutual influences within the family but also the broader social context outside the family. ADHD does not exist in isolation from the influences of friends and relatives, the child's school, the neighborhood, and the family's cultural and/or religious affiliations. For example, over three-fourths of parents of children with ADHD report stigmatizing experiences as a result of their child's ADHD, including feelings of social isolation and dismissive attitudes by health professionals (e.g., dosReis, Barksdale, Sherman, Maloney, & Charach, 2010; Mikami, Chong, Saporito, & Na, 2013).

This theoretical framework not only serves to guide research questions and methods in the study of ADHD, but it also is intended to highlight how clinicians can best approach assessment and treatment of the disorder. Assessment should focus on not only the child with ADHD but also the familial and social-contextual factors that may serve to exacerbate or ameliorate the child's symptoms and level of functioning. In turn, treatment must recognize and incorporate the parental, family, and social resources surrounding the child with ADHD and work to maximize the strengths of the child and family, while minimizing the impact of existing individual, familial, and social risk factors.

PARENT–CHILD RELATIONSHIPS AND ADHD

Using the framework of this developmental–transactional model as a backdrop, we now turn to a discussion of what is known about the centerpiece of the model, parent–child interactions, within families of children diagnosed with ADHD. Reviews of research characterizing parent–child interactions in families of children with ADHD have consistently yielded a picture of high levels of parenting stress and conflicted parent–child interactions characterized by both increased directiveness or authoritarian parenting and reduced warmth or positivity (e.g., Deault, 2010; Johnston & Mash, 2001; Theule et al., 2013). As would be expected, the specific nature of the interactions and stressors varies with development; however, the fundamental nature of the impairment is revealed in the fact that these disruptions in parent–child interactions

have been found across children, ranging in age from toddlerhood to adolescence (Johnston & Lee-Flynn, 2011). Variations in the interactions of parents with boys versus girls with ADHD, or in mother–child versus father–child relationships are not well understood because the majority of studies have focused on mothers and sons. However, a sufficient number of studies suggest possibly important differences related to both parent and child gender (e.g., Lifford, Harold, & Thapar, 2009; Peris & Hinshaw, 2003; Pfiffner, McBurnett, Rathouz, & Judice, 2005) that we highlight the need for further research in this area.

Although a developmental–transactional model emphasizes bidirectionality and reciprocity in parent–child interactions, this view must accommodate evidence of differential strength in parent-to-child versus child-to-parent effects, and of differential pathways of influence of the child's ADHD symptoms compared to other aspects of his or her functioning. That is, while some studies support specific links between early parenting and the development or severity of child ADHD symptoms (e.g., Ellis & Nigg, 2009; Harold et al., 2013; Hawes, Dadds, Frost, & Russell, 2013; Keown, 2012; Thorell, Rydell, & Bohlin, 2012), more studies point to effects of child ADHD on parenting. Early research manipulating the child's medication status (e.g., Barkley & Cunningham, 1979; Danforth, Barkley, & Stokes, 1991) converges with more recent, sophisticated longitudinal studies testing bidirectional influences (e.g., Burke, Pardini, & Loeber, 2008) to support child ADHD symptoms as primary drivers of parenting difficulties such as overreactivity or inconsistency. An illuminating demonstration of these effects is provided in experimental studies that indicate interaction with child actors displaying ADHD and disruptive symptoms elicits feelings of inadequacy, stress, depression, and hostility in parents, as well as corresponding increases in physiological stress measures (e.g., heart rate) and subsequent alcohol consumption (Pelham & Lang, 1999). Moving beyond simple unidirectional mechanisms of causality, evidence increasingly points to more complex, interactive patterns of influence between parenting and child ADHD symptoms. Specifically, ineffective parenting styles, in combination or interaction with the child's inattentive or impulsive nature, appear to set the stage for the development of child disruptive behaviors (i.e., oppositional or conduct problems) and perhaps emotional problems such as anxiety or depression (Harold et al., 2013; Johnston & Mash, 2001).

Most studies of parent–child interactions in families of children with ADHD are quite clear in showing that parenting and parent–child relationship problems are more closely linked to child disruptive behaviors rather than to ADHD symptoms (e.g., Burke et al., 2008; Johnston & Mash, 2001). This pattern is found not only in cross-sectional studies but also in more convincing longitudinal studies, in which initial levels of both child ADHD and disruptive behavior problems, as well as a variety of other family and parent risk factors, are controlled. Such longitudinal studies consistently demonstrate that parenting difficulties (e.g., low responsiveness, low positivity, overreactivity, inconsistency) are predictive of increases in or maintenance of disruptive behavior over time in children with ADHD (e.g., Biederman, Mick, Faraone, & Burback, 2001; Chronis et al., 2007; Lifford et al., 2008). Supporting a causal chain of events consistent with the transactional model, longitudinal studies, exemplified by that of Harvey, Metcalfe, Herbert, and Fanton (2011), indicate that parenting difficulties such as overreactive discipline play a mediating role between initial levels of child ADHD symptoms and subsequent disruptive behavior problems.

The pattern of results showing that disruptions in parenting, in combination with youth ADHD symptoms, are particularly strongly tied to comorbid disruptive behaviors has been demonstrated across the developmental spectrum from preschoolers (e.g., Cunningham & Boyle, 2002) to adolescents (Edwards, Barkley, Laneir, Fletcher, & Metevia, 2001; Gau & Chang, 2013). Parents' setting of firm, consistent, and reasonable limits on behavior and encouraging appropriate behavior are crucial in protecting against the development of disruptive problems in young children with ADHD (Harvey et al., 2011); recent studies of adolescents with ADHD show that similar parenting skills are relevant in preventing serious negative outcomes for these youth. For example, youth ADHD symptoms have been shown to interact with poor parental monitoring in predicting problems such as youth alcohol use or delinquency (e.g., Molina et al., 2012; Walther et al., 2012). Thus, although the family environment does not appear critical in the origin of child ADHD symptoms, family factors such as parent–child interactions do emerge as crucial in predicting the development or sparing of serious child outcomes such as conduct problems or substance abuse. The personal, familial, and societal costs of these negative consequences for children with ADHD are more than sufficient to motivate

careful and continued attention to the role of family context in this disorder.

Some of the most exciting recent work that focuses on parenting in families of children with ADHD incorporates potential genetic risks, such as variations on the *DAT1* or *DRD4* gene, and examines the interactions of these child genetic risks with parenting behaviors as determinants of both child ADHD symptoms and comorbid emotional or disruptive behaviors (e.g., Li & Lee, 2013; Martel et al., 2011; Martel, Nikolas, Jernigan, Friderici, & Nigg, 2012; Nikolas, Klump, & Burt, 2012; Sonuga-Barke et al., 2009). Consistent with the bidirectional and reciprocal relations expected by a transactional model, other work in this area has focused on how genetic risk for ADHD in parents interacts with child disruptive behavior problems to predict negative parenting (e.g., Lee et al., 2010). Although studies in this domain are still relatively rare and the results are not entirely consistent, they do point to an emergent understanding of how genetic and behavioral influences may combine in determining the developmental trajectories of children with ADHD, and they highlight potential differences in both parents' and children's genetic susceptibility to environmental influences, such as parenting styles or child problems (Belsky & Pluess, 2009).

Despite considerable current and past research in relation to parent–child interactions and child ADHD, much remains unknown. For example, there is a need for further specification of how individual parent or child characteristics, such as gender or developmental stage, as well as broader contextual factors, such as culture, may moderate the pattern of relations between parenting and child ADHD. Similarly, in contrast to the well-established associations of parenting and comorbid disruptive behavior problems, relatively little work has examined how parenting and parent–child interactions may be related to other common ADHD comorbidities such as anxiety or depression, academic and learning problems, or social problems with peers.

PARENTAL COGNITIONS

In understanding parent–child interactions in families of children with ADHD, research has focused on not only behavioral interactions between parents and child but also parents' cognitions about their children and about themselves as parents, and how these cognitions may shape the parent–child relationship (e.g., Hoza, Johnston, Pillow, & Ascough, 2006; Johnston & Ohan, 2005). This work is grounded in a cognitive-behavioral framework and posits that in order to understand fully how parents behave with their children we must examine parents' cognitions, such as expectations for child behavior, attributions regarding child intentionality, and attitudes toward childrearing that may underlie parental actions. Consistent with the patterns of association found among parenting behaviors, child ADHD, and comorbid disruptive problems, studies focused on parenting cognitions typically indicate that there are some differences between the cognitions of parents of children with ADHD and parents of typically developing children (e.g., Gerdes & Hoza, 2006; Johnston & Freeman, 1997). However, these differences may well be driven by child characteristics. In contrast, consistent and unique predictive linkages have been discovered between maladaptive parental cognitions, such as child-blaming attributions, and disruptive behavior problems in children with ADHD. For example, studies have shown that negative parental attributions for child behavior are uniquely predictive of greater child disruptive behavior over time, even accounting for initial levels of child ADHD, disruptive problems, and other family risk factors (e.g., Johnston, Hommersen, & Seipp, 2009; Williamson & Johnston, in press). It appears that child ADHD symptoms may set the stage for parents to adopt problematic cognitions about the child, and these parental cognitions then function to impair parenting and to fuel the development of more problematic child disruptive behavior.

In addition to attributions for child behavior, other research on parental cognitions has sought to understand how parents of children with ADHD think about their role as parents. Not surprisingly, an individual's sense of parenting efficacy seems to be negatively impacted by the experience of parenting a child with ADHD (Mash & Johnston, 1983) and may mediate between parental factors such as depression and parenting problems (Gerdes et al., 2007). Although a reduced sense of parenting efficacy seems to mark a reluctance to adopt effective parenting strategies (Johnston, Mah, & Regambal, 2010), parenting interventions, when used, serve to improve parents' sense of competence and also their satisfaction or enjoyment in the parenting role (Daley & O'Brien, 2013; Pisterman et al., 1992).

Cognitions, such as parents' sense of their own ability to parent a child with ADHD effectively or the causal explanations they develop for their children's

behavior, hold promise as potentially modifiable characteristics. These may be useful in promoting parents' ability to cope with and manage a child's ADHD symptoms in a way that disrupts the negative cycle leading from difficult child ADHD symptoms to less effective parenting choices, and ultimately to more serious child disruptive behavior problems. For example, a recent study by Chronis-Tuscano and colleagues (2013) illustrates the success of an intervention that targeted not only parenting skills but also depressive symptoms in mothers of children with ADHD, with a focus on strategies designed to address directly maladaptive cognitions about the child and one's ability as a parent, as well as the feelings and parenting behaviors associated with these thoughts. Other converging evidence supporting the importance and potential impact of parental cognitions comes from a study by Lench, Levine, and Whalen (2013), who demonstrated that in families of children diagnosed with ADHD, in which parents continued to see the child's characteristics in a positive light, there were fewer negative parent–child interactions, less parental frustration, and greater optimism regarding the child's future than in families in which parents did not hold these positive views of the child. Importantly, these positive differences persisted despite there being no difference between the two types of families in the levels of child ADHD or comorbid symptom severity.

We note one caveat relative to the previous comments about the importance of parental cognitions in families of children with ADHD. Although we believe that parents of children with ADHD would be well advised to avoid adopting child-blaming explanations that can lead to both parent and child hostility, and to increase their own sense of parenting efficacy, these more positive cognitions must be balanced with, and grounded in, reality. For example, adopting explanations for child behavior that overemphasize the child's ADHD status may lead to permissive or overprotective approaches to parenting that do not serve the child's best interests (Hinshaw, 2005). Instead, it may be most useful for parents to endorse attitudes that, while not blaming the child for ADHD behaviors, do, within reason, hold the child accountable for developing (with help and guidance from parents, teachers or other mentors) skills and strategies that will minimize the negative impact of the symptoms over time. The power of parenting attitudes that communicate this expectation of the child's ability to function independently was recently demonstrated in a study by Thomassin and Suveg (2012), who showed that high levels of parental support for the child's autonomy served as a buffer to reduce the association between child ADHD symptoms and poor task persistence. Similarly, just as feeling defeated may reduce parents' willingness to learn and try new parenting strategies, holding an extreme or illusory positive view of one's parenting ability may also serve as a barrier to developing and evolving as an effective parent. We believe that finding this balance between overly positive or negative versus realistic cognitions about the child and one's parenting ability represents one of the greatest challenges facing parents of children with ADHD. Interventions geared to assist parents in thinking critically, but optimistically, about both their own and their children's behavior (e.g., Chronis-Tuscano et al., 2013) hold promise as tools for reducing parental stress and frustration, and enhancing the positive reciprocity of parent–child interactions over time.

INDIVIDUAL PARENTING FUNCTIONING

ADHD

The strong heritability of ADHD symptoms implies that many parents of children with the disorder also are affected. Estimates indicate that over half of adults with ADHD have children with the disorder, and up to half of children with ADHD have a parent with high levels of ADHD symptoms (e.g., Biederman, Faraone, Mick, & Spencer, 1995; Chronis et al., 2003; Kessler et al., 2006). With the growing recognition of ADHD as a disorder common among multiple family members, accumulating studies indicate that ADHD symptoms in parents are associated with a range of both parent and child difficulties, including difficulties in parenting (Johnston et al., 2012), increased severity of child ADHD symptoms and disruptive behaviors (Agha, Zammit, Thapar, & Langley, 2013; Zisser & Eyberg, 2012), peer difficulties (Griggs & Mikami, 2011), and diminished response to treatment (Chronis-Tuscano et al., 2011; Sonuga-Barke, Daley, & Thompson, 2002). A major challenge in understanding the links between child outcomes and parental ADHD symptoms is parsing the direct and indirect contributions of both genes and behaviors to these relations. Although the links between parental ADHD and child problems may reflect the passive shared genetic associations of biological children and parents (e.g., Lifford, Harold, & Thapar, 2009), it is likely that the effects of parental ADHD on children also are mediated by the behav-

iors that transpire between parents and children (e.g., Herbert, Harvey, Lugo-Candelas, & Breaux, 2013), as well as more complex patterns of moderation of the child's genetic vulnerabilities by exposure to variations in parent–child interactions (e.g., Sonuga-Barke et al., 2009). Indeed, a recent report using data from two adoption-based studies demonstrated the importance of (biologically unrelated) mothers' hostility for the course of child ADHD symptoms, as well as the role of early child impulsivity as an evocative influence on the hostility of biologically unrelated mothers. This then predicted the course of child ADHD symptoms (Harold et al., 2013). Additionally, in this study, biological mothers' ADHD symptoms were significantly related to child impulsivity–activation; and adoptive mothers' ADHD symptoms were significantly correlated with their hostile parenting. This study was not only able to control for the effects shared genes may have on both child ADHD and parenting but it also examined the effects of child behavior on parenting in a genetically controlled fashion. Studies such as this provide very strong evidence for the reciprocal–transactional influence of child and parent on one another, and suggest convincingly that despite the strong influence of genes on ADHD behavior, parenting behavior also exerts an important influence on the course of child ADHD.

Whether measured dimensionally or categorically, higher levels of ADHD symptoms in parents consistently have been associated with increased parent–child conflict, and with elevations in difficulties in parental control, including harsh or overreactive discipline, lax or inconsistent discipline, poor monitoring of child behavior, chaotic homes with poor routines and structure, and harsh responses to children's expressions of emotions (Johnston et al., 2012; Mazursky-Horowitz et al., in press). These associations between ADHD symptoms in parents and problems with the negative or control aspects of parenting have been documented by both self-report and observational measures of parenting, and within samples of children as young as infants and as old as adolescents or young adults. In addition, the associations often appear even when researchers control for other aspects of parent and/or child psychopathology (e.g., parental depression, child disruptive behaviors).

In contrast to the consistent associations between parental ADHD and negative or control-related parenting behaviors, the associations between parental ADHD and positive, emotionally responsive aspects of parenting are somewhat less consistent (Johnston et al., 2012). Some studies indicate that ADHD symptoms are associated with reduced parental warmth/responsiveness (e.g., Chronis-Tuscano et al., 2008; Landau, Amiel-Laviad, Berger, Naama, & Auerbach, 2009; Semple, Mash, Ninowski, & Benzies, 2011), whereas others have not found these negative associations between parental ADHD and more positive parenting (e.g., Mokrova, O'Brien, Calkins & Keane, 2010; Murray & Johnston, 2006), or have found associations only for inattentive and not for hyperactive-impulsive symptoms (e.g., Chen & Johnston, 2007). This pattern of inconsistent findings alerts us to nuances in how parental ADHD symptoms are related to parenting, and suggest differences that may be tied to the dimension of ADHD symptoms measured and/or the aspects of parenting under consideration.

Psychogiou, Daley, Thompson, and Sonuga-Barke (2007, 2008) have posed the intriguing possibility that parental ADHD may interact with child ADHD to produce, in some instances, a buffering effect. In these studies, when mothers had higher levels of ADHD symptoms, child ADHD symptoms were associated with more positive, rather than more problematic, parenting, an effect that has been theorized to indicate increased empathy or tolerance for children with ADHD among parents who themselves experience the symptoms. However, these findings were unique to mothers in the Psychogiou and colleagues studies, and have not always been replicated in other samples (Johnston & Lee-Flynn, 2011). Other recent evidence (Lui, Johnston, Lee, & Lee-Flynn, 2013) suggests that the interactions may reflect a combination of actual increased positivity among parents with ADHD symptoms and potential overreporting of positive parenting by parents with high levels of ADHD symptoms, consistent with a general positive bias in the self-reports of individuals with ADHD (Owens, Goldfine, Evangelista, Hoza, & Kaiser, 2007).

In summary, parents with high levels of ADHD symptoms clearly struggle with maintaining a consistent, calm, and organized approach to managing child behavior. In contrast, the relations between parental ADHD symptoms and the positive aspects of parent–child relationships are less consistent. There is even the possibility that, under some circumstances, parental ADHD symptoms may contribute in a positive fashion to parent–child interactions. It is obvious that much further research with respect to adult ADHD and parenting is needed. The field awaits replications and extensions of existing findings before firm conclu-

sions can be drawn, and before the multiple pathways through which parental ADHD symptoms may exert their impact on child development are understood.

Depression

A wealth of evidence suggests that mothers of children with ADHD experience elevated levels of stress and depressive symptoms (Deault, 2010; Johnston & Mash, 2001). Approximately half of all mothers of children with ADHD have experienced at least one major depressive episode in their lifetime (Chronis et al., 2003). Importantly, a history of maternal depression uniquely predicts negative long-term outcomes for children with ADHD, including the development of later conduct problems, depression, and suicidal behavior (Chronis et al., 2007; Chronis-Tuscano et al., 2010), making maternal depression an important consideration for clinicians who treat children with ADHD.

Within our overarching model, it is important to acknowledge possible genetic associations between parental depression symptoms and child ADHD. For instance, depression and ADHD share some common genetic underpinnings given that the serotonergic and dopaminergic systems have been implicated in both disorders (Eley et al., 2004; Faraone & Mick, 2010; Hawi et al., 2002; Levinson, 2006; Li, Sham, Owen, & He, 2006; Nestler & Carlezon, 2006). However, it also is useful for clinicians to understand the link between ADHD and maternal depression within a developmental–transactional framework whereby parental depressive symptoms and child ADHD and disruptive behavior problems reciprocally influence one another at a behavioral level (e.g., Nicholson, Deboeck, Farris, Boker, & Borkowski, 2011).

In terms of child effects, parents of children with ADHD may experience depressive symptoms in part as a result of decreased environmental reinforcement associated with child ADHD and disruptive problems (Chronis-Tuscano & Clarke, 2008; Lewinsohn, Hoberman, Teri, & Hautzinger, 1985). As we have discussed, compared to parents of typically developing children, parents of children with ADHD often experience fewer positive interactions with their children, lower parenting efficacy, more parenting stress, and have fewer opportunities to engage in activities they enjoy due to the amount of time and effort they invest in parenting a child who requires high levels of supervision and assistance.

As one example, our ongoing work suggests that mothers of children with ADHD often feel the need to leave their jobs to be more available to attend school meetings and appointments during the day as well as to provide needed supervision and homework support for their children during after school hours. Such decisions may yield benefits for the child, but perhaps at the cost of leaving mothers more vulnerable to depression. Indeed, across several studies, employment has been shown to be a protective factor for women who have children with special needs (Lewis, Kagan, Heaton & Cranshaw, 1999) and may be a source of competency experiences, which can contribute to overall well-being (Lewinsohn, Hoberman, Teri, & Hautzinger, 1985). Specifically among parents of children with ADHD, mothers' working hours are related to less time devoted to child care, which is linked to more effective parenting and fewer conduct problems in the children (Harvey, 1998). Thus, due to the demands of parenting a child with ADHD, mothers may have fewer opportunities to participate in activities that are pleasurable or that contribute to feelings of competence in other domains and may, as a result, experience more stress and depression (Chronis-Tuscano & Clarke, 2008; O'Brien, Merson, Sauber, & Chronis-Tuscano, 2013).

Just as child ADHD may increase the risk of parental depression, a wealth of evidence from studies of families of children with ADHD and those of typically developing children demonstrates that depression can negatively impact the manner in which parents interact with their children (Johnston & Mash, 2001; Lovejoy, Graczyk, O'Hare, & Neuman, 2000; Wilson & Durbin, 2010). In particular, parents who are depressed may have difficulty noticing the child's efforts and positive behavior, have a low threshold for and react emotionally to child misbehavior, be disengaged and less interactive with the child, or be less motivated to participate in treatments that required effort and persistence. Within our transactional framework, these parenting behaviors can fuel future child disruptive behavior problems, which then contribute further to parental stress and depressive symptoms in a cyclical manner. Parental depression also can contribute to interparental conflict, which may exacerbate inconsistent parenting and poor child adjustment.

Perhaps because of the gender divergence in the prevalence of depression, with women having significantly higher rates than men, much less is known about depression that may occur in fathers of children with ADHD. However, recent studies are beginning to shed light on the relationship between paternal depression and child ADHD symptoms. The few studies that have examined the effects of paternal depression on offspring

outcomes have found links to both child ADHD symptoms and externalizing (i.e., disruptive behavior) and internalizing symptoms more broadly (Kane & Garber, 2004). For example, in a sample of 3-year-old children, paternal depression was related to increased child hyperactivity, even after researchers controlled for the effects of maternal depression (Ramchandani, Stein, Evans, & O'Connor, 2005). Similar links are found in school-age samples (Harvey et al., 2011; Ramchandani et al., 2008). Importantly, a recent study revealed that paternal (but not maternal) depression predicted the persistence of child ADHD into adulthood, highlighting the need for further research and clinical attention regarding depression in fathers (Lara et al., 2009). Finally, a recent meta-analysis focusing on depression in fathers reported small, but significant, effect sizes of paternal depression on both positive and negative parenting (Wilson & Durbin, 2010). Interestingly, these effect sizes mirrored those found in studies that examined parenting in depressed mothers. Thus, although studies are beginning to show that paternal depression may have important and unique effects on child adjustment, the pathways through which maternal and paternal depression might differentially be linked to various child outcomes, such as the persistence of ADHD and development of comorbid conditions, warrant further investigation.

Antisocial Behavior

Some parents of children with ADHD (approximately 3–13%; Chronis et al., 2003) have a history of or current antisocial behavior and criminal involvement, although, in contrast to the research on depression, which has included predominantly mothers, here the focus has been mostly on fathers. There is substantial evidence of links between parental antisocial behavior and both child ADHD and disruptive behavior problems (Chronis et al., 2003). A recent study identified parental antisocial behavior as a key predictor of the persistence of child ADHD into adulthood, highlighting its importance as a prognostic indicator (Lara et al., 2009).

Research has begun to clarify the extent to which the associations between parent antisocial behavior and child ADHD symptoms can better be attributed to genetic and/or environmental factors. Child ADHD symptoms have been related to a history of arrests and/or alcohol use disorders in biological, rather than adoptive, parents—suggestive of a genetic link (Beaver, Nedelec, Rowland & Schwartz, 2012) and consistent with a general genetic liability from parent antisocial behavior to both child ADHD and disruptive behavior disorders (e.g., Bornovalova, Hicks, Iacono & McGue, 2010). At the same time, genetically informed studies have revealed the strongest evidence for disorder-specific risk transmission for psychopathology from parent to child (e.g., Clark, Cornelius, Wood & Vanyukov, 2004). In other words, when multiple forms of parental psychopathology are considered, child ADHD seems to be best predicted by ADHD in either parent, while, in contrast, it is child disruptive behavior (particularly CD) that seems to be most closely related to parental antisocial behavior.

In addition, the genetic contribution to ADHD appears to be much stronger than the genetic contribution to antisocial/disruptive behavior problems. For instance, in a recent study, whereas both genetic and environmental factors accounted for the resemblance between parental antisocial behavior and child disruptive behavior problems, the resemblance between parental antisocial behavior and child ADHD was attributed entirely to genetic factors (Silberg, Maes & Eaves, 2012). Together, these studies point to the likelihood of the genetic associations between parental antisocial behavior and child ADHD being mostly caused by the co-occurrence of child ADHD and disruptive disorders, and the co-occurrence of parent antisocial behavior and ADHD.

Antisocial behavior in parents constitutes a risk for not only maladaptive parenting but also many other environmental disadvantages, such as poverty, interparental conflict, or the child's exposure to violence. Consistent with the central role of parent–child interactions as contributors to the functioning of children with ADHD, at least some studies have found evidence of the mediating role of parental negativity and/or poor supervision in the pathway from parental antisocial behavior to the development of conduct problems in children with ADHD (e.g., Conger, Neppl, Kim, & Scaramella, 2003; Pfiffner et al., 2005). In summary, in line with a developmental–transactional model, both direct and indirect pathways tie antisocial behavior in a parent to maladaptive family interactions, poor child outcomes, and disturbances in the other parent's functioning or the interparental dyad.

Alcohol/Substance Abuse

As with research on antisocial behavior, studies have documented alcohol- and drug-related problems in parents of children with ADHD, as well as an increased

risk for ADHD and disruptive behavior problems in children of fathers with substance use disorders (many of whom had ADHD and CD as children; Chronis et al., 2003; Clark et al., 2004). Risk for child behavioral problems is greatest when both parents have substance abuse problems (Osborne & Berger, 2009). Also in line with the links between child ADHD and other forms of parental psychopathology, genetic transmission forms at least part of the explanation for this association. For example, Knopik and colleagues (2006) found support for a genetic link between maternal alcohol use disorders and offspring risk for ADHD. However, as we discussed previously, consistent with disorder-specific risk transmission, studies that have assessed a broad range of parental psychopathology have found that child ADHD is best predicted by ADHD in the mother and/or father, more so than parental alcohol/substance use (e.g., Clark et al., 2004).

Viewed within a transactional framework, substance use in the parent may be seen as both cause and effect of child ADHD/disruptive behavior problems. It likely interacts with other family variables, such as parenting or other forms of parental psychopathology, in complex ways. As one illustration of the possible directions of effect between child ADHD and parental substance abuse, we consider a series of experimental studies by Lang, Pelham, and colleagues (e.g., Pelham & Lang, 1999). These studies have clearly documented "child effects" on the amount that adults drink following difficult interactions with deviant children. In the first of these studies, college student participants interacted with child confederates who were well behaved or who displayed behaviors characteristic of a child with ADHD and disruptive behavior problems. Interestingly, even though interacting with the deviant child confederate produced distress in both males and females, only male students drank more following these interactions (Lang, Pelham, Johnston & Gelernter, 1989). However, in later studies with parents, they found that not all parents drink more following difficult interactions with children showing symptoms of ADHD and/or disruptive behavior problems. The effects of stressful parent–child interactions on alcohol consumption seem to be most pronounced in parents with a family history of alcoholism (Pelham et al., 1998) and/or parents with higher levels of anxiety and depressive symptoms (Kashdan, Adams, Kleiman, Pelham, & Lang, 2013). In summary, these experimental studies suggest that, while not all parents of children with ADHD drink more in response to stressful interactions with their children, some are at risk for these child-induced effects. It is therefore important for clinicians to assess parents' level of stress reactivity and tendency to engage in stress-induced drinking.

Turning to the effects of parental substance use on parenting, this same series of experimental studies also examined the effects of drinking on parents' perceptions of their children and parenting behaviors while interacting with the child confederates. Intoxicated parents perceived fewer behavioral problems in deviant confederates, although alcohol consumption did not affect ratings of the pleasantness of the interaction or the effects of the interaction on parent mood and stress levels (Lang, Pelham, Atkeson & Murphy, 1999). Importantly, however, intoxicated parents were observed to be more permissive, off-task, and directive, and less attentive in interactions with child confederates (Lang et al., 1999)—behaviors suggesting that alcohol impaired their ability to provide proper support, supervision, and feedback to the child.

Similarly, although rarely studied in relation to child ADHD, the broader literature suggests that illicit drug use in parents is associated with observed ineffective parenting, which in turn is associated with child disruptive behavior problems (Bailey et al., 2013). Moreover, parental neglect (Dunn et al., 2002) and punitiveness (Miller, Smyth, & Mudar, 1999) are more often seen in drug- and alcohol-abusing parents than in other parents. The possibility that children with ADHD may be particularly susceptible to the negative effects of less effective parenting within families of alcohol/drug-abusing parents highlights the need for further study in this area.

In summary, the extant literature demonstrates effects of child ADHD and disruptive behavior on parental alcohol consumption, as well as effects of alcohol/substance use on parents' perceptions of child behavior and observed parenting behavior. These processes are likely to be most pronounced in families with a history of alcohol/substance abuse and dependence, and among parents who experience depression or anxiety in addition to stress-induced drinking.

Interparental Conflict and Divorce

The clinical presentation of children with ADHD is often compounded by a family history of marital instability, exposure to interparental conflict, and divorce. Parents of children with ADHD are at least three times more likely to be separated or divorced compared to

parents of children without ADHD (Barkley, Fischer, Edelbrock, & Smallish, 1991). Not only are parents of children with ADHD more likely to divorce, but they also have a shorter latency to divorce compared to parents of children without the disorder (Wymbs et al., 2008b). Strikingly, results of a Danish study suggested that 10 years after birth of a child with ADHD, parents had a 75% greater probability of ending their relationship than did parents of a child without ADHD (Kvist, Nielsen, & Simonsen, 2013).

Risk for interparental conflict and divorce in families of children with ADHD may be exacerbated in part by parents' own mental health problems, such as those considered in previous sections (e.g., antisocial behavior in fathers; Wymbs et al., 2008b). For instance, adults with ADHD are more than 5 times more likely to be divorced currently and 15 times more likely to have ever been divorced than adults in the general population (Klein et al., 2012). At the same time, recent twin studies have suggested little role for parental genetic factors as an explanation for the higher divorce rate in parents of children with ADHD (Schermerhorn et al., 2012). In a study of genetically identical adult twins, in which one of the adults was parent to a child with ADHD and the other was not, ADHD in the child predicted parental divorce and interparental conflict. This association held when researchers controlled for genetic risk, parent psychopathology, timing of parental divorce, and forms of offspring psychopathology other than ADHD. Together, these studies provide convincing evidence for "child effects" on interparental conflict and divorce.

Whether parents of children with ADHD are married, separated, or divorced, they often experience disagreements regarding the severity of the child's symptoms, the extent to which the ADHD symptoms impair the child's functioning, and what treatment approach, if any, to take (Stein, Diller, & Resnikoff, 2001). Parents of children with ADHD also are more likely to disagree about how to manage the child's difficult behavior (Johnston & Behrenz, 1993). In particular, disagreements related to the child, relative to other sources of interparental conflict, have been linked to child behavior problems (Nikolas et al., 2012). Furthermore, these childrearing disagreements are likely to be reciprocally linked to not only interparent inconsistencies in responses to the child but also parental distress and marital discord.

As with parent–child interactions, there is growing evidence that coexistence of child and parent disruptive or antisocial behavior can exacerbate conflict between parents of children with ADHD. Within an ADHD sample, paternal antisocial behavior and the severity of child disruptive behavior symptoms predicted the timing of divorce (Wymbs et al., 2008b). In another study, adolescents with ADHD and comorbid CD reported witnessing more frequent and unresolved interparental conflict compared to adolescents without ADHD, adolescents with ADHD only, or adolescents with ADHD and oppositional defiant disorder (Wymbs, Pelham, Molina, & Gnagy, 2008a). Providing the strongest evidence of child effects are experimental studies indicating that both during and after interacting with a child confederate who is behaving like a child with ADHD, parents communicated more negatively with one another (Wymbs & Pelham, 2010). And these child effects were stronger for parents of children with comorbid disruptive behavior problems. Moreover, negative parenting partially mediated the causal pathway between disruptive child behavior and negative communication between parents (Wymbs, 2011). In summary, these studies suggest that child disruptive behavior contributes to both negative parenting and increased interparental conflict, in line with our transactional model. Thus, as with other aspects of family functioning, we see that co-occurring disruptive behavior problems compound the associations between child ADHD and interparental conflict and divorce.

Turning to the effects of interparental discord on children with ADHD, we know from years of developmental research that interparental discord, particularly when it occurs in the child's presence, can contribute to poor child outcomes. Confirming these effects in the context of child ADHD, the child's perceptions of interparental conflict (self-blame in particular) are associated with parent and teacher ratings of the child's inattention and hyperactivity– impulsivity, even after researchers control for a number of other risk factors (Counts, Nigg, Stawicki, Rappley & Von Eye, 2005). Importantly, developmental research in this area demonstrates that the child's perspective is critical because the child's perception of interparental conflict is more predictive of child behavior problems than the parents' reports of conflict (Grych & Fincham, 1990). Clinicians are thus advised to assess inter-parent discord using both parent and child reports in the formulation.

Providing further evidence for reciprocal effects among child ADHD, disruptive behavior problems, and interparental conflict, prospective longitudinal research indicates that over a 1-year period, marital discord predicts child emotional and behavioral dysregu-

lation; at the same time, child behavioral dysregulation is linked to subsequent higher interparental conflict (Schermerhorn, Cummings, DeCarlo, & Davies, 2007). Not only is there evidence for reciprocal interparental and child effects, but recent work also has focused on how interparental discord may interact with child genetic risk in determining outcomes for children with ADHD. For example, in recent studies by Nikolas and colleagues (2012, 2013), the child's tendency to blame him- or herself for interparental conflict moderated genetic and environmental (i.e., interparental conflict) influences on child ADHD.

Together, work in understanding interparental discord in families of children with ADHD fits within a pattern of bidirectional and reciprocal influences operating between the child and parents. In other words, child ADHD and disruptive behavior problems both contribute to, and are influenced by, interparental discord, often via inconsistencies in parenting behavior and disruptions in the parent–child relationship. In addition, parental psychopathology and other family stressors contribute to these interparental processes to produce a cumulative picture of influences on the child's developmental trajectory.

SIBLING RELATIONSHIPS AND ADHD

Sibling relationships play a critical role in the family (Feinberg, Solmeyer, & McHale, 2012). Interactions with brothers and sisters are often proposed as the first testing grounds for children's development of important social competencies (Brody, 2004), and children's perceptions of differential parental treatment of siblings are strong predictors of adjustment outcomes (Buist, Deković, & Prinzie, 2013). The strong heritability of ADHD combined with shared environmental influences (e.g., Hicks, Foster, Iacono, & McGue, 2013), place siblings of children with ADHD at elevated risk for both ADHD and a range of other behavioral and emotional problems (e.g., Listug-Lunde, Zevenbergen, & Petros, 2008; Steinhausen et al., 2012). This collection of facts—including the potential of siblings to steer children toward more or less socially skilled developmental trajectories, the elevated likelihood of problems among siblings of children with ADHD, and the higher likelihood of differential allocation of parental resources or affection when one sibling has ADHD—might lead one to expect that sibling relationships of children with ADHD have been the target of considerable research. However, this is not the case. What little research there has been confirms increased conflict in the sibling relationships of children with ADHD, particularly if there are comorbid disruptive behavior problems along with ADHD (e.g., Mikami & Pfiffner, 2008). Much less is known about the mechanisms underlying this conflict or its implications for children's outcomes.

Future research focused on sibling relationships of individuals with ADHD, across the lifespan, may provide insight into growth-promoting or detrimental factors in these relationships. It is possible that poor sibling relationships may deprive the child with ADHD of the chance to develop even rudimentary social skills, thus setting the stage for increased interpersonal problems as the child enters the world outside of the family. At the same time, a supportive and accepting sibling relationship may provide a crucial buffer or place of safety throughout the life of the individual with ADHD. Research in this area is challenged by the need to disentangle genetic and environmental influences on sibling relationships, to account for the complexity in sibling relationships due to birth order and gender variations, and to examine these relationships as they develop and exist in parallel to the individual developmental pathways and parent–child relationships of each of the siblings.

CONCLUSIONS

As the research reviewed in this chapter illustrates, our understanding of the role of families in child ADHD has evolved considerably over the past 35 years. From early incorrect and harmful views of bad parenting as the cause of child ADHD through a period of research in which family contributions were limited to genetic influences on the neurobiology of ADHD, we have emerged to a place where the role of family in child ADHD can be seen as more complex and nuanced, with multiple reciprocal and dynamic interactions among child and parent genetic vulnerabilities, parenting and family context, and extrafamilial influences. Although we have considered different aspects of family functioning in separate sections of this chapter, we hasten in this final section to point out the many interrelationships and shared influences among these factors. As outlined in the transactional model, each aspect of child, parent, and family functioning is by definition part of a network of mutual and associated influences. And these multiple linkages mean that the presence

of risk factors in one area (e.g., parental depression) heralds elevated risks in other areas (e.g., interparental discord) as well. On the other hand, strengths within the child or the family, such as positive interactions or effective monitoring, may exert a protective influence.

We conclude with thoughts regarding how clinicians can best utilize the information presented in this chapter. The evidence points clearly to the necessity of careful and full consideration of family characteristics (including both risk and protective factors) when evaluating and treating children with ADHD. On the one hand, clinicians must appreciate the multiple difficulties that may characterize families of children with ADHD, and the unfortunate potential of these parental and family challenges to place children with ADHD on a pathway to the development of more serious disruptive behavioral and emotional problems.

On the other hand, to the extent that these specific risk factors are modifiable, we believe that there are substantial opportunities for clinicians to work collaboratively with families to alter the child's environment in a way that minimizes the negative impact of the ADHD symptoms on the family, prevents the development of more serious problems, and functions to optimize the functioning of all family members. Thus, the interrelated nature of child and parent functioning in families of children with ADHD presents both a challenge and an opportunity. While there is the risk of multiplying and escalating problems, the mutual and reciprocal influences also mean that positive changes in any aspect of child, parent, or family functioning have the potential to contribute positively to development in other domains.

KEY CLINICAL POINTS

- ✓ Parent–child interactions form the core of a set of larger family and social experiences that impact the development of children with ADHD.
- ✓ Child ADHD symptoms contribute to parenting difficulties, and child ADHD and parenting problems together contribute to the development of more serious disruptive behavior problems.
- ✓ Parents who have a low sense of parenting efficacy or who endorse child-blaming explanations for child misbehavior are at greater risk for ineffective parenting, and their children are at increased risk for the development of disruptive behavior problems.
- ✓ Clinicians should be aware of the potential of interventions aimed at parenting behavior and cognitions because these provide avenues to the prevention of serious disruptive behavior problems in children with ADHD.
- ✓ ADHD in both parents and children within a family is relatively common.
- ✓ Parental ADHD symptoms are predictive of difficulties with providing calm and consistent discipline, consistent structure/organization, and supervision. Parental ADHD symptoms are less consistently associated with problems with positive parenting or responsiveness.
- ✓ Clinicians should always consider the possibility of parental ADHD when children are referred with the disorder, and assess the extent to which parental ADHD symptoms may be impacting parenting or treatment progress.
- ✓ Approximately half of all mothers of children with ADHD have experienced clinical depression, and even more experienced heightened parenting stress and subclinical levels of depressive symptoms. Depression in fathers also is associated with child ADHD and disruptive behavior problems.
- ✓ Maternal depression is associated with the later development of depression and suicidal behavior, as well as the maintenance or exacerbation of conduct problems, in children with ADHD.
- ✓ Consistent with a transactional framework, exposure to difficult child behavior may contribute to the development of depression in parents. Likewise, parental depression can impact the quality of parenting and contribute to interparental conflict—both of which influence child adjustment.
- ✓ Clinicians should be keenly aware of parent stress and depression in families of children with ADHD, particularly as these factors relate to parenting and treatment participation/outcome.
- ✓ Antisocial behavior is present in some parents of children with ADHD. Antisocial behavior in parents is more closely associated with child disruptive behaviors (particularly CD) than with ADHD per se, and is often comorbid with adult ADHD.
- ✓ Parent antisocial behavior can have direct and indirect influences on the child via parenting, interparental conflict, exposure to violence, and other environmental risks (e.g., poverty).

- ✓ In families of children with ADHD, alcohol/substance use problems may be present in one or both parents.
- ✓ A subset of parents with anxiety and depressive symptoms may respond to challenging interactions with their children by engaging in stress-induced drinking.
- ✓ Given that alcohol consumption and drug use can influence parents' perceptions of their children and their behavior during parent–child interactions, clinicians should be aware of a family history of alcohol and drug problems, as well as the parent's tendency to engage in stress-induced drinking.
- ✓ Parents of children with ADHD are more likely to experience interparental conflict and divorce. Child disruptive behavior problems and parental psychopathology exacerbate risk for interparental conflict and divorce.
- ✓ There is evidence of "child effects" on interparental conflict. At the same time, exposure to interparental discord has a negative impact on child adjustment.
- ✓ Children's perceptions of interparental conflict, and their tendency to blame themselves for this conflict, are important for clinicians to consider because both predict poor child adjustment.
- ✓ Clinicians should strive to help parents to work collaboratively to provide consistent structure and discipline, while minimizing the extent to which the child is exposed to interparental conflict.
- ✓ Siblings of children with ADHD are at elevated risk for both ADHD and other problems.
- ✓ Little research has addressed sibling relationships, but clinicians may find that sibling relationships have the potential either to exacerbate the difficulties of children with ADHD or to provide helpful support throughout development.

CHAPTER 8

Peer Relationships of Children with ADHD

Julia D. McQuade and Betsy Hoza

A substantial portion of children with attention-deficit/hyperactivity disorder (ADHD) demonstrate significant struggles in their social relationships and behavior. In fact, revisions to the description of ADHD in DSM-5 now include social activities as a domain of functioning that can be negatively affected by the symptoms of inattention, hyperactivity, or impulsivity (American Psychiatric Association, 2013). It is not hard to see how these symptoms may interfere with social interactions. Interrupting, talking excessively, noisiness, and difficulty waiting for their turn are likely to make children with ADHD appear intrusive and annoying to peers during play activities (Pelham & Bender, 1982). Similarly, distraction and failure to listen are likely to interfere with the ability to attend to peers effectively, and to notice and respond to social cues (Cadesky, Mota, & Schachar, 2000). Effective assessment and treatment of youth with ADHD must involve consideration of the child's social functioning not only within the broader peer group but also in terms of their dyadic friendships, social behaviors, and social-cognitive skills. In addition, unique challenges emerge during adolescence, when peer interactions can involve risky behaviors (e.g., substance use, sexual behavior) and may also take electronic and online forms (e.g., texting, social media). In this chapter we review what is currently known about the social impairments of children with ADHD across these contexts. When available, evidence of differences in presentation across genders and DSM-5 presentations of ADHD (formally referred to as "subtypes" in DSM-IV) is noted.

PEER RELATIONSHIPS

Peer Acceptance and Rejection

When peers are asked to nominate the classmates they like and dislike as friends, children with ADHD are likely to be nominated by the majority of their classmates as being disliked and by few as being liked (Gresham, MacMillian, Bocian, Ward, & Forness, 1998). In fact, in a review, Hoza (2007) estimated that between 50 and 80% of children with ADHD could be classified as rejected by their broader peer group. Children with all three presentations of ADHD (combined, predominantly inattentive, and predominantly hyperactive/impulsive) were at increased risk for peer rejection, though risk may have been highest among those with the combined presentation of ADHD (Gaub & Carlson, 1997). Children with ADHD and comorbid oppositional defiant disorder (ODD) or conduct disorder (CD) also have higher rates of peer rejection than

children with ADHD alone (Mrug et al., 2009). However, there did not appear to be gender differences in rates of peer rejection and lack of acceptance in youth with ADHD (Hoza, Mrug, et al., 2005). In general, children with ADHD reported liking their peers more than their peers reported liking them (Hoza, Mrug, et al., 2005; Mrug et al., 2009); this suggests that although children with ADHD may see many children within their peer group as desirable friends, this viewpoint is unlikely to be reciprocated.

Of significant concern were findings that peer rejection develops rapidly and is resistant to change (Hoza, 2007). For instance, as early as the first day of a summer academic program, campers rated children with ADHD as less desirable as friends than control children (Erhardt & Hinshaw, 1994). Pelham and Bender (1982) observed nonhyperactive peers' responses to hyperactive children when placed in a playgroup together for 90 minutes. They found that the nonhyperactive peers often began complaining about the hyperactive child's behavior within minutes. In addition, when asked how much they liked playing with the hyperactive child at the end of the play session, nonhyperactive peers reported their extreme dislike of the hyperactive children (Pelham & Bender, 1982). Thus, it appears that, almost immediately, peers find the social interaction style of children with ADHD aversive. What is more, these results suggest that children with ADHD may quickly re-create their rejected status when entering new peer groups.

Other evidence suggests that negative peer regard is not easily reversed, even with intensive evidence-based treatments that reduce the symptoms of ADHD (Hoza, Gerdes, et al., 2005). This may in part be due to the intractable nature of children's social reputations and peers' expectations of children with ADHD (Hoza, 2007). For example Harris, Milich, Corbitt, Hoover, and Brady (1992) found that if children expected to interact with a child who displayed symptoms of ADHD, then they were less friendly toward that child and more likely to describe that child's behavior as being hyperactive than if they had no expectations about the child. Most importantly, these differences were found regardless of whether the child did indeed have ADHD. This suggests that even if negative social behaviors improve, peers may continue to view the child with ADHD in a negative light. Hoza (2007) highlighted these findings and argued that in order to address the peer rejection of children with ADHD, their social reputation within their broader peer group must be changed.

Rejection by the broader peer group also appears to be a marker of risk for both internalizing and externalizing problems in children with ADHD. Among males and females with and without ADHD, childhood peer rejection is found to predict increased risk for adolescent substance use, delinquency, anxiety, and global impairments over and above the risk associated with an ADHD diagnosis (Mrug et al., 2012). Results from a female-only sample suggested that childhood peer rejection may act as an additive risk factor above and beyond the risk incurred by a diagnosis of ADHD. Specifically, peer rejection predicted increased risk for adolescent externalizing problems, internalizing problems, eating pathology, and poor academic achievement (Mikami & Hinshaw, 2006). Studies that used nonclinical samples provide insight into how peer rejection may increase risk for later maladjustment. Specifically, children who are rejected by peers are likely to be socially isolated, which may limit social support and subsequently increase risk for internalizing problems such as depression (Bell-Dolan, Reaven, & Peterson, 1993). Children who are rejected by peers are also more likely to turn to other rejected peers as friends; such peers may be more likely to model and encourage delinquent behaviors, thus increasing risk for externalizing problems (Berndt, 1999). Indeed one study revealed that among a broad range of risk factors, peer rejection was the strongest predictor of later psychological maladjustment in a nonclinical sample of children (Cowen, Pederson, Babigian, Izzo, & Trost, 1973).

Dyadic Friendships

In addition to rejection by the broader peer group, children with ADHD also are less likely to have reciprocated friendships (i.e., when two children mutually nominate one another as a friend). For instance, using a subsample of children from the Multimodal Treatment Study of Children with ADHD (MTA; MTA Cooperative Group, 1999), Hoza, Mrug, and colleagues (2005) found that 56% of children with ADHD had no reciprocated friendships, 33% had one reciprocated friendship, and only 9% had two reciprocated friendships. In contrast, 32% of comparison children had no reciprocated friendships, 39% had one reciprocated friendship, and 22% had two. Other evidence suggests that a lack of any dyadic friendships may be even greater among children with clinically elevated symptoms of inattention and hyperactivity that co-occur with conduct problems. Gresham and colleagues (1998) found that

more than 70% of children with this symptom profile had no reciprocated friendships as compared to less than 25% of control children. Though evidence is limited, it appears that males and females with ADHD are equally likely to lack dyadic friendships (Hoza, Mrug, et al., 2005).

Children with ADHD also appear to differ in whom they befriend. Although children with ADHD and comparison children are equally likely to identify socially accepted children as desired friends, these socially accepted children are less likely to name a child with ADHD as someone they want as a friend (Hoza, Mrug, et al., 2005). This may deny children with ADHD the opportunity to interact and learn from more socially skilled children, and limit the options of whom they can befriend. Research examining the characteristics of the mutual friends of children with ADHD revealed that their friends are more likely also to demonstrate symptoms of ADHD, noncompliance, and deviance (Bagwell, Molina, Pelham, & Hoza, 2001; Blachman & Hinshaw 2002; Normand et al., 2011; Whalen & Henker, 1985). It may be that peers with similar behavioral problems are more willing to befriend children with ADHD or, as Normand and colleagues (2011) suggested, children with ADHD are specifically attracted to peers with similar social goals (e.g., sensation seeking, deviance).

Despite the likelihood that children with ADHD seek out friends whose symptom profiles are similar to theirs, this does not translate into better friendship quality. In fact, when Normand and colleagues (2011) examined the friendships of children with and without ADHD, they found that both children with ADHD and their identified friend mutually perceived less positive features (e.g., validation, companionship, help, intimacy, and conflict resolution) and were less satisfied in their dyadic friendship relative to comparison children and their friend. Children with ADHD also perceived more negative features (e.g., aggression, exclusivity, and conflict) in these friendships, though this perception was not shared by the friend. During social interaction tasks with their identified friend, children with ADHD also were more likely to violate rules when the task was competitive and were more insensitive, self-centered, and dominant in their negotiation style when the task involved sharing (Normand et al., 2011). Thus, it may be the behavior of the child with ADHD, rather than the friend's behavior, that increases negativity within the friendship. Other evidence suggests that the friendships of girls with ADHD may specifically be characterized by higher levels of relational aggression (e.g., gossiping, spreading rumors, and intentional exclusion) both within the friendship and directed toward others (Blachman & Hinshaw, 2002).

Given the higher incidence of negative behaviors within the friendships of children with ADHD, it may not be surprising that these children also have less stable friendships over time (Blachman & Hinshaw, 2002; Normand et al., 2013). Normand and colleagues found that at 6-month follow-up, 25% of children with ADHD were no longer mutually friends with their friend from 6 months earlier. In contrast, only 9% of control children lost their mutual friendship. They also found evidence to suggest that children with ADHD may be more likely to lose friends because their friends' dissatisfaction with the friendship increases over time. At 6-month follow-up, the friends of children with ADHD were more dissatisfied and perceived less positive features in the friendship than they did at baseline. Importantly, children with ADHD did not perceive these same declines in their friendship quality, suggesting that they may fail to notice problems within the friendship as they emerge.

Preserving friendships may be especially important for children with ADHD. Evidence suggests that the presence of a best friend is protective against more global peer rejection (Blachman & Hinshaw, 2002) and a greater number of friendships is protective against peer victimization (Cardoos & Hinshaw, 2011). Greater intimacy with a best friend (e.g., self-disclosure of secrets and problems) also may buffer risk for increased social problems over time in children with elevated ADHD symptoms (Becker, Fite, Luebbe, Stoppelbein, & Greening, 2013). Despite the more short-term benefits of dyadic friendships, long-term studies suggest that lack of a best friend did not predict behavioral and emotional maladjustment or global impairment 6 to 8 years later, although greater peer rejection did (Mrug et al., 2012). Even if dyadic friendships do not predict long-term outcomes, Mikami (2010) argued that it may be more effective to focus on cultivating or improving specific friendships for children with ADHD rather than attempting to shift the perception of an entire peer group.

Bullying and Victimization

The peer relationships of children with ADHD also may be characterized by higher incidences of both vic-

timization and bullying. Evidence suggests that children with ADHD are more likely to be victimized by peers in verbal (e.g., teasing), physical (e.g., pushing or shoving), and relational (e.g., damaging social relationships) ways relative to comparison children (Wiener & Mak, 2009). For instance among 9- to 14-year-old children, 58% of those with ADHD were victimized several times a week by peers, compared to 14% of comparison children (Wiener & Mak, 2009). Not only are children with ADHD more likely to be victimized, they also are at risk for engaging in bullying behaviors themselves. For instance, Unnever and Cornell (2003) found that middle school students with ADHD were more likely to be victimized two to three times a month relative to comparison children (34 vs. 22%), but they were also more likely to bully peers (13 vs. 8%). Some evidence suggests that rather than ADHD symptoms, it is the presence of comorbid ODD that predicts engagement in bullying (Wiener & Mak, 2009). The experience of victimization or engagement in bullying also has been found to increase risk for social and emotional maladjustment in children with ADHD. For instance, Taylor, Saylor, Twyman, and Macias (2010) found that relative to youth with ADHD who were not victimized, those who were victimized had greater co-occurring parent-rated internalizing and externalizing problems and more self-reported depression symptoms. In addition, youth with ADHD who were victimized and also engaged in bullying were found to have the highest levels of internalizing problems and depression symptoms within the ADHD sample.

SOCIAL BEHAVIORS

Peer difficulties among children with ADHD may partly stem from their intrusive, annoying, and disruptive social interaction style (Pelham & Bender, 1982; Whalen & Henker, 1992). For example, in small playgroups, children with ADHD were found to display high frequencies of negative verbalizations (e.g., teasing, name calling), negative nonverbal behaviors (e.g., hitting, noncompliance, intruding on others' activities), and loud or disruptive behaviors (e.g., running around, loud or repeated yelling; Pelham & Bender, 1982). During play and structured classroom activities, children with ADHD were rated as more noncompliant, disruptive, and aggressive than control children (Erhardt & Hinshaw, 1994). Also, during a social leadership task with younger unknown peers, children with ADHD displayed more hostile affect, disruptiveness, criticism, and overinvolvement than did comparison children (Buhrmester, Whalen, Henker, MacDonald, & Hinshaw, 1992). Peers may be especially intolerant of the disruptive and noncompliant behavior that children with ADHD tend to exhibit (Erhardt & Hinshaw, 1994; Mrug, Hoza, Pelham, Gnagy, & Greiner, 2007). Mrug and colleagues (2007) found that in a summer camp program, rule breaking, failure to pay attention during activities, and complaints were the strongest predictors of peer rejection in children with and without ADHD.

Some children with ADHD may also engage in aggressive behaviors. Risk for aggression appeared greatest among children with the combined presentation of ADHD (Hodgens, Cole, & Boldizar, 2000; Maedgen & Carlson, 2000) and children with comorbid ODD or CD symptoms (Abikoff et al., 2002; Ohan & Johnston, 2007). The type of aggressive behaviors displayed may also differ between genders. Relative to comparison children of the same gender, males with ADHD were more likely to engage in both physical and verbal aggression, whereas females with ADHD were more likely to engage only in verbal aggression (Abikoff et al., 2002). In female samples, it has been found that girls with ADHD are at higher risk for engaging in both overt and relational forms of aggression relative to girls without ADHD (Zalecki & Hinshaw, 2004). Relational aggression appears to be highest among girls with ADHD and comorbid ODD, though girls with ADHD alone still demonstrate higher rates than controls (Ohan & Johnston, 2007). The quality of relationally aggressive behaviors also may differ in girls with and without ADHD. Ohan and Johnston used a simulated chat room task to examine relationally aggressive behaviors in girls with and without ADHD. Results indicated that girls with ADHD were more likely to use overt and less skillful forms of relational aggression (e.g., stating in posted messages that they were ignoring or did not like another player). In contrast, control girls used more planned and covert forms of relational aggression (e.g., divulging one player's secrets to strengthen their relationship with a different player; Ohan & Johnston, 2007). Covert and skillful forms of relational aggression have been found to predict greater popularity and social power in nonclinical samples (Heilbron & Prinstein, 2008); however, girls with ADHD may be unlikely to accrue this social benefit from their more overt relationally aggressive gestures.

Importantly, children with ADHD typically do not differ from comparison children in their use of positive prosocial behaviors (Buhrmester et al., 1992; Mikami, Huang-Pollock, Pfiffner, McBurnett, & Hangai, 2007; Pelham & Bender, 1982) suggesting that it is not a lack of positive social interaction that drives negative peer relationships. Instead, children with ADHD often are described as being "socially busy" and may be more likely to initiate social interactions relative to peers without the disorder (Whalen & Henker, 1985, 1992). They also may present as more emotionally intense. Evidence suggests that those with combined type ADHD demonstrate more intense emotional displays of both positive and negative affect relative to comparison children (Maedgen & Carlson, 2000). Although not necessarily negative in nature, the fact that children with ADHD engage in a higher frequency of social interactions and are more emotionally intense may nonetheless increase their visibility by peers; this may create more opportunities for unwanted or negative peer interactions (Whalen & Henker, 1985).

Subtypes of ADHD

It is important to note that the previous descriptions best characterize the social behaviors of children with the combined and predominantly hyperactive–impulsive presentations of ADHD. Studies that have differentiated between the social behaviors of children diagnosed with DSM-IV combined type and inattentive type ADHD find that those with the predominantly inattentive type are more likely to appear as socially withdrawn, passive, and shy (Hodgens et al., 2000; Lahey, Schaughency, Strauss, & Frame, 1984; Maedgen & Carlson, 2000). For instance, during a playgroup with newly acquainted peers, children with inattentive type ADHD were rated by observers as high in social withdrawal relative to children with combined type ADHD and control children (Hodgens et al., 2000). Children with inattentive type ADHD also were rated by teachers as less assertive than children with combined type and comparison children (Solanto, Pope-Boyd, Tryon, & Stepak, 2009). Although the social behaviors of children with predominantly inattentive type ADHD may be qualitatively different, research indicates that these behaviors are still associated with peer dislike (Hodgens et al., 2000) and suggests that the subtypes do not differ in global social impairment (Solanto et al., 2009). Of course, these subtypes are now cast as "presentations" in DSM-5. These presentations may differ based on the severity of the predominant ADHD symptom dimension but do not represent distinct or static diagnostic categories.

SOCIAL-COGNITIVE SKILLS

Social-cognitive deficits also may contribute to the social impairments of children with ADHD. Although researchers have noted that some children with ADHD may lack appropriate social knowledge and skills (Grenell, Glass, & Katz, 1987; Wheeler & Carlson, 1994) this is not necessarily always the case. It is possible that many children with ADHD have social skills in their repertoires but primarily demonstrate social performance deficits; in other words, they have difficulty *applying* social skills effectively (de Boo & Prins, 2007; Wheeler & Carlson, 1994). In support of a social performance deficit, studies reveal that children with ADHD are poor monitors of their social behavior and have difficulty modulating behavior in accordance with shifting environmental demands (Landau & Milich, 1988; Whalen, Henker, Collins, McAuliffe, & Vaux, 1979). For example, Landau and Milich (1988) observed the social behaviors of children with and without ADHD when they were asked to shift between the roles of "host" and "guest" during a TV talk show game with another child. They found that control children were able to change their behavior in accordance with the two roles (e.g., answering more questions as the guest than as the host). However, children with ADHD failed to modulate their behavior between the two roles; instead they tended to adopt one interaction style and to use that style regardless of the shifting environmental demands or the response of the other child (Landau & Milich, 1988). The social performance deficits that children with ADHD display may result in part from deficits in key social-cognitive skills, including social information-processing, emotion recognition, and perceptions of social performance.

Social Information Processing

According to Crick and Dodge's (1994) reformulated social information-processing (SIP) model, individuals process social information in multiple stages. This includes encoding relevant social cues, interpretation of social information, setting a social goal, generating

and evaluating potential responses, and selecting a response. Evidence suggests that children with ADHD demonstrate a unique pattern of SIP, which may help explain their social performance deficits. For example, relative to comparison children, children with ADHD encode fewer social cues when presented with hypothetical social vignettes (Andrade et al., 2012; Matthys, Cuperus, & van Engeland, 1999). When children with ADHD do not have comorbid ODD or CD, their errors in encoding tend to be nonsystematic (Andrade et al., 2012; Cadesky et al., 2000; Sibley, Evans, & Serpell, 2010), suggesting that they are primarily a result of inattention to social information rather than biased attending. Children with ADHD also have greater difficulty integrating and organizing social cues coherently and are more likely to base their interpretation of social situations on the most recently supplied social information (Milch-Reich, Campbell, Pelham, Connelly, & Geva 1999). This is likely to affect their interpretation of social situations and their ability to make informed decisions about how they should respond. In addition, when asked to generate possible responses to social dilemmas, children with ADHD think of fewer responses than do comparison children (Matthys et al., 1999; Zentall, Cassady, & Javorsky, 2001). Thus, children with ADHD may fail to encode key social cues, have difficulty using those cues effectively to understand a social situation, and have greater difficulty identifying appropriate social responses. As a result, children with ADHD are likely to miss important social information and may persist in their use of negative or inappropriate behaviors.

Children with ADHD and comorbid ODD or CD may demonstrate a different pattern of SIP that is more consistent with aggressive children (Crick & Dodge, 1994). Matthys and colleagues (1999) found that boys with ADHD and comorbid ODD or CD were more likely to generate aggressive responses to hypothetical social dilemmas and to report greater confidence in their ability to use aggression relative to comparison children; this pattern of responding was not found in children with ADHD without this comorbidity (Matthys et al., 1999). However, in a sample of girls with ADHD, a diagnosis of ODD or CD was not associated with the generation of more aggressive responses or biased interpretations of hostility (i.e., a hostile attributional bias). In addition, SIP patterns only weakly predicted aggressive behavior in girls with ADHD, though associations were stronger for comparison girls (Mikami, Lee, Hinshaw, & Mullin, 2008). This may suggest that, at least among girls with ADHD, aggressive behavior results more from impulsivity and poor emotion regulation than from deficient SIP. Given that few studies have examined the implications of SIP for behavior in children with ADHD, additional research is needed.

Emotion Recognition

More limited evidence suggests that children with ADHD also may have specific difficulty identifying emotions. Incorrect identification of emotion has been found both when children are presented with spoken sentences and when they view pictures of faces (see Uekermann et al., 2010, for a review). Some evidence suggests that the errors in emotion identification made by children with ADHD are random in nature (Cadesky et al., 2000), suggesting that they primarily result from inattention. However, other evidence suggests that children with ADHD may have specific difficulty identifying anger or fear in facial expressions, and may be more likely to perceive these expressions as neutral or sad (Williams et al., 2008). Failure to read emotions in others may directly impair the ability of children with ADHD to monitor peer feedback. Given the tendency of children with ADHD to behave in emotionally intense ways (see Chapter 3), failure to notice anger or fear may be especially problematic. In these situations, children with ADHD may not realize that their intensity is making peers uncomfortable, and they may therefore persist in these behaviors.

Positively Biased Self-Perceptions

When children with ADHD rate their social competence on self-report measures, on average, they tend to overestimate their competence relative to how their teacher or parent rates their competence (Hoza, Pelham, Dobbs, Owens, & Pillow, 2002; Hoza et al., 2004). This overestimation of competence, termed a "positive bias" (or, in earlier work, a "positive illusory bias"), is found when examining self-perceptions of social competence, as well as competence in other domains (e.g., academic competence, behavioral conduct). This positive bias also is more common and more extreme in children with ADHD than in comparison children (see Owens, Goldfine, Evangelista, Hoza, & Kaiser, 2007, for a review) and does not result merely from

more impaired competence (McQuade et al., 2011). Yet not all children with ADHD exhibit this bias. A substantial subset of children with the combined or hyperactive/impulsive presentations of ADHD demonstrate a positive bias; however, children with the inattentive presentation of ADHD generally to not show a positive bias (Owens & Hoza, 2003).

In addition to evidence of inflated self-perceptions of competence as compared to parent or teacher ratings, children with ADHD, on average, also demonstrate a positive bias when asked to evaluate their *actual* social performance in other contexts. For instance, Hoza, Waschbusch, Pelham, Molina and Milich (2000) asked children with and without ADHD to complete a social interaction task with a child confederate and manipulated their success or failure during the task. On average, children with ADHD rated their social performance during the task as more favorable than did comparison children, despite being rated as less socially effective by objective observers. Importantly, this overly positive self-evaluation was present even in the failure condition, when social failure was blatant (e.g., when the confederate gave clear verbal and nonverbal cues of disinterest; Hoza et al., 2000). Failure of children with ADHD to acknowledge or perceive their social impairments also is found in other areas of social functioning. For instance, children with ADHD failed to report declines in their dyadic friendship that were reported by their friend (Normand et al., 2013). They also failed to report that they engaged in bullying despite endorsement of these behaviors by parents and teachers (Wiener & Mak, 2009).

It is not clear whether the presence of a positive bias in children with ADHD is a result of self-protective motivations or impaired self-monitoring (Owens et al., 2007), and there is evidence to support both possibilities. For instance, Diener and Milich (1997) found that during a social interaction task, children with ADHD overestimated how much their partner liked them only when they received no feedback about their performance during the task. However, when children with ADHD were provided with positive feedback, they did not overestimate their partner's liking. This would suggest that children with ADHD demonstrate a positive bias primarily as a defensive strategy that they may use to counter feelings of inadequacy. If such feelings are assuaged, children with ADHD may have no reason to overestimate their performance. Yet other evidence suggests that a positive bias may result from impairments in executive functioning (discussed in Chapter 4), which may limit social reasoning and perspective-taking ability. Specifically, McQuade and colleagues (2011) compared the executive functioning skills of control children and children with ADHD, with and without a positive bias. Results indicated that children with ADHD and a positive bias in social competence demonstrated greater deficits in a range of executive functioning skills compared to the other groups. This may suggest that children with ADHD with a positive bias have cognitive deficits that impair their ability to engage in effective self-evaluation.

Findings from a study by Hoza, Vaughn, Waschbusch, Murray-Close, and McCabe (2012) suggest that children with ADHD may have an especially difficult time accurately reporting on their social competence relative to other domains of functioning. Specifically, Hoza and colleagues examined how children with and without ADHD rated their competence when told that they could earn a dollar for each item that was rated the same as their teacher. They found that with this potent motivator, children with ADHD significantly reduced their overestimation of academic and behavioral conduct relative to teacher report but continued to demonstrate a positive bias in social competence. One possible reason for this finding is that children with ADHD have greater difficulty accurately judging their social competence, perhaps because social feedback is more subtle, or because of cognitive impairments that affect SIP. An alternative possibility, however, is that admitting to impairments in social functioning is especially difficult for some children with ADHD and that, even with motivation, they continue to deny their social struggles.

Although the reason for a positive bias is still not fully understood, failure to acknowledge or perceive social impairments is likely to have negative implications for the social functioning of children with ADHD. Researchers have proposed that accurate self-perceptions may be necessary for individuals to adjust their behavior and to learn from prior mistakes (Colvin & Block, 1994). Thus, children with a positive bias would be expected to be more likely to persist in social impairments over time. Indeed, Mikami, Calhoun, and Abikoff (2010) found that over the course of a behavioral summer treatment program, children with ADHD with a social positive bias showed a decline in peer liking at the end of the summer, whereas those without a positive bias became better liked. The researchers also found

that children with ADHD acquired a greater number of friends at the end of treatment only when they did not have a positive bias in behavioral conduct; those that did have this bias showed no improvement in friendships. It is concerning that this pattern of results was found in the context of a therapeutic summer program in which explicit feedback regarding behavior and instruction in social skills was provided. Those children with a positive bias may have failed to acknowledge the social feedback supplied and may therefore have persisted in their use of maladaptive social strategies.

Other evidence suggests that children with ADHD with a positive social bias may demonstrate a distinct pattern of negative social behaviors. Specifically, Linnea, Hoza, Tomb, and Kaiser (2012) compared the social behaviors of children with ADHD, with and without a positive social bias, and comparison children during a laboratory social interaction task. Children with ADHD with a positive bias were rated by coders as less friendly, responsive, and engaged than both comparison children and children with ADHD without a positive bias. Children with ADHD and a positive bias also exhibited higher rates of odd behaviors, were more likely to appear inattentive, and were more helpless than comparison children; those with ADHD without this bias did not show impairments on these factors (Linnea et al., 2012). A positive bias in behavioral conduct also may specifically increase risk for aggressive behavior among children with ADHD (Hoza, Murray-Close, Arnold, Hinshaw, & Hechtman, 2010; Murray-Close et al., 2010); this may result from greater defensiveness when they receive negative social feedback (Baumeister, Smart, & Boden, 1996). Thus, it appears that children with ADHD and a positive social or behavioral bias are more likely to demonstrate persistent social impairment and greater negative behaviors. Given that acknowledgment of social impairments is likely a necessary prerequisite for adjusting behavior and improving over time, it makes sense that we would see more impaired social functioning among children with ADHD when they demonstrate a positive bias.

UNIQUE SOCIAL CHALLENGES IN ADOLESCENCE

For most children with ADHD, the symptoms of the disorder (Barkley, Fischer, Edelbrock, & Smallish, 1990) and their social impairments (Bagwell et al., 2001) persist into adolescence. However, the developmental period of adolescence may introduce unique social challenges for youth with ADHD. For instance, adolescents with ADHD are more likely to engage in social behaviors that specifically promote deviancy and vulnerability to risky behaviors (Whalen, Jamner, Henker, Delfino, & Lozano, 2002). Whalen and colleagues found that adolescents with high levels of ADHD symptoms were more likely to drink alcohol or smoke cigarettes, to spend more time socializing with friends, and to spend less time with family. The researchers proposed that this pattern of behaviors may suggest that adolescents with ADHD are less well monitored by parents and may therefore have greater opportunity to be exposed to socially risky situations. Comorbid CD may further increase socially risky behavior in adolescents with ADHD. One study found that relative to comparison adolescents and adolescents with ADHD without comorbid CD, adolescents with ADHD and comorbid CD were less likely to be involved in conventional adolescent activities, such as school or community activities. In addition, these adolescents also were more likely to have friends who were using drugs and alcohol. In fact, 64% of parents of adolescents with ADHD and comorbid CD disapproved of their child's friends, compared to 38% of adolescents with ADHD without comorbid CD and 28% of parents of adolescents without ADHD (Bagwell et al., 2001). Other evidence suggests that association with deviant peers increases the likelihood that adolescents with ADHD will engage in substance use themselves (Marshal & Molina, 2006; Marshal, Molina, & Pelham, 2003). Furthermore, deviant peer behavior may more strongly influence the likelihood of substance use in adolescents with ADHD relative to comparison children (Marshal et al., 2003). This risk may be greatest when these adolescents have comorbid ODD or elevated CD symptoms (Marshal & Molina, 2006). Thus, not only are adolescents with ADHD more likely to be drawn to deviant peers, but also they may be particularly impressionable and more likely to mimic their undesirable behaviors.

In addition to substance use, adolescents with ADHD also are more likely to engage in risky sexual behaviors. One study revealed that relative to comparison males, males with a childhood diagnosis of ADHD engaged in sexual activity and intercourse at an earlier age, had more sexual partners, had more sex with newly acquainted peers, had more casual sex without condom use, and had a greater frequency of partner pregnancies

by early adulthood (Flory, Molina, Pelham, Gnagy, & Smith, 2006). Males with ADHD may have increased engagement in these risky sexual behaviors regardless of comorbid disorders (Flory et al., 2006); however, in females, CD, rather than ADHD, may predict greater risk (Monuteaux, Faraone, Gross, & Biederman, 2007). Some evidence suggests that a positive bias in behavioral or social competence may partially explain (i.e., mediate) the association between childhood ADHD and risky sexual behavior in young adulthood (Hoza et al., 2013). This could suggest that adolescents with ADHD are likely to engage in risky sexual behavior because of impaired self-monitoring or poor insight (see Chapter 11 for more on this topic).

The landscape of social interaction for adolescents also has undergone drastic changes in recent years, with increased use of electronic and online social interactions using e-mail, texting, chat rooms, instant messaging, and social media pages such as Facebook. Among a sample of high school students, 90% reported having an e-mail account, 65% reported using instant messaging, and 88% had a profile on at least one social networking site (Reich, Subrahmanyam, & Espinoza, 2012). Research has not directly examined social media use among adolescents with ADHD. However, evidence does indicate that youth with ADHD demonstrate a pattern of aversive and negative social behaviors during online chat room tasks that is similar to their behaviors in live social interactions (Mikami et al., 2007; Ohan & Johnston, 2007). Thus, it is likely that their social impairments also manifest in online interactions with peers. Given that youth with ADHD experience peer rejection and bullying in face-to-face interactions, they may also be at higher risk for victimization by cyberbullying (e.g., bullying through e-mail, instant messaging, chat room, Web, or text interactions). Indeed, in a sample of 10- to 20-year-olds with a diagnosis of either ADHD or an autism spectrum disorder, 21% reported being cyberbullied in the past 2 months but only about 6% reported engaging in cyberbullying (Kowalski & Fedina, 2011). Because a comparison group was not included, it is unclear how these rates compare to normative samples of children and adolescents. Although additional research is sorely needed in this area, the social profile outlined thus far suggests that adolescents with ADHD are likely to demonstrate problems in their peer relationships when online or when using a cell phone. Given their engagement in other risky social behaviors, it also is possible that adolescents with ADHD may engage in risky online behaviors such as posting inappropriate pictures, befriending people they do not know, or posting private or potentially damaging personal information.

CONCLUSION

Peer problems are common and often enduring associated impairments for youth with ADHD. Not only are these children more rejected and less accepted by peers (Hoza, Mrug, et al., 2005), but they also have fewer reciprocal friendships (Mikami, 2010), and when they do form friendships, these friendships are less enduring and of lower quality (Normand et al., 2011, 2013). Unfortunately these patterns of peer dysfunction form quickly in new peer groups (e.g., Pelham & Bender, 1982) and are hard to alter (Hoza, Gerdes, et al., 2005).

The reasons for these peer difficulties are not fully understood, although the very behaviors that characterize ADHD (e.g., impulsivity, hyperactivity, disruptiveness) are likely to be noxious to peers. Children with ADHD are found to be annoying, intrusive, and disruptive in their social interaction style (Pelham & Bender, 1982). They also may be socially eager, attempting to interact as much as (or more than) typical peers, and often with greater emotional intensity (Whalen & Henker, 1992). Despite interest and desire for friendship, their attempts may often be unsuccessful. Overtly negative social behaviors are more typical of children with combined type and hyperactive–impulsive type ADHD, whereas those with inattentive type ADHD may present as socially withdrawn and shy (Hodgens et al., 2000). Although these social behavior profiles differ, all three subtypes are more likely to be disliked by their peers (Hodgens et al., 2000).

Research on the underpinnings of peer dysfunction in this population suggests that even those youth with ADHD who possess appropriate social skills may still have difficulty performing them appropriately in social situations (de Boo & Prins, 2007). Whether this performance deficit stems from inattention to social cues, poor emotion recognition and regulation, impaired SIP, faulty self-monitoring in ongoing social situations, or a combination of these factors has not been definitively determined (McQuade & Hoza, 2008). However, what is certain is that peer dysfunction is an impairing problem, more often than not affecting the happiness and well-being of these youth and placing them at risk for long-term maladjustment (Mrug et al., 2012). Thus, whenever present, peer relationship problems should

be considered a critical target of intervention for youth with ADHD.

KEY CLINICAL POINTS

- ✓ Children with ADHD are more likely to be rejected and less likely to be accepted by the broader peer group.
- ✓ Peer rejection in children with ADHD develops quickly and is resistant to change. Persistence of peer rejection may partly be influenced by the social reputation of the child with ADHD.
- ✓ Children with ADHD are less likely to have reciprocal friendships and are more likely to befriend children with similar behavioral challenges.
- ✓ The friendships of children with ADHD are more negative and less positive in quality, and less stable over time.
- ✓ Children with ADHD are at higher risk for not only being victimized by peers but also engaging in bullying behaviors.
- ✓ Peer rejection, fewer or poorer quality friendships, victimization, and bullying predict greater emotional and behavioral problems in children with ADHD.
- ✓ Children with ADHD, especially the combined and predominantly hyperactive–impulsive presentations, display high rates of intrusive, annoying, and disruptive behavior during social interactions with peers.
- ✓ Aggressive behavior is more common among children with the combined presentation of ADHD, especially with comorbid ODD or CD. Studies using female samples suggest that they may be more relationally aggressive in addition to overtly aggressive.
- ✓ There is a lack of evidence suggesting differences in use of positive social behaviors among children with and without ADHD.
- ✓ Children with ADHD are more socially busy and emotionally intense, which may create more opportunities for negative social interactions with peers.
- ✓ Children with the predominantly inattentive presentation of ADHD are more likely to be shy, withdrawn, and passive in their social interactions with peers; despite differences in social behavior, children with this subtype are still rejected by peers and socially impaired.
- ✓ Children with ADHD demonstrate a distinct pattern of SIP impairments; they encode fewer social cues, have greater difficulty interpreting social situations, and generate fewer effective social responses.
- ✓ The SIP pattern of children with ADHD and comorbid ODD and CD may be specifically characterized by greater ability to generate aggressive responses and greater confidence in using them.
- ✓ Some evidence suggests that children with ADHD may have specific impairments in identifying emotions in others' faces or in spoken sentences.
- ✓ A subset of children with ADHD demonstrate positively biased self-perceptions of social competence and performance.
- ✓ Children with ADHD and a positive bias are less likely to show improvements in their peer relationships, demonstrate a greater frequency of negative social behaviors, and are more aggressive.
- ✓ Adolescents with ADHD may be less well monitored by parents, placing them at increased risk for engaging in socially risky behaviors.
- ✓ Adolescents with ADHD and comorbid CD are more likely to associate with deviant peers and to have friends who use substances; such association may increase their own engagement in substance use, especially if they have comorbid ODD or CD.
- ✓ Adolescents with ADHD are at higher risk for engaging in sexually risky behaviors.
- ✓ Youth with ADHD are likely at higher risk of experiencing social impairments when using online social media and cell phones, though research investigating online behaviors is lacking.

CHAPTER 9

Developmental Progression and Gender Differences among Individuals with ADHD

Elizabeth B. Owens, Stephanie L. Cardoos, and Stephen P. Hinshaw

It is widely known that attention-deficit/hyperactivity disorder (ADHD) is a highly heritable, neurodevelopmental condition affecting many individuals around the world. In the United States, between 6.0 and 9.5% of children and youth have a current diagnosis of ADHD (Barkley, 2006; Visser, Danielson, Bitsko, Perou, & Blumberg, 2013). These estimates, along with U.S. Census data (*www.census.gov/prod/cen2010/briefs/c2010br-03.pdf*), indicate that in 2010, between 3.2 and 5.1 million school-age youth were affected. Among these millions of children and adolescents with ADHD, concurrent psychiatric comorbidities and functional impairments in a wide range of domains—academic, social, psychiatric, and personal well-being—are well documented and widely acknowledged. However, much of what is known about ADHD applies mainly to school-age boys. As ADHD researchers have broadened their focus in recent years, it has become clear that the presentation and nature of ADHD changes over time and perhaps across genders. Our chapter concerns just this variability in presentation. What happens over time to children and adolescents with ADHD? What is the typical developmental trajectory of the disorder and its symptoms, and what are the typical outcomes during adolescence and adulthood? Furthermore, are there important differences between the sexes, especially in terms of developmental progressions or long-term outcomes?

Beyond the scientific relevance of these questions is a more fundamental rationale. Parents of children with ADHD, and the clinicians involved, want to know as much as they can about their childrens' likely futures. Families need to know what to expect. They may wonder whether their child's course will be similar to or different from what is typical and whether his or her future depends on gender, co-occurring psychiatric problems, learning disabilities, or treatment efforts. Thus, we begin our chapter with a discussion of long-term, prospective, longitudinal studies of children who have received a diagnosis of ADHD (or its equivalent) during childhood. We review relatively recent studies with a thorough baseline assessment of ADHD diagnostic status, a control group, and a follow-up assessment at least 4 years later. More distal projects and articles (e.g., Weiss, Hechtman, Milroy, & Perlman, 1985) have produced important findings, but these have been well reviewed elsewhere and are not included here. We include only findings from samples of children and youth who received a categorical designation, DSM-based or otherwise, of ADHD. We do not include studies that assessed only dimensionally measured symptoms related to ADHD, such as "attentional difficulties."

From these prospective longitudinal studies we derive evidence regarding the typical changes in ADHD diagnoses and symptoms over time, from childhood through adulthood. We also derive information concerning outcomes for children and adolescents with ADHD across various domains of psychopathology and impairment, including externalizing and internalizing problems, substance use and abuse, educational and occupational attainment, social functioning, and driving. We do not consider neuropsychological outcomes (although we do consider neuropsychological functioning in the section "Gender Differences") because the focus of our chapter is psychosocial and adaptive functioning, and because a review of cognitive and neuropsychological features would take us far beyond our page limits.

We highlight at the outset that many outcomes for which children with ADHD are at risk are not obtained by all (or even most) children with this condition. Clearly, what is typical for the group does not apply to every member of the group. *Multifinality*, whereby a specific risk factor is associated with a range of outcomes, is the rule with ADHD (Cicchetti & Rogosch, 1996). Moderators and mediators that can explain varyious developmental outcomes include comorbidities, ADHD subtype, neuropsychological functioning, and treatment utilization. We briefly review evidence for these, as well as gender.

Except in the section "Gender Differences," we do not include studies of adults who have self-referred for ADHD treatment or who have otherwise been ascertained as adults. The population of individuals who present with ADHD symptoms in adulthood may be rather different from the population that is identified and diagnosed during childhood, even though many of those adults recall ADHD symptoms as children (Barkley, Murphy, & Fischer, 2008). Furthermore, Mannuzza, Klein, Bessler, and Shrout (2002) estimate that only 27% of adults who recall having ADHD as a child would have met strict diagnostic criteria during that developmental time frame. Whereas data from these individuals can provide important information about ADHD in adults, they are not particularly relevant to questions regarding developmental progression.

After our review and discussion of the longitudinal course, typical outcomes, and moderators of outcomes, we discuss gender differences across the age span. In this section a number of investigations (many cross-sectional) are available for review. We consider gender differences in prevalence, manifestations (e.g., comorbidities, social functioning, neuropsychological functioning), and treatment response. Of particular note, given the developmental theme of our chapter, we focus on whether long-term outcomes are different for girls and boys, and whether ADHD manifests differently between the sexes over time.

THE LAY OF THE LAND: THE PRIMARY LONGITUDINAL STUDIES

Long-term longitudinal studies of clinical child populations and control participants are expensive and difficult to execute. Thus, the information on which we base this first section of our chapter is drawn from a limited number of research projects, although the number of articles produced by these research projects is large. Below are overviews of participants and procedures employed by the major longitudinal projects, in roughly chronological order.

From consecutive referrals by parents, teachers, and pediatricians to a Los Angeles-based outpatient mental health clinic in the early 1970s, James Satterfield and his colleagues recruited European American boys (ages 6–12) for a study of delinquency outcomes and preventive treatments. Using standardized measures administered to parents and teachers, 180 boys were diagnosed as hyperactive. Had the criteria existed at the time, all participants probably would have met criteria for the DSM-III (American Psychiatric Association, 1980) diagnosis of attention deficit disorder (ADD) with hyperactivity. The 110 boys recruited first received 2.1 years of medication treatment, and 70 subsequently recruited boys received 1.8 years of medication plus individualized psychosocial treatment. Eighty-eight control children, matched for sex, age, IQ, and social class, were recruited from local schools. Nine years later, official arrest records for 81 of the medication-treated group and 50 of the multimodal-treated group were obtained when the children averaged 17 years of age. These same records were obtained in early adulthood (ages 19–25) and middle adulthood (ages 32–42), at which point arrest records were available on over 90% of the participants.

Salvatore Mannuzza, Rachel Klein, and their colleagues ascertained a sample of children with hyperactivity in New York City in the early 1970s. From over 1,000 children referred to a psychiatric clinic, 115 were identified as hyperactive based on teacher report and a DSM-II (American Psychiatric Association, 1968) diagnosis of hyperkinetic reaction (for Cohort 2, below,

hyperactivity at home was also required). All children were European American and middle class. The sample was 92% male; only 19 participants were girls. A control group without childhood behavior problems, n = 100, was ascertained at the adolescent follow-up from nonpsychiatric departments of the same medical center to which the probands were referred. Additionally, a replication sample of 111 children with ADHD and 78 controls was obtained shortly thereafter using the same screening and recruitment strategies as the first cohort and with a highly similar follow-up schedule. These children have been followed during adolescence (mean age 18), early adulthood (mean age 25), and most recently during adulthood, 33 years after baseline (in their early 40s). At adolescent follow-up, 98% of Cohort 1 and 89% of Cohort 2 were assessed; at young adult follow-up, 90% of Cohort 1 and 83% of Cohort 2 were assessed; and at the 33-year follow-up, the retention rate was 65% for the participants with ADHD and 76% for the controls.

Importantly, in both the original and the replication samples, children referred primarily for aggression or antisocial behavior were screened out prior to participation. The investigators' intent was to study a group of "pure" hyperactive children without co-occurring externalizing problems. The authors contend that all children in the study would have met the more modern criteria for ADHD combined presentation (ADHD-C). Unlike some prior investigations and like most of the investigations since, follow-up assessors were blind to group status.

Russell Barkley and Mariellen Fischer began the next large, longitudinal study of children with ADHD in Milwaukee, WI, by recruiting and enrolling 158 children in 1979 and 1980. Children, ages 4–12, were referred to a university medical clinic and considered to meet research diagnostic criteria for ADHD when (1) scores on hyperactivity rating scales exceeded two standard deviations above the mean; (2) the parent reported significant behavior problems at home; (3) the parent or teacher complained of inattention, impulsivity, and hyperactivity; and (4) symptom duration was at least 12 months. DSM criteria were not used, but it is quite likely that all participants would have met DSM-III-R criteria for ADHD. Although cross-setting symptomatology was not required, most children displayed problematic behavior in multiple settings, and all had an early age of symptom onset. Notably, given the requirement of elevated scores on a parent-rated hyperactivity index, most children were also aggressive or defiant. This sample was 91% male and 94% European American. They, and 81 control participants who were referred by participants, have been assessed four times: at recruitment during childhood, during adolescence (age range 12–17), during young adulthood (age range 19–25), then during adulthood (mean age 27). Retention rates of participants with ADHD have ranged across age, with average retention rates across publications reported to be between 78 and 93%.

Joseph Biederman and his colleagues have conducted two long-term longitudinal studies of children and adolescents with ADHD using highly similar methodologies in each. The first study involved boys ages 6–17 who were recruited and enrolled in the 1980s. Probands were referred from a pediatric psychopharmacology clinic and from primary care pediatric practices. One hundred forty boys who met DSM-III-R (American Psychiatric Association, 1987) criteria for ADHD according to a structured diagnostic interview administered to parents and children older than 12 were enrolled, as were 120 control boys recruited from the same pediatric practices that referred the ADHD probands. All boys were European American and middle class. Initial follow-up occurred 4 years later and retention was very high (91%). At the 10-year follow-up (mean age 22) 80% of participants with ADHD and 88% of controls were retained.

In the subsequent girls' study, parallel recruitment and assessment strategies were used. Ultimately, 140 probands and 122 controls ages 6–18 were enrolled. Unlike the boys' study, a small percentage of nonwhite (6% of the ADHD group and 11% of the control group) and lower-income children were included. After their initial assessment, these girls were followed up 5 years later at the mean age of 17, at which time 88% of the participants with ADHD and 92% of the controls were reassessed. These girls were also reassessed during young adulthood (mean age 22), approximately 11 years (range 8–14) after their baseline assessment. At that point, retention of the participants with ADHD and controls was fair (69 and 75%, respectively). Of note, in both the boys' and girls' studies, subtypes (combined vs. predominantly inattentive) were not diagnosed because DSM-III-R (American Psychiatric Association, 1987) diagnostic criteria were used, but it is believed that the vast majority of participants would have met current criteria for ADHD-C.

In New York City between 1990 and 1997, Jeffrey Halperin, Jeffrey Newcorn, and colleagues recruited 169 children ages 7–11 from local schools and medi-

cal practices. The children were referred for behavior problems and assessed using the Parent version of the Diagnostic Interview Schedule for Children (DISC), either version 2.1 (Fisher et al., 1993) or version 2.3 (Shaffer, Fisher, Dulcan, & Davies, 1996). Enrolled children met criteria for ADHD according to DSM-III-R (American Psychiatric Association, 1987), and most would have met DSM-IV (American Psychiatric Association, 1994) criteria for ADHD-C. The sample was ethnically diverse (24% European American, 26% African American, 35% Hispanic), mostly low income, and mostly male (88%). A control group of 85 children was recruited through direct advertisement in the probands' neighborhoods. Fifty-one percent of these children were followed up once, 9 years later, when they were ages 16–21 (mean age 18.2).

The Multimodal Treatment Study of Children with ADHD (the MTA) was the largest child clinical trial ever sponsored by the National Institute of Mental Health. Originally, 579 school-age children with ADHD were recruited at six sites in the United States and Canada from mental health settings, pediatricians, advertisements, and schools. They were carefully diagnosed using DSM-IV criteria for ADHD-C, according to the Parent version of the DISC, version 2.3 (Shaffer et al., 1996), supplemented with up to two symptoms identified by teachers for children falling just below the DISC diagnostic threshold. Children averaged 8.5 years old (range 7.0–9.9 years), were 80% male, and 61% European American. They were randomized to one of four 14-month-long treatment conditions: medication only, behavioral treatment only, medication plus behavioral treatment, and community control. Treatment occurred between 1994 and 1997, with initial follow-ups at 10- and 22-months posttreatment. Since a 6-year postbaseline follow-up, participants have been assessed every 2 years, with data collection coming to an end in 2013, 16 years after baseline. At each follow-up, priority was placed on obtaining multiinformant and multimethod data across domains of functioning, with a particular emphasis on substance use and disorder outcomes.

William Pelham, Brooke Molina, and colleagues conducted the Pittsburgh ADHD Longitudinal Study (PALS), in which 364 probands were recruited between 1999 and 2003 as adolescents and young adults (ages 11–28) for a study of predictors of alcohol and drug abuse. Between 1987 and 1996, when they were ages 5–17 years, all had been diagnosed with ADHD according to DSM-III-R or DSM-IV criteria as part of their participation in a summer treatment program. Additionally, 240 controls recruited primarily through pediatric practices matched the probands in terms of age, sex, ethnicity, and parental education level. The total PALS sample was 89% male and 82% European American. After adolescent ascertainment, these participants were followed yearly five times, with excellent retention (over 90%).

Benjamin Lahey and William Pelham recruited preschoolers (ages 3–6 years) in consecutive years at two sites. In Chicago, children were recruited from a psychiatry clinic. In Pittsburgh, half of the children were recruited from a psychiatry clinic and half from an advertisement. Two hundred fifty-five children who met symptom criteria for ADHD based on parent–teacher rating were enrolled. Given that the children had not yet entered the formal school environment, the cross-situational impairment was not required for eligibility, but all children showed impairment in at least one setting, and most showed impairment in two. Controls, who matched probands in terms of sex, ethnicity, and age, were recruited from schools similar to those attended by the probands. Eighteen percent of the sample was female, and 36% were nonwhite. Children were followed up yearly for 14 years, with the last assessment occurring during late adolescence. Retention rates were high (80–92% across assessments 6–14 years after baseline); measures emphasized psychiatric symptoms and impairment.

The Berkeley Girls with ADHD Longitudinal Study (BGALS) began in 1997 and is ongoing; a fourth wave of data collection began in the Fall of 2013. Girls ages 6–12 were recruited and enrolled in a naturalistic, observational, 5-week summer program that operated for three summers: 1997 (n = 79); 1998 (n = 77) and 1999 (n = 72). Through a multigated screening and diagnostic process, a total of 140 girls diagnosed with ADHD according to DSM-IV criteria, and 88 age- and ethnicity-matched comparison girls without ADHD, were assessed at baseline. Diagnostic status was established using the Parent versions of the DISC-IV (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) and the Swanson, Nolan, and Pelham–IV (SNAP-IV; Swanson, 1992) ratings. Ninety-three of the girls were diagnosed with ADHD-C, and 47 with predominantly inattentive type ADHD (ADHD-PI). The sample, representative of the San Francisco East Bay area, is 53% white and socioeconomically diverse. Girls were first seen during childhood, then followed up during adolescence (mean age = 14.2 years) and young adulthood

(mean age = 19.6 years). Retention at the first follow-up was 92%, and that at the second was 95%. At each assessment point, data were collected from multiple informants (parents, teachers, peers, self, objective testing) regarding multiple domains of symptoms and impairments.

Of note, girls with ADHD-PI, as well as ADHD-C, participated in the BGALS study, allowing comparison of subtype differences not possible in previous studies that used DSM-III or DSM-III-R criteria, or focused only on children with ADHD-C. This study, the MTA, and Biederman's girls' study, are to our knowledge the only three long-term longitudinal studies that include a large number of girls with ADHD. Additionally, although not an epidemiological or true community sample, girls in the BGALS study were recruited from multiple sources, including schools and direct advertisements. Some children were referred from physicians, but unlike the previous longitudinal studies reviewed here, many were not. As noted below, participant recruitment strategies are an important consideration when interpreting and generalizing findings from studies of children with ADHD.

Across these studies, a few characteristics are noteworthy. With few exceptions, most children with ADHD followed longitudinally have been boys. Nearly all participants have been from the United States. The majority have been white and middle class, although the Newcorn/Halperin participants were primarily nonwhite and the BGALS sample was only 53% white. For various reasons, including the lack of established ADHD subtype diagnoses at the time of ascertainment in most samples, ADHD subtypes have not been documented, except in the BGALS sample. In most cases, participant presentation was consistent with the ADHD-C subtype. Importantly, the majority of children followed prospectively have been identified through referral to psychiatric or mental health facilities, although a sizable minority have been referred by teachers and schools or recruited through direct advertisement. To our knowledge, only two prospective longitudinal studies of children with and without ADHD have employed true community samples: August and colleagues (2006) and Bussing, Mason, Bell, Porter, and Garvan (2010). August and colleagues screened over 7,000 children in grades 1–4 at 22 schools in Minnesota and ultimately identified 205 children who met full DSM-III-R criteria for ADHD. Some of these children (n = 131) were followed up in late adolescence (36% attrition), at a mean age of 18. Bussing and colleagues randomly sampled 1,615 children from over 12,000 public school children in kindergarten through fifth grade in North Florida. Girls were oversampled, and the sample was demographically diverse. Four hundred seventy-six were identified as high risk for ADHD, but ultimately only 169 were diagnosed with ADHD and agreed to participate. These children, and a control group, were followed up, ultimately until age 17.

THE DEVELOPMENTAL PROGRESSION OF ADHD

Diagnostic Status and Symptoms over Time

ADHD was once believed to be a transient childhood problem that typically resolved by adolescence or adulthood. The sum total of evidence from longitudinal research reveals that this is clearly not the case. Some earlier reports showed ADHD diagnostic persistence, when self-reported, to be quite low. For example, only 8–11% of probands showed continuing self-reported ADHD at adolescent follow-up, with rates depending on definition of persistence (Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1993). Similarly, Barkley, Fischer, Smallish, and Fletcher (2002) documented that only 5% of hyperactive probands self-reported persistence into young adulthood. According to Hill and Schoener's (1996) meta-analysis of nine studies utilizing mostly self-report at follow-up, the diagnostic rates of ADHD decline 50% every 5 years. Their findings suggest that, by adulthood, very few people diagnosed as children continue to meet criteria for ADHD (0.05% of adults at age 40), implying that most children with ADHD will "grow out of it."

However, answers to the question about developmental progression depend on how persistence is defined and whom one asks (Barkley et al., 2002; Mannuzza, Klein, & Moulton, 2003). When parents are queried about their children's continuing symptoms and impairment, the picture is vastly different from that portrayed by the previously cited findings. For example, in Barkley's sample, using DSM-III-R diagnostic criteria, parent report produced a persistence rate of 72% at adolescence (Barkley, Fischer, Edelbrock, & Smallish, 1991). In young adulthood, this rate was 46%, compared to the 5% reported previously (Barkley et al., 2002). When developmentally referenced criteria were used (i.e., when normative declines in inattention, hyperactivity, and impulsivity were considered), the rate of parent-reported ADHD persistence increased to

66%, and the rate of self-reported ADHD persistence increased to 12%. Importantly, evidence suggests that parent report has more predictive validity than self-report, especially in terms of its concurrent and longitudinal associations with impairment (Barkley et al., 2002). A diagnostic lesson is that exclusive reliance on self-reported symptomatology is highly likely to lead to false-negative designations in the world of ADHD assessment.

Similarly, in the Mannuzza samples, when based on parent report, rates of ADHD persistence into adolescence increased from 8 and 11% (depending on cohort) to 40 and 43%, respectively (Gittelman, Mannuzza, Shenker, & Bonagura, 1985; Mannuzza et al., 1991). Of note, this rate of persistence into adolescence, even when parent-reported, is somewhat lower than findings from the Barkley, Biederman, and Hinshaw samples, probably because children with aggression and antisocial behavior were screened out of the recruitment process. These lower rates may obtain in a "pure" ADHD sample, whereas higher rates obtain in more representative samples when typical comorbidities are allowed. Similarly, Molina and colleagues (2009) reported that even according to parents, only 30% of their original sample retained the diagnosis 8 years later during adolescence, probably because most of the children in their sample received intensive treatment for ADHD.

Other, more recent studies clearly show high rates of parent-reported ADHD persistence into adolescence and adulthood, whether narrowly defined by DSM diagnostic criteria or more broadly defined based on symptom level and impairment. August, Braswell, and Thuras (1998) showed that during early to midadolescence, 69% of their participants still met criteria for ADHD. In the BGALS study, only 39 of the 128 girls with childhood ADHD assessed at the 5-year follow-up during adolescence no longer met full diagnostic criteria. Of those with an original ADHD-PI diagnosis, 76% continued to meet full ADHD diagnostic criteria during adolescence, according to parents, as did 66% of the girls with ADHD-C (Hinshaw, Owens, Sami, & Fargeon, 2006). In contrast, only 10% met diagnostic criteria on the DISC according to self-report during adolescence. At the 10-year follow-up (Hinshaw et al., 2012), rates of full ADHD diagnostic persistence were somewhat lower. Of those with a childhood diagnosis of ADHD-PI, 61% retained an ADHD diagnosis at young adulthood, as did 56% of those with ADHD-C. Only 15% of probands met criteria on the self-report DISC. Of note, these persistence levels do not account for changes in subtype; they reflect how many girls with a particular childhood diagnosis had any type of ADHD at follow-up.

In estimating the persistence versus remission of ADHD over time, Biederman and colleagues not only examined the rates at which children continued to meet full diagnostic criteria for ADHD (syndromatic persistence) but also included girls and boys who fell just short of the symptom criteria and demonstrated significant functional impairment (symptomatic persistence) in estimates of persistence versus remission of ADHD over time. Accordingly, in the female sample during adolescence, 82% showed either type of ADHD persistence (Biederman et al., 2006a). As young adults, 62% of these girls showed symptomatic or syndromatic persistence (Biederman, Petty, Fried, et al., 2010). Among the boys, as adolescents, 85% retained full or subthreshold ADHD and full recovery was rare (Biederman, Faraone, Milberger, & Guite, 1996; Biederman, Mick, & Faraone, 2000). During young adulthood, 63% continued to have either syndromatic or symptomatic ADHD, and an additional 15% had low symptom levels but were functionally impaired (Biederman, Petty, Evans, Small, & Faraone, 2010).

It follows that because, at a diagnostic level, childhood ADHD tends to persist, ADHD symptoms also tend to persist across time. At the same time, ADHD symptom presence should be judged in relation to what is expected given one's age. As a function of development, ADHD symptoms of inattention, hyperactivity, and impulsivity can and do decline over time (e.g., 18-year-olds are not as physically active, forgetful, or disorganized as 6-year-olds), but generally remain much higher in individuals with childhood ADHD compared to those without (Biederman et al., 2000; Hart, Lahey, Loeber, Applegate, & Frick, 1995; Loya & Hinshaw, 2013). For example, during both childhood to adolescence (Fischer, Barkley, Edelbrock, & Smallish, 1990) and adolescence to adulthood (Fischer, Barkley, Smallish, & Fletcher, 2005), all children show normative improvements on objective measures of inattention and impulsivity, but children diagnosed with ADHD still remain significantly more inattentive and impulsive than those without a childhood ADHD diagnosis. Loya and Hinshaw (2013) showed the same for parent-reported symptoms of inattention, impulsivity, and hyperactivity among girls. All decline significantly from childhood until early adulthood, but they remain four to 11 times as high in girls with childhood ADHD compared to girls without. Among girls and boys, this

overall decline in symptoms occurs gradually across childhood and adolescence, then accelerates by early adulthood (Monuteaux, Mick, Faraone, & Biederman, 2010). It appears that symptoms of hyperactivity–impulsivity show less stability, in the form of greater declines, than symptoms of inattention (August et al., 1998; Biederman et al., 2000; Fischer, Barkley, Fletcher, & Smallish, 1993b; Hart et al., 1995), at least until young adulthood, after which time the symptom types are equivalently stable (Biederman, Petty, Evans, et al., 2010). Thus, at the symptom level, children with ADHD typically continue to exhibit and to be impaired by inattention and disorganization as they grow into adolescents and adults, even as the level of their symptoms (particularly hyperactive–impulsive symptoms) declines with normative development.

In summary, data obtained primarily from clinically referred children (both boys and girls) suggest that according to parents, rather than participants, ADHD persists at high levels into adolescence and at moderate levels into adulthood. Wilens, Biederman, and Spencer (2002) estimated that half of children rigorously diagnosed with ADHD will continue to meet diagnostic criteria for the disorder as adults. In line with this conclusion, and using a community-based sample of children with ADHD, Bussing and colleagues (2010) showed that 44% continued to meet full diagnostic criteria during adolescence. When persistence of ADHD is defined by continuing symptoms and significant impairment (rather than meeting full diagnostic criteria), as many as two-thirds of children diagnosed with ADHD show persistence into adulthood (Faraone, Biederman, & Mick, 2006). This is true despite normative declines in symptoms of inattention, hyperactivity, and impulsivity. It is important to remember that data about the developmental progression of ADHD are obtained primarily from referred children rather than from undetected children with ADHD in the community. We know less about what happens to children who have ADHD but are not identified as needing help. Additionally, most children in the relevant investigations met criteria for what is now called ADHD-C. Persistence rates for children with ADHD-PI may be lower (as suggested by Hart et al., 1995). However, the limited data collected from children with ADHD-PI followed long term (Hinshaw et al., 2006, 2012), as well as the observation that inattentive symptoms seem to more stable than hyperactive–impulsive ones, suggest that this may not be the case. Moreover, although rates of diagnostic persistence are high—and continued ADHD symptoms and impairment over the long term are expected—there are exceptions. A minority recover or at least improve substantially over time. This may be encouraging news for parents and clinicians.

The latter finding prompts questions about what predicts remission versus persistence. Biederman and colleagues (Biederman, Faraone, Milberger, & Guite, 1996; Biederman, Petty, Evans, et al., 2010) have suggested that increased symptom severity, psychiatric comorbidities, greater impairment, and family history of ADHD are all factors that moderate outcome in the sense that they are associated with increased likelihood of ADHD persistence across time. As noted below, the majority of investigations assessing moderators of outcome have concerned prediction of functional impairments (e.g., Barkley & Fischer 2010, 2011; Fischer, Barkley, Fletcher, & Smallish, 1993a; Miller & Hinshaw, 2010), substance abuse outcomes (e.g., DeSanctis et al., 2008; Marshal, Molina, & Pelham, 2003), or externalizing behavior such as criminality (e.g., Babinski, Hartsough, & Lambert, 1999; DeSanctis, Nomura, Newcorn, & Halperin, 2012; Satterfield & Schell, 1997; Satterfield, Swanson, Schell, & Lee, 1994; Satterfield et al., 2007; Sibley et al., 2011). Continued investigation of which children with ADHD are more or less likely to show persistence versus remission is an important additional step in our understanding of the developmental progression of ADHD. It is also necessary for targeting intervention efforts toward those most likely to show persistence and therefore need treatment.

Expected Outcomes and Moderators of Outcome

Beyond persistence of ADHD symptoms and diagnoses, what are the expected outcomes for children diagnosed with ADHD? The outcome domains most often investigated include externalizing problems (conduct disorder [CD], oppositional defiant disorder [ODD], criminality, antisocial personality disorder [ASPD]), internalizing problems (anxiety and depression), substance use and abuse or dependence, academic functioning, occupational functioning, driving problems, social functioning, and overall impairment. A plethora of longitudinal research over the past 25 years shows that childhood ADHD is a statistical, but not necessarily causal, risk factor for poor outcome in all of these domains. However, there are important caveats. As noted earlier, symptoms and impairment at follow-up depend on who is queried. In many instances, children with

ADHD do not report symptoms and impairment when their parents or others who know them well clearly do. In addition, whether outcome is compromised depends on how it is conceptualized and measured. For example, in the substance use and abuse domain, whether or not ADHD is a risk factor depends on the substance in question and whether the dependent variable reflects trying the substance, frequency of using the substance, or developing a diagnosable substance-related disorder.

When ADHD does clearly portend poor outcome, one must ask whether the finding is related to ADHD specifically or to some correlate of ADHD, such as psychiatric comorbidity at baseline. In particular, when adolescent or adult psychiatric comorbidity is found to be more common among children with ADHD than among controls, is this because baseline comorbidities are simply continuing later in life? When prospective associations between ADHD status and adolescent or adult outcome are statistically significant, are the children with ADHD doing poorly in an absolute and clinically significant sense, or are they simply doing somewhat more poorly than controls? Crucially, when ADHD does predict a poor outcome, it means that the chance of a poor outcome is heightened but not inevitable. In other words, (1) not everyone with ADHD will show the negative outcome, and (2) ADHD itself may not be causal; comorbidities or associated impairments at baseline may instead be the actual cause. Furthermore, the range of outcomes within a given domain, even among children all diagnosed with ADHD, is wide. Therefore, we must ask which baseline variables predict or moderate—or which intervening variables mediate or explain—the particular outcome in question.[1]

Externalizing Domain

Adolescent and adult outcomes in the externalizing domain have been well researched, with a clear take-home message: Childhood ADHD is a risk factor for later externalizing problems at all ages for both boys and girls. Risk for 1-year prevalence of antisocial outcomes (ODD, CD, ASP) was increased in girls at adolescence, and the difference between ADHD and control groups remained significant after researchers controlled for non-antisocial baseline psychopathology (Biederman et al., 2006a), with very similar results obtained for boys (Biederman, Faraone, Milberger, Curtis, et al., 1996). According to Hinshaw and colleagues (2006), parent-reported rates of ODD and CD diagnoses, and the level of externalizing problems (according to both parents and teachers), were higher for girls with ADHD-C or ADHD-PI relative to controls, and these differences survived statistical adjustment for child age and IQ, socioeconomic status (SES), and baseline anxiety and depression (but not baseline CD/ODD), with effect sizes moderate to very large. However, the variety of self-reported delinquent acts was not different for girls with ADHD and controls. Also using data from this sample, Owens, Hinshaw, Lee, and Lahey (2009) showed that 58% of those girls with childhood ADHD had poor adjustment in the externalizing domain during adolescence (as measured by parent and teacher report of ODD symptoms) compared with only 9% of the control girls. Using parallel methodology in a separate, mostly male sample, Lee, Lahey, Owens, and Hinshaw (2008) showed 66% of the ADHD group to be poorly adjusted in the externalizing domain during adolescence versus 21% of comparison children. Using the PALS sample, Babinski, Pelham, Molina, Gnagy, and colleagues (2011) also found higher levels of delinquency severity by young adulthood, with a moderate effect size (d = 0.54), although group differences were not adjusted for baseline demographics or psychopathology.

In line with these findings, among their boys with childhood ADHD (and in contrast to comparison participants), Gittelman and colleagues (1985) found increased rates of CD at adolescence, with those demonstrating persistent ADHD most likely to show antisocial outcomes. Mannuzza, Klein, Abikoff, and Moulton (2004) reported increased rates of CD during adolescence among children with ADHD. The risk for antisocial outcomes persisted when they statistically controlled for age and SES (with baseline antisocial behavior controlled by design); it was more likely when ADHD did not remit. Still, the risk did not depend on the continued presence of ADHD; a childhood diagnosis of ADHD without comorbid conduct problems was enough to increase risk. Also using this sample, Mannuzza, Klein, Konig, and Giampino (1989) reported more arrests, convictions, and incarcerations by late adolescence among the boys with ADHD versus comparison boys. Similarly, Barkley and colleagues (1990) reported that at adolescent follow-up, 59% of their participants with childhood ADHD had CD or ODD. The participants with childhood ADHD also exhibited more criminal behavior. In a more recent report, Barkley, Fischer, Smallish, and Fletcher (2004) indicated that the increased adolescent antisocial behavior

among children with ADHD is primarily drug-related, especially among those with a CD diagnosis.

Virtually every other report of adolescent outcome among children with ADHD reveals similar findings. Satterfield and colleagues used official arrest records to document the long-term criminality outcomes of their samples of hyperactive boys, most of whom had comorbid externalizing problems at baseline. At follow-up in adolescence, these hyperactive boys showed higher rates of felony offenses, but not minor offenses, than controls. Using the PALS sample followed to age 17, Sibley and colleagues (2011) found all children with ADHD to be at risk for earlier age of delinquency and increased severity and variety of delinquency, but the children with ADHD and CD had worse delinquency outcomes than the children with ADHD and ODD or ADHD alone. Furthermore, there were no differences between children with and without ADHD in mild offending prevalence during adolescence. Lahey and colleagues (2007) found higher levels of CD among adolescent boys and girls, with differences maintained when controlling for baseline symptoms of CD. Extending such findings from primarily clinic-referred children, in a community sample, Bussing and colleagues (2010) found increased risks for CD, ODD, and juvenile delinquency among both girls and boys with ADHD followed into adolescence. Similarly, Yoshimasu and colleagues (2012) used archived data to examine a large birth cohort of all children born between 1976 and 1982 in Rochester, MN. Through a multigated screening procedure, 379 children were identified as having ADHD according to DSM-IV (American Psychiatric Association, 1994) criteria. Their increased risk for adolescent CD or ODD was large (hazard ratio = 9.54) and significant, with the risk equivalent for girls and boys. This finding held when the researchers statistically adjusted for maternal education, but they did not control for baseline psychiatric comorbidities.

Adult outcome of children with ADHD in the externalizing domain is highly similar to what is reported among adolescents. Hinshaw and colleagues (2012) found increased rates of parent-reported CD and ODD diagnoses, as well as higher levels of parent- and self-reported externalizing problems among girls with ADHD followed into young adulthood. Yet the variety of self-reported delinquent acts was not different across ADHD and comparison participants. All differences survived control of baseline demographics, internalizing (but not externalizing) comorbidities, and child IQ. Similarly, Biederman, Petty, Evans, and colleagues (2010) documented increased risk for self-reported CD, ODD, and ASP in their female sample. These ADHD versus comparison differences were obtained using both lifetime and one-year prevalence rates and survived control of baseline demographics and all types of psychopathology. Results for boys followed into young adulthood were quite similar, except that the significant difference in one-year prevalence of antisocial disorders did not survive statistical control for baseline antisocial disorders (Biederman et al., 2006b). Across these highly comparable samples of girls and boys with ADHD, the hazard ratio for lifetime antisocial disorders was 7.2 among girls (Biederman, Petty, Evans, et al., 2010) and 5.9 among boys (Biederman et al., 2006b).

By young adult follow-up, hyperactive boys followed by Satterfield and colleagues had earlier arrests, more arrests for violent crimes, and higher rates of arrest and incarceration than control boys, but the number of children who subsequently were arrested only once did not differ across the groups (Satterfield & Schell, 1997). Importantly, SES, IQ, and family type were not controlled. However, at the follow-up in midadulthood, those with childhood hyperactivity showed greater arrest rates (44 vs. 15%), conviction rates (29 vs. 8%), and incarceration rates (26 vs. 8%) than controls, with IQ and SES covaried. Importantly, most children with ADHD did not go on to develop criminal records, and no child with ADHD alone became a chronic offender. Thus, a history of aggression or antisocial behavior appears crucial for the prediction. In other words, the risk for later criminality was not due to childhood ADHD per se but appeared to result from ADHD's increasing the risk for subsequent antisocial psychopathology (CD/ODD), which increased risk for adult offending.

Mannuzza, Klein, Bessler, Malloy, and LaPadula (1998) found higher rates of ASP during early adulthood among their ADHD versus control participants (12 vs. 3%). Well into adulthood, Klein and colleagues (2012) found more ASP (16 vs. 0%) among their participants followed to age 41. At age 38, official records showed that in contrast to comparison boys, those with ADHD had more arrests (47 vs. 24%), convictions (42 vs. 14%), incarcerations (15 vs. 1%), felonies (14 vs. 1%), and violent offenses (19 vs. 3%). Importantly, these differences were entirely accounted for by ASP or substance use disorder in adolescence, which were predicted by earlier ADHD (Mannuzza, Klein, & Moulton, 2008). As in the Satterfield sample, the majority of children with ADHD did not become criminals, and the large majority did not develop ASP. Similarly, Wymbs and

colleagues (2012) found that intimate partner aggression in adults who had ADHD as children was partially accounted for by the development of ASP.

In summary, during adolescence and adulthood according to parent and official reports, and sometimes self-report, a childhood diagnosis of ADHD is statistically associated with increased risk for externalizing-related psychiatric problems (CD, ODD, ASP), as well as antisocial and criminal behavior. Often but not always, the increased risk for antisocial outcomes during adolescence is related to the presence of comorbid externalizing problems during childhood. Antisocial outcomes during adulthood seem to depend almost exclusively on the development or presence of externalizing problems during adolescence and not directly to the presence of ADHD during childhood. Although Gaub and Carlson (1997) reported that rates of co-occurring externalizing problems are lower in girls than in boys (more on this issue, below), the risks for developing externalizing problems appear equivalent across gender. In other words, girls in general are less likely to exhibit externalizing behavior than boys, regardless of ADHD status, but when girls with ADHD are compared to girls without ADHD, their risk of developing externalizing problems is equal to that of boys with ADHD compared to boys without ADHD. Despite increased risk, many, if not most, children with ADHD do *not* go onto to develop externalizing problems or engage in criminal behavior. Finally, because the vast majority of children studied thus far had or would have met criteria for ADHD-C, it is not known whether or not ADHD-PI confers the same longitudinal risk. Among females, Hinshaw and colleagues (2006, 2012) did find that that on five of seven measures across adolescence and young adulthood, the risk for externalizing outcomes was equivalent across ADHD subtype. Exceptions were greater frequency of parent-rated CD diagnosis during adolescence, and higher levels of parent-rated externalizing problems during young adulthood among girls with ADHD-C than among those with ADHD-PI.

Internalizing Domain

Although many have reported increased risks for later internalizing problems among children with ADHD, the evidence for this association is not as robust or uniform as it is for the relation between childhood ADHD and later externalizing problems. The caveats discussed earlier (e.g., considering whether ADHD is a statistical or causal risk factor, considering whether internalizing problems develop over time or are a continuation of previously existing psychopathology) also apply to the assessment of internalizing outcomes among children with ADHD. However, as noted below, gender may be a relevant factor here.

Most recently, Biederman, Petty, Fried, and colleagues (2010) reported increased risk of mood (hazard ratio = 6.8) and anxiety (hazard ratio = 2.1) disorders among girls with ADHD followed to young adulthood, with differences between girls with ADHD and comparison girls surviving control of baseline demographics and all types of psychopathology. At the adolescent follow-up of the same sample, 1-year prevalence of major psychopathology—defined as depression with severe impairment or multiple anxiety disorders or bipolar disorder or psychosis—was increased among girls with childhood diagnoses of ADHD, and differences survived statistical control of baseline psychopathology. Differences in the presence of less severe but clinically significant forms of depression and anxiety were not tested. Although the elevated risk for severe internalizing problems was similar in Biederman's sample of boys during adolescence (Biederman, Faraone, Milberger, Curtis, et al., 1996), it did not obtain in his sample of boys during young adulthood (see below). Lee and colleagues (2008) demonstrated that 36% of children with ADHD are poorly adjusted in the internalizing domain at adolescence compared to only 11% of controls (a significant difference). Likewise, using a parallel methodology with the BGALS sample, Owens and colleagues (2009) found 51% of girls with childhood ADHD to have relatively high levels of parent-reported symptoms of depression and anxiety during adolescence compared to 15% of the comparison girls. Chronis-Tuscano and colleagues (2010) reported increased risk through age 18 years for major depressive disorder or dysthymia (hazard ratio = 4.32) among 125 participants with early childhood ADHD, especially among the girls. Lahey and colleagues (2007) found that the higher rates of adolescent major depression and anxiety disorders for boys and girls with early diagnoses of ADHD remained significant when they controlled for baseline internalizing symptoms. Fischer, Barkley, Smallish, and Fletcher (2002) found that children with ADHD were at high risk for major depressive disorder as young adults, especially those who developed comorbid CD during adolescence. Babinski, Pelman, Molina, Waschbusch, and colleagues (2011) found increased levels of parent-reported, but not self-reported, internalizing problems for men and women. In their community-

identified sample of children with and without ADHD, Bussing and colleagues (2010) found increased risk for anxiety and depressive disorders by adolescence. All girls, with and without ADHD, were at greater risk for anxiety and depression than boys. Yet Yoshimasu and colleagues (2012) reported increased risk for adolescent mood (hazard ratio = 3.67) and anxiety (hazard ratio = 2.94) disorders to be equivalent across genders. These results survived statistical adjustment for maternal education, but baseline comorbidities were not covaried.

Others have failed to find an association between childhood ADHD and later internalizing problems. In none of the reports from Mannuzza and Klein were boys with ADHD found to be at current or lifetime risk for later internalizing problems at any age (Klein et al., 2012; Mannuzza et al., 1991, 1993, 1998). At the follow-up in adolescence of the Hinshaw and colleagues (2006) sample, only some measures of internalizing problems differentiated between girls with ADHD and comparison girls. There were no differences on parent-reported comorbid anxiety or depression; teacher-rated internalizing problems and self-reported depressive symptoms were no longer significant after statistical adjustment of child IQ and age, SES, and baseline ODD/CD. Only parent-reported internalizing symptoms differentiated the groups, with both ADHD-C and ADHD-PI subtypes showing far higher levels than comparisons (effect sizes close to 0.9). At follow-up in young adulthood (Hinshaw et al., 2012), girls with ADHD and comparison girls did not self-report differences in internalizing problems; parent-reported differences in internalizing comorbidities and levels of internalizing symptoms did not survive control of baseline demographic variables and comorbidities. Similarly, Babinski, Pelman, Molina, Waschbusch, and colleagues (2011) did not find self-reported differences in internalizing symptoms for adult men or women. Although Biederman and colleagues (2006b) did find that boys, by young adulthood, were at increased lifetime (but not 1-year) risk for anxiety disorders, the differences between boys with ADHD and comparison boys did not remain after controlling for baseline demographics and comorbidities. These investigators also found increased risk for lifetime and 1-year major psychopathology (including depression), but only lifetime risk remained significant after statistical controls were applied.

In summary, childhood ADHD does appear to increase risk for later internalizing problems, especially during adolescence, but evidence is mixed, and associations often do not hold once baseline demographics and psychiatric comorbidities are considered. On balance, the link between childhood ADHD and later internalizing problems seems to be somewhat stronger for girls than for boys, but this association is not unique to children with ADHD. By adolescence, girls are at higher risk for internalizing problems than are boys, regardless of ADHD status (Hinshaw, 2009).

Substance Use and Abuse

Substance use and abuse are widely studied outcomes of childhood ADHD. Generally, the empirical evidence suggests that ADHD is a risk factor in this domain. However, not all specific outcomes receive consistent support, and some studies fail to find a link between childhood ADHD and later substance use-related outcomes. Results vary depending on the substance studied and whether the variable at hand is "ever used," age at first use, frequency of use, rate of progression to abuse or dependence, or the presence or absence of a substance use disorder. Even across significant findings for similar outcome variables, effect sizes vary.

NICOTINE

Typically, cigarette smoking frequency is used as a measure of nicotine use and dependence. Molina and colleagues (2013), Barkley, Fischer, Edelbrock, and Smallish (1990), Elkins, McGue, and Iacono (2007), Milberger, Biederman, Faraone, Chen, and Jones (1997), and Molina and Pelham (2003) each demonstrated that childhood ADHD is positively associated with cigarette use during adolescence. The latter two studies also documented earlier initiation of smoking among children with ADHD, and Elkins and colleagues demonstrated that ADHD symptoms predict early onset of smoking, with consistent results for girls and boys. Flory, Malone, and Lamis, (2011) found that childhood ADHD symptoms predict cigarette smoking frequency in 10th grade for both boys and girls, controlling for race, SES, and early externalizing problems. However, Bussing and colleagues (2010) reported no differences in tobacco use among community-identified girls and boys at age 16. Similarly, Babinski, Pelman, Molina, Gnagy, and colleagues (2011) did not find that girls with ADHD smoke more frequently than comparison subjects during adolescence or young adulthood. Furthermore, some investigators document a significant role of comorbid conduct or externalizing problems in the genesis of frequent cigarette use

(Burke, Loeber, & Lahey, 2001). For example, according to Barkley and colleagues, 32% of boys with childhood hyperactivity alone smoked during adolescence, whereas 65% of those with hyperactivity and conduct problems did so. Milberger and colleagues found that smoking rates were highest among children with ADHD and comorbid baseline psychopathology. Similarly, Molina and Pelham found that persistent ADHD, especially in concert with CD, was much more strongly associated with later cigarette use than was nonpersistent ADHD.

ALCOHOL

The evidence for increased later use of alcohol among children with ADHD is not as compelling as it is for other psychoactive substances (Charach, Yeung, Climans, & Lillie, 2011; Lee, Humphreys, Flory, Liu, & Glass, 2011), perhaps because alcohol use and abuse occur at high rates among adolescents and adults in general. Molina, Pelham, Cheong, Marshal, and Gnagy (2012) found no increased risk for alcohol use frequency at age 17 among children with ADHD, although ADHD plus low parental monitoring did predict alcohol use. Babinski, Pelham, Molina, Gnagy, and colleagues (2011) found no self-reported problems with binge drinking in adolescence or young adulthood among women. Barkley and colleagues (1990) did not find increased rates of alcohol use among boys during adolescence, based on both mother and child report. Gittelman and colleagues (1985) and Mannuzza and colleagues (1991) found no increased risk for alcohol use disorder in boys with ADHD followed into adolescence; their results were paralleled by Klein and colleagues (2012) when the same boys were followed to mean age 41. Elkins and colleagues (2007) did not find that ADHD predicts alcohol use during adolescence, although symptoms of hyperactivity and impulsivity did predict age of initiation (controlling for CD), with results consistent across gender. Molina and Pelham (2003) found no increased risk for trying alcohol or for alcohol disorders in their follow-up of children with ADHD, although there was an association with increased frequency of drunkenness, with increased risk for children with persistent ADHD or with comorbid CD. Molina and colleagues (2013) found increased rates of ever using alcohol among children with ADHD-C in the MTA followed into adolescence, but rates of alcohol disorders were not different between children with ADHD and comparison children.

ILLICIT SUBSTANCES

In contrast to the results regarding alcohol use and abuse, there is more evidence suggesting an increased risk for later use and abuse of illicit psychoactive substances among children with ADHD (Charach et al., 2011), although, again, the evidence is not uniform. Molina and Pelham (2003) reported increased frequency and earlier initiation of illicit drug use among children with ADHD followed into adolescence, with large effects, especially for children with persistent ADHD. Children with ADHD also used marijuana more frequently than children without ADHD, although the risk for ever trying marijuana was not elevated. Molina and colleagues (2013), in the most definitive study to date, reported more repeat use of marijuana by adolescence among children in the MTA (all with ADHD-C) compared to controls. Mannuzza and colleagues (1991) reported increased drug use at adolescence in boys with ADHD. Although the differences were not significant after they controlled for SES, the effect size was very large. Among the same boys followed to mean age 41, Klein and colleagues (2012) found increased risk for illicit drug use disorders. Similarly, Elkins and colleagues (2007) found childhood ADHD to predict illicit drug use, but not marijuana use, during adolescence, with findings consistent across gender and moderated by CD. Controlling for conduct problems, race, and SES, Malone, Van Eck, Flory, and Lamis (2010) found that ADHD symptom trajectory predicted onset of illicit drug use. Babinski, Pelham, Molina, Waschbusch, and colleagues (2011) found increased parent-reported use of marijuana among boys, but not girls, with ADHD followed to young adulthood. However, they found no self-reported differences in marijuana use at young adulthood for either sex. Barkley and colleagues (1990) found no evidence of illicit substance use differences among boys with and without hyperactivity. Bussing and colleagues (2010) showed no differences in reports of ever having used marijuana for girls or boys, with and without ADHD, but the sample was followed only until age 16, and differences might emerge later in development.

ANY PSYCHOACTIVE SUBSTANCE

Rather than computing risk for use of particular substances, a number of researchers have analyzed composite variables indexing use or abuse of a range of psychoactive substances. Not surprisingly, given the

varying patterns reported earlier, the empirical literature is mixed regarding whether childhood ADHD is associated with generalized risk for later substance use or abuse. Biederman and colleagues (2006a; Biederman, Petty, Fried, et al., 2010) did find that girls with ADHD have higher lifetime and 1-year prevalence of substance use disorders of any kind than comparison girls during both adolescence and young adulthood. However, differences during adolescence did not survive control of baseline psychopathology (thus, they were not specific to ADHD), and neither did the 1-year prevalence differences during early adulthood. Among boys with and without ADHD, Biederman's team did not find any differences in substance use disorders during adolescence (Biederman, Faraone, Milberger, Curtis, et al., 1996) and the differences found during young adulthood (Biederman et al., 2006b) did not hold with statistical adjustment for baseline psychopathology. However, during early adolescence, Biederman and colleagues (1997) found that progression from use to abuse, and from abuse to dependence, was accelerated in boys with ADHD. Also, psychoactive substance use disorders were related to the presence of CD but not ODD.

Molina and colleagues (2013) found elevated rates of any substance use (beyond a single drink or cigarette), any substance use disorder, and number of substances used among the MTA children with ADHD-C followed into adolescence. Gittelman and colleagues (1985) also found increased rates of substance use disorder at adolescence in boys with ADHD, with rates especially high when ADHD was persistent and when CD was comorbid. Similar findings emerged when this sample was followed into adulthood (Mannuzza et al., 1993, 1998). For example, during adulthood, 16% of children with ADHD had a drug abuse disorder compared to 4% of controls. Note that although the odds ratio was large (4.6), the absolute likelihood of developing a drug use disorder in this sample, in which participants with comorbid antisocial problems were excluded, was small. Results held with statistical control of SES.

Among community samples, risks for illicit drug use and abuse are documented. In August and colleagues (2006), only children with ADHD plus an externalizing disorder were at risk; individuals with ADHD only were not. In Yoshimasu and colleagues (2012), the hazard ratio, with controls for maternal education, was 4.03 and equivalent between genders. Of note, Hinshaw and colleagues (2006, 2012) reported no differences in overall substance use severity (a composite measure of variety of substances used and frequency of use) among girls with ADHD followed to adolescence and to adulthood.

SUMMARY

The literature regarding risk for substance use and abuse posed by a childhood ADHD diagnosis is so varied as to almost preclude a summary. At a general level, childhood ADHD does pose some risk for substance use problems during adolescence and possibly during adulthood. In particular, early age of initiation and increased use and abuse of nicotine and illicit substances (but not necessarily marijuana) are predictable from childhood ADHD status. However, empirical support for the association between childhood ADHD and later use and abuse of alcohol is weak. Gender does not reliably moderate any longitudinal, predictive associations. Sometimes associations between ADHD and later substance use are found for girls and sometimes they are not, as is also true for boys. It may be that results depend specifically (1) on the type of substance studied and/or (2) how use or abuse is operationalized and measured. It may also be that there is wide variability in outcome, so that ADHD is associated with risk for later substance use and abuse for some youth but not others (i.e., there is heterogeneity of risk). Thus, identifying moderators of outcome (i.e., factors on which the association between ADHD and later substance use and abuse depends) may be more fruitful than continued assessment of whether at a group-level ADHD is associated with later substance use or abuse.

One such moderator (or mediator, if measured during longitudinal assessments) of the relation between childhood ADHD and later substance use and abuse is comorbid or subsequent psychopathology, especially CD (August et al., 2006; Barkley et al., 2004; Burke et al., 2001; Chilcoat & Breslau, 1999; Looby, 2008; Mannuzza & Klein, 2000; Molina & Pelham, 2003; Nigg, 2013). Realmuto and colleagues (2009) found that risk for later drug was heightened only among those who during childhood had comorbid externalizing problems, even if those problems remitted by adolescence. However, the risk incurred by CD does not absolve the risk for substance use problems associated with earlier ADHD because in many cases ADHD leads to CD. In other words, CD may be the proximal risk factor and statistically accounts for the association between ADHD and substance use problems, but ADHD may be the original, distal risk factor (Molina & Pelham 2014).

Others factors, including maltreatment (DeSanctis et al., 2008) and deviant peer association (Marshal et al., 2003), may moderate or mediate the link between childhood ADHD and later substance use and abuse. Recent theoretical models articulating hypothesized pathways to substance use and abuse enumerate these factors and their putative mediating/moderating roles (Molina & Pelham, 2014). Substance use and abuse among children with ADHD is not as widespread as commonly believed. For example, using Biederman's samples of girls and boys, Wilens and colleagues (2011) estimated the hazard ratio for any substance use disorder to be 1.47. A childhood diagnosis of ADHD, if uncomplicated by concurrent or subsequent externalizing problems or other psychopathology, does not pose a notable risk for most later substance use problems among girls or boys, with the probable exception of increased nicotine use.

A discussion of risk for substance abuse in children with ADHD would not be complete without a comment on whether stimulant treatment moderates this risk. First of all, when observational studies show any association between an intervention (in this case, stimulant medication) and either a positive or negative outcome, the association could be related to the intervention selection bias (Larzelere, Kuhn, & Johnson, 2004). That is, factors driving who decides to seek or accept medication and who does not may be substantially responsible for the outcome, rather than the intervention per se. If children who take stimulants appear to have poor outcomes, it may be because their ADHD was more severe, driving parents to seek medical treatment. Alternatively, more positive outcomes may be related to parental education or income, concern for the child's welfare, or access to other interventions rather than to the medication per se.

Some researchers fear that treating ADHD with stimulant medication might increase risk for psychoactive substance use and abuse as children grow. They postulate that early exposure increases sensitization to psychoactive drugs (Lambert, 2002). Even some who recognize that treatment with stimulants is clearly effective and indicated for many children nevertheless express concern about later increased drug use (Vitiello, 2001). However, at this point, little evidence supports the sensitization hypothesis. Most studies report no association between stimulant medication use during childhood and later substance use or abuse (e.g., Biederman et al., 2008; Chilcoat & Breslau, 1999; Winters et al., 2011). Molina and colleagues (2013) showed no increased—or decreased—risk for adolescent substance use or abuse/dependence associated with stimulant medication treatment in the MTA sample. This conclusion was also reached by Humphreys, Eng, and Lee (2013) in their meta-analysis of studies examining the relation between stimulant medication use and later psychoactive substance use.

Furthermore, some find stimulant treatment to be negatively associated with risk for substance use *disorders*, although this relation has not been tested or established for more general substance use outcomes. For example, Biederman (2003) found risk of substance use disorder to be three to four times more likely in children with ADHD not treated with stimulants than in those treated with stimulants. Katusic and colleagues (2005) also found stimulant therapy to be associated with reduced risk for later substance abuse among boys, controlling for SES. Mannuzza, Klein, Truong, and colleagues (2008) found that earlier use of stimulant therapy protects against substance disorder outcomes.

There is also evidence that stimulant treatment is associated with reduced risk for other undesirable outcomes, including major depression during adolescence (Daviss, Birmaher, Diler, & Mintz, 2008) and psychopathology during young adulthood (Biederman, Monuteaux, Spencer, Wilens, & Faraone, 2009). It is also associated with higher achievement scores and high school grade point average (GPA), when researchers control for initial ADHD symptom severity (Powers, Marks, Miller, Newcorn, & Halperin, 2008). Barbaresi, Katusic, Colligan, Weaver, and Jacobsen (2007) also found that stimulant treatment is associated with positive long-term school outcomes (decreased absenteeism, fewer grade retentions, and higher reading scores) among children with ADHD, as did Scheffler and colleagues (2009), who found that initial stimulant use was associated with increases in reading and math scores among a representative national sample of elementary schoolchildren with ADHD. In all, the bulk of the empirical evidence suggests that stimulant medication does not increase or decrease risk for later substance use and abuse. However, some evidence suggests it may function as a protective factor by reducing risks for poor outcome by ameliorating the long-term effects of childhood ADHD.

Academic Functioning

Not surprisingly, children who by definition have trouble paying attention are likely to have problems learning in a traditional school environment (see Chapters 6 and 12), but the picture across development bears

closer scrutiny. Hinshaw and colleagues (2006) reported lower standardized achievement scores in math and reading, as well as lower teacher ratings of academic performance among girls with ADHD followed into adolescence, compared to controls, with deficits equivalent for girls with ADHD-C and ADHD-PI. However, only the differences in math achievement withheld control for baseline demographics, child IQ, and comorbidities. At young adulthood follow-up, math and reading scores were also equally compromised for girls with ADHD-C and ADHD-PI, and the total years of education obtained was lower for girls with ADHD. Yet only the reading score deficit survived the same statistical controls. Using the same sample, Owens and colleagues (2009) found that 35% of the girls with ADHD have both reading and math achievement scores that are one or more standard deviations below the mean during adolescence, compared to only 4% of controls. Lee and colleagues (2008) demonstrated highly similar results (18 vs. 6%) in a sample of mostly boys.

Hyperactive boys followed to adolescence (Fischer et al., 1990) had lower scores than comparison boys on standardized tests of spelling, reading, and arithmetic when researchers controlled for child IQ and maternal education. They also had more school-related disciplinary problems (e.g., 46% had been suspended and 11% expelled vs. 15 and 2%, respectively, for controls), but these differences were primarily accounted for by comorbid CD (Barkley et al., 1990). Among the grown-up hyperactive group, 32% did not graduate from high school, compared to 0% of the control participants, with differences remaining when researchers controlled for IQ (Barkley, Fischer, Smallish, & Fletcher, 2006). Mannuzza, Klein, Bessler, Malloy, and Hynes (1997) also documented poor educational outcomes over the long-term for boys with ADHD, who in young adulthood had completed two fewer years of education than controls, a difference that held when researchers controlled for IQ. Mannuzza and colleagues (1993) documented the same: 12.1 years versus 14.6 years of education for the participants with ADHD and controls, respectively. Of the boys with ADHD, 20% did not graduate from high school, compared to 2% of the controls. Accordingly, at their midadulthood follow-up, Klein and colleagues (2012) found that 17% of participants with ADHD had not graduated from high school versus 1% of controls. In terms of college graduation, the rate for participants with ADHD was 21%, and that for those without ADHD was 47% (without controls for IQ or SES). As in the Barkley and colleagues (2006) sample, poorer educational outcomes were related to ASP. Babinski, Pelham, Molina, Gnagy, and colleagues (2011) documented in women with a history of childhood ADHD greater academic impairment (according to parent- but not self-ratings); more frequent grade retention and need of academic support; and lower spelling, math, and reading achievement scores. These differences, however, did not withstand adjustment for IQ (although one could argue that covarying IQ is an example of overcontrol; see Miller & Chapman, 2001). Utilizing PALS participants, Kuriyan and colleagues (2013) found children (mostly boys) with ADHD to be worse off on almost all educational variables assessed, including achievement scores, disciplinary problems at school, and level of post–high school education. However, they noted that results for individual children were wide ranging. Children with ADHD who did not have academic or disciplinary problems at school were not at risk for lower educational attainment. Extending the findings to a community sample, Bussing and colleagues (2010) found increased use of special services, more grade retention, lower graduation rates, and lower test scores among children with ADHD, with no differences between girls and boys.

In summary, childhood ADHD predicts significant academic and educational attainment problems for girls and boys during adolescence and young adulthood, with some attenuation in findings when IQ is controlled. Furthermore, two studies suggest that the risk associated with childhood ADHD is contingent on the presence of a learning disability (Faraone, Biederman, Monuteaux, Doyle, & Seidman, 2001) or other features sometimes associated with ADHD (lower IQ, reading ability, and SES; Trampush, Miller, Newcorn, & Halperin, 2009). Thus, although childhood ADHD is associated with risk for later academic and educational problems, it is likely to be part of a multifaceted causal pathway.

Occupational Functioning

The relatively few studies that have followed children with ADHD through adulthood have all reported that they have more employment problems than do children without ADHD. Still, deficits do not obtain on every measure of employment, and participants do not report occupational impairment as often as their parents. Barkley and Fischer (2011) reported lower Hollingshead Job Index scores and fewer hours worked among participants with ADHD by adulthood; those with persistent ADHD also had lower work quality, more trouble on the job (i.e., being fired or disciplined), more hostility

with supervisors, and more job turnover compared to controls and to those with nonpersistent ADHD (Barkley & Fischer, 2011). Barkley, Fischer, Smallish, and Fletcher (2006) reported that boys with both persistent and nonpersistent hyperactivity were more often fired from jobs and had lower job performance, and were more likely to have experienced homelessness (Fischer & Barkley, 2006) by young adulthood than were boys who were not hyperactive as children. Similarly, Mannuzza and colleagues (1993, 1997) found that their participants with ADHD had lower occupational rank in early adulthood but were not more likely to be unemployed than participants without childhood ADHD. Results were partly, but not exclusively, determined by concomitant ASP. Klein and colleagues (2012) found lower employment rates, salaries, and SES among their boys with ADHD at age 41, but effects dissipated after they controlled for ongoing mental disorder. Babinski, Pelham, Molina, Gnagy, and colleagues (2011) found parent-reported, but not self-reported, problems with job performance among women with childhood ADHD. Both men and women self-reported lower SES (Babinski, Pelham, Molina, Waschbusch, et al., 2011). Kuriyan and colleagues (2013) reported lower occupational status, lower maximum hourly salary, and more job loss among those with childhood ADHD versus those without.

Clearly, childhood ADHD signals increased risk for poor occupational functioning and attainment in adulthood. At this point, however, the mechanisms of the association are not completely illuminated. It may be that continuing symptoms of ADHD have a negative impact on success in the workplace, but is also may be that the link is mediated by lower educational attainment or the development of other mental health problems prior to adulthood, as suggested by Klein and colleagues (2012) and Kuriyan and colleagues (2013). It is also unknown whether employment problems resulting from childhood ADHD are present in women to the same extent as in men, although the small-sample Babinski, Pelham, Molina, Waschbusch, and colleagues (2011) investigation suggests that this may be the case.

Driving Problems

Investigators have begun to examine the driving behavior and consequences associated with a childhood diagnosis of ADHD. Fischer, Barkley, Smallish, and Fletcher (2007) have carefully studied these outcomes using official records, self-report, actual driving tests, and a driving simulator. When hyperactive children become drivers, their performance is worse on almost every measure of driving behavior and related outcomes measured during young adulthood, including more traffic citations (e.g., reckless driving and driving without a license), greater frequency of license suspensions, more damage during crashes, less safe driving behavior, more impulsive errors, and slower reaction times. Similarly, Olazagasti and colleagues (2013) reported more at-fault accidents and more accidents involving injury among their ADHD participants followed to age 41. Hinshaw and colleagues (2012) did not find differences in driving offenses and violations at young adulthood follow-up when based on self-report, although significant differences did emerge based on parent report. Although the literature base thus far is small, it is reasonable to conclude that childhood ADHD is a significant risk factor for unsafe and illegal driving behavior (see Chapters 11 and 29).

Social Skills and Relationships

During adolescent follow-up, Hinshaw and colleagues (2006) found significant teacher- and parent-reported social skills deficits among girls with ADHD-C and ADHD-PI, with large effects that survived stringent statistical controls. Teachers rated girls with ADHD-C, but not those with ADHD-PI, as less preferred by peers than those without ADHD. There was also more parent-rated peer conflict for all girls with ADHD, and the effect size for controls versus those with ADHD-C was larger than for those with ADHD-PI (1.07 vs. 0.62). These differences survived statistical control of child age and IQ, SES, and importantly, all baseline comorbidities. In the same sample, Owens and colleagues (2009) found 60% of girls with ADHD to be poorly adjusted in the social skills domain during adolescence according to parents and teachers, versus only 17% of the comparison girls. Lee and colleagues (2008) found 63% of adolescents with childhood ADHD to be poorly adjusted in the social skills domain versus 29% of the control children. In the peer domain, Owens and colleagues found 40% of girls with ADHD to be unpreferred according to teachers versus only 12% of the control girls. The comparable figures according to Lee and colleagues were 49% (ADHD) and 16% (controls).

In adulthood, Barkley and colleagues (2006) found that boys who had been hyperactive as children had fewer closer friends, trouble keeping friends, and according to parents, more social problems than compari-

son boys. Fischer and Barkley (2006) found no differences in number of social relationships in young adults with hyperactivity, but relationship quality was poorer (e.g., fewer close friends, more arguing, trouble keeping friends). Klein (2012) reported more divorces by age 41 among adults who had had childhood ADHD. Finally, on five of seven measures, parents reported that their adult daughters had problems with family and friends (Babinski, Pelham, Molina, Gnagy, et al., 2011). However, paralleling other investigations, the women self-reported relationship problems on only two of 10 measures (romantic relationships and conflict with mother). Clearly, childhood ADHD portends social and relationship problems later in life, although the database supporting this conclusion is not large.

Overall Impairment

Two studies, Lee and colleagues (2008), using the Chicago–Pittsburgh preschool sample, and Owens and colleagues (2009), using the BGALS sample, used parallel methodology to address this question of overall impairment via person-centered analyses. Rates of positive adjustment across the domains of ADHD symptoms, externalizing problems, internalizing problems, peer acceptance, social skills, and academic functioning (only in Owens et al., 2009), were calculated. In both, few children with ADHD showed cross-domain positive adjustment during early adolescence. In Lee et al. only 15% of the children, who were mostly boys, showed positive adjustment in at least four of five domains compared to 64% of the comparison children. In Owens and colleagues the comparable figures were 16% (girls with ADHD) and 86% (comparisons). Others who have looked at overall impairment dimensionally also report much poorer functioning over the long term in children with ADHD. For example, Hinshaw and colleagues (2006) reported effect sizes of 1.07 (ADHD-PI vs. controls) and 1.20 (ADHD-C vs. controls) during adolescence on their parent-reported overall impairment measure. These differences were not accounted for by child age or IQ, SES, or baseline comorbidities. At young adulthood follow-up, results were nearly identical (Hinshaw et al., 2012). In Barkley and Fischer (2011), parents rated participants with persistent and nonpersistent ADHD as more impaired than control boys in all 10 domains assessed; according to self-report, only those with persistent ADHD were impaired across domains. Similarly, Klein and colleagues (2012) found that children with ADHD followed into adulthood (age 41) showed deficits on 11 of 12 measures of adult functioning. In their community sample, Bussing and colleagues (2010) found higher levels of parent- and self-reported overall impairment, and lower self-reported quality of life, among children with ADHD followed into adolescence compared to control participants. Undoubtedly, both girls and boys with ADHD typically experience significant and pervasive impairment in adolescents and into adulthood.

Other Domains

Other negative outcomes of childhood ADHD have been documented, although replication is needed. Regarding self-harm, Hinshaw and colleagues (2012) reported greatly increased risk for self-injury and suicide attempts by young adulthood among girls with ADHD-C but not ADHD-PI. Similarly, Chronis-Tuscano and colleagues (2010) reported increased risk for attempting suicide through age 18 years, especially among girls. Reports of risky behavior during adolescence and adulthood are also emerging. Olazagasti and colleagues (2013) reported more head injuries, emergency department admissions, and sexually transmitted diseases by middle adulthood in boys with ADHD. Barkley and colleagues (2006) documented risks for earlier sexual intercourse and increased likelihood of earlier parenthood, both of which were related to severity of lifetime CD. Flory, Molina, Pelham, Gnagy, and Smith (2006) also reported increased risky sexual behavior (earlier sexual activity, more partners, more casual sex, more partner pregnancies) among boys with ADHD as young adults. Results were moderated by CD, but ADHD alone also posed a risk.

Although parents of children with ADHD often appear to be concerned about their children's self-esteem, evidence for the association between ADHD and low self-esteem is mixed. Slomkowski, Klein, and Mannuzza (1995) did find lower self-esteem during adolescence among children with ADHD (d = 0.5), but self-esteem did not moderate or mediate adult outcomes. Babinski, Pelham, Molina, Gnagy, and colleagues (2011) found parent- but not youth-reported low levels of self-esteem among grown-ups who as children had ADHD. Hinshaw and colleagues (2006) found small ADHD versus control group differences in adolescents on self-perceptions of social and scholastic competence that did not survive control of baseline comorbidities, IQ, or SES, and found no differences on any measure of self-esteem during young adulthood (Hinshaw et al., 2012).

Finally, a small body of literature does consistently support the relation between childhood ADHD and later personality disorders for both men and women (Fischer et al., 2002; Miller, Miller, Newcorn, & Halperin, 2008; Yoshimasu et al., 2012), especially among those with persistent ADHD or comorbid CD.

Summary

Clearly, for both boys and girls, childhood ADHD is associated with increased risk for poor outcome in adolescence and adulthood in the externalizing, academic, occupational, driving, social skills, and overall impairment domains. In most cases ADHD continues to be associated with negative outcomes when researchers adjust for key baseline covariates (especially IQ and comorbid psychopathology), suggesting that risk is related to ADHD per se and not to features associated with the diagnosis. There is also substantial evidence that childhood ADHD increases risk for later substance use and abuse, although findings regarding particular substances and measures of use and abuse are highly variable. The evidence that suggests childhood ADHD increases risk for later internalizing problems is weakest, but it does exist.

Importantly, evidence suggests increased statistical risk, meaning that, on average, certain negative outcomes are more likely in a group of children with ADHD than in a group of children without ADHD. However, outcomes of children with ADHD are variable, and conclusions about what is typical do not extend to all individuals. Whether a particular child with ADHD will experience negative outcomes always depends on baseline or co-occurring characteristics (moderators) and intervening variables (mediators). For example, as noted repeatedly in this chapter, comorbid externalizing problems—especially CD—or the development of externalizing problems during adolescence are clearly factors on which outcome for a particular child would depend with respect to many domains of outcome. Maltreatment (DeSanctis et al., 2008, 2012; Guendelman, Owens, Galan, Gard, & Hinshaw, 2013), ADHD subtype (Hinshaw et al., 2012), executive functioning deficits (Barkley & Fischer, 2011; Miller & Hinshaw, 2010; Miller, Nevado-Montenegro, & Hinshaw, 2012), social disability (Greene, Biederman, Faraone, Sienna, & Garcia-Jetton, 1997), family instability and adversity (Fischer et al., 1993a), and emotional impulsiveness (Barkley & Fischer, 2010) have each been identified as moderating particular outcomes in children with ADHD. At the same time, deviant peer association (e.g., Marshal et al., 2003), impulsivity (Swanson, Owens, & Hinshaw, in press), and low levels of emotional well-being (Latimer et al., 2003) have been identified as mediators of certain outcomes. Not surprisingly, each of these factors predicts poorer adjustment later on, and all essentially reflect additional risks or challenges at the level of the child, peer group, or family.

Treatment, of course, is also a potential mediator. A plethora of evidence suggests that in the short term, both pharmacological and psychosocial treatments are beneficial (Hinshaw, Klein, & Abikoff, 2007). But long-term prospective studies suggest that longer term outcomes of treated and untreated children are equivalent (e.g., Molina et al., 2009). This discouraging finding may occur because factors associated with treatment seeking or treatment continuation after a randomized trial, such as symptom severity or impairment, may be responsible for outcome rather than the treatment itself. It is also important to remember that ADHD is a chronic condition requiring long-term management, yet it is not clear that current, evidence-based, time-limited interventions necessarily persist in their effectiveness over the long haul. Thus, short-term treatment does not appear to mediate long-term outcome.

Unfortunately, a full discussion of the extant literature regarding mediators and moderators of outcome in children with ADHD is beyond the scope of this chapter. Still, what is known about moderators and mediators of outcome for children with ADHD is sparse and is a key area for future research. For now, it should be understood that when attempting to predict outcome or prognosis for an individual child, the child's and the family's particular strengths and weaknesses, as well as those at the level of the school, need to be fully considered.

GENDER DIFFERENCES[2]

We begin by noting the uphill battle that has been fought for clinical and research recognition of the presence and impact of ADHD in females. Believed to be a male disorder for much of the 20th century, only in the past few decades has recognition been given to the reality of ADHD in girls and women, with mounting evidence for the substantial impairments incurred by females with this condition (seminal meta-analyses: Gaub & Carlson, 1997; Gershon, 2002; long-term

follow-up investigations: Biederman, Petty, Fried, et al., 2010; Hinshaw et al., 2012). The clinical reality of ADHD in girls and women, paired with the official wisdom for many years that females could not really "have" ADHD, led to countless instances of underrecognition of the presence of ADHD, internalization of negative sequelae of symptomatology, and inaccessibility of relevant services (see Nadeau, Littman, & Quinn, 1999, for poignant case examples).

Along these lines, once it became recognized that girls and women can and do experience symptoms and attendant problems linked to ADHD, there was considerable effort to demonstrate substantial differences in the ways that relevant symptoms are expressed in males and females (e.g., hyperverbal behaviors in girls/women vs. hyperactive behaviors in boys/men). Moreover, some have contended that the optimal means of evaluating ADHD would be to compare appropriate symptoms to sex-specific norms as opposed to sex-neutral norms (e.g., McGee & Feehan, 1991; Waschbusch & King, 2006). The objective was to acknowledge that a substantial number of females, with extreme symptomatology compared to other females (if not to males), show clear impairment.

Overall, despite some evidence that sex-specific norms may be recommended, there are difficulties with the argument that simply altering relevant symptomatology to the point that sex differences are minimized or eliminated is valid. Some might argue, for example, that men are underrecognized and underdiagnosed with major depression, relative to women, in part because "male equivalents" (e.g., antisocial behavior, substance abuse) are not counted as part of depressive symptomatology. However, making the assumption that these symptom domains are automatically linked to depression is tantamount to asserting that there are no meaningful differences or divergent validity across various patterns of symptoms. Clearly, clinicians should be alert to the possibility of sex-specific expression of ADHD-related symptoms, but we cannot agree that changing the diagnostic criteria to encourage sex-parity in diagnosis is warranted. Indeed, it is well known that most neurodevelopmental disorders show a male predominance (e.g., autism spectrum disorders; early-onset conduct disorder; Tourette syndrome). ADHD, at least during childhood, is no exception (see American Psychiatric Association, 2013). In most, if not all, of the research reviewed below, the diagnostic criteria have been gender/sex-neutral rather than specific.

Despite efforts to distinguish male-like and female-like expressions of ADHD, there are few known gender differences in the developmental progression of ADHD and its core symptoms from childhood to adulthood, and there are few reliable gender differences in expected developmental outcomes of childhood ADHD. A possible exception with respect to the latter is heightened risk for internalizing problems among girls, which is true for all girls, not just those with ADHD. In this section we consider the information available about gender differences from cross-sectional studies. Most study participants are children and adolescents, and findings from these two populations are considered together. When information about gender differences in adults with ADHD is available, we consider it separately. Because the main focus of this section of the chapter is gender differences, the database for the review below comprises investigations that directly compare males and females with ADHD (in childhood, adolescence, and adulthood) with respect to a number of important symptomatic and impairment-related domains of outcome.

However, before we continue, we emphasize that the study of girls with ADHD as they develop into teens and young women—even without direct comparisons to boys—is important in its own right. Indeed, the relative paucity of data on girls and women with ADHD until relatively recently means that the overwhelming majority of inferences about developmental progressions concern male pathways. Thus, we believe that a brief review of issues salient for females with ADHD is warranted.

First, girls with ADHD, as they head toward adolescence and adulthood, maintain difficulties, relative to matched comparison females, in the essential outcome domain of psychiatric comorbidity. Indeed, Biederman, Petty, Fried, and colleagues (2010) found significant differences in lifetime rates of antisocial disorders, mood disorders, anxiety disorders, eating disorders, substance dependence, and developmental disorders in a 10-year follow-up of girls with ADHD. Hinshaw and colleagues (2012) yielded similar findings with respect to externalizing and internalizing disorders by follow-up in young adulthood. Yet significant differences with respect to rates of eating disorders or substance abuse/dependence were not found (see also Babinski, Pelham, Molina, Gnagy, et al., 2011). Note that in the BGALS investigation, significant differences between ADHD and comparison groups with respect to eating-related symptomatology at follow-up in adolescence (Hinshaw

et al., 2006) were no longer significant by the follow-up in young adulthood (Hinshaw et al., 2012), in large measure because of "catch-up" in eating disorder symptoms in the comparison sample by late adolescence.

Second, in terms of functional impairment, it is evident that girls with ADHD, relative to matched comparison girls, maintain significant deficits in academic achievement, social/interpersonal relationships, and need for service utilization (Hinshaw et al., 2012). Such persisting impairments often survive statistical control of demographic, comorbidity-related, and cognitive (i.e., IQ) covariates, revealing some specificity of ADHD–impairment linkages. Even though, in some cases, symptom levels had dropped below the DSM thresholds for continued ADHD diagnoses, clear impairments typically remained years after initial childhood diagnosis.

We also note provocative findings from the past several years with respect to the outcome domain of self-harm. Chronis-Tuscano and colleagues (2010) found that by adolescence, suicidal ideation and suicide attempts were far more prevalent in youth with ADHD than in comparison youth, particularly those with impulsive as opposed to purely inattentive symptomatology, with the small female subsample exhibiting particularly high risk for suicide attempts, significantly greater than that of the male subsample. Moreover, Hinshaw and colleagues (2012) found that by young adulthood, girls with ADHD-C, but not ADHD-PI or matched comparison girls, were at markedly higher risk for both suicide attempts (22 vs. 8 vs. 6%, respectively) and nonsuicidal self-injurious behavior (51 vs. 29 vs. 19%, respectively).

In short, girls with ADHD display clear comorbidities and impairments as they develop. It may also be the case that the gender-atypicality of many symptoms of ADHD (particularly extreme levels of impulsivity) place girls and women with ADHD at particularly high risk for continuing impairments. We now examine whether and how ADHD and its correlates manifest differently in boys and girls.

Prevalence, Subtypes, Core Symptoms, and Impairment

Like the early assumption that children outgrow ADHD by adulthood, it was formerly believed that ADHD in girls was extremely rare. Some estimates, based on clinical samples (i.e., those presenting for treatment or psychiatric referral), put the gender ratio as high as 9:1 (American Psychiatric Association, 1994). However, in the general population, things are different. At least during childhood and adolescence, males do predominate, but at a far lower ratio. In fact, two large community samples found the gender ratio to be 2.3:1.0 (Bauermeister et al., 2007; Ramtekkar, Reiersen, Todorov, & Todd, 2010), which is consistent with Arnold's (1996) gender ratio estimate of 2:1 to 3:1. This same ratio was reported in a meta-analysis of epidemiological studies of adults (Hooman & Ganji, 2012), although others have reported that the prevalence of ADHD in adults is equivalent for males and females (de Zwaan et al., 2012; Debjani, Cherbuin, Butterworth, Anstey, & Easteal, 2012). Thus, in the general population, ADHD is clearly less common in girls than in boys (though not necessarily in women vs. men), but it still occurs much more frequently in females than would be anticipated given reported gender ratios in clinical samples.

In the MTA study, for example, where recruitment was performed through school, pediatric, and mental health sources, as well as advertisements, there was a 4:1 boy-to-girl ratio among 7- to 9-year-olds (MTA Cooperative Group, 1999). Only ADHD-C was sampled, however, leading to questions about gender differences in subtype prevalence. Some investigations suggest that among girls, the ratio of ADHD-C to ADHD-PI is smaller than it is for boys. In other words, girls with ADHD may be more likely than boys to have the ADHD-PI subtype (Biederman et al., 2002; Hartung et al., 2002; Milich, Balentine, & Lynam, 2001), even though ADHD-C is more prevalent (at least in clinically referred samples).[3] However, in a large sample of siblings of children with ADHD, Biederman and colleagues (2005) found no gender differences in subtype (58% of ADHD females and 61% of males had ADHD-C; 25% of ADHD females and 27% of males had ADHD-PI). Similarly, Graetz, Sawyer, and Baghurst (2005) found no differences in subtype prevalence rates across girls and boys, nor did O'Brien, Dowell, Mostofsky, Denckla, and Mahone (2010), Ghanizadeh (2009), or Nolan, Volpe, Gadow, and Sprafkin (1999). Gender equivalence in subtype rates has been found among men and women with ADHD as well (Rasmussen & Levander, 2009). As is true for general prevalence rates, it may be that the ratio of ADHD-C to ADHD-PI for males and females is more similar in community as opposed to clinical samples.

Related to this issue is whether the core symptoms of ADHD vary across gender. Some studies suggest that boys with ADHD, on average, have higher levels

of hyperactive–impulsive symptoms than girls (Elkins, Malone, Keyes, Iacono, & McGue, 2011; Hartung et al., 2002; Hasson & Fine, 2012; Newcorn et al., 2001). Therefore, because a diagnosis of ADHD-C requires the presence of hyperactivity–impulsivity symptoms in addition to inattentive symptoms, boys also have higher levels of total ADHD symptoms (Monuteaux et al., 2010; Newcorn et al., 2001; Thorell & Rydell, 2008). In addition, one study reported higher levels of inattention in preschool-age boys with ADHD than in girls (Hartung et al., 2002), but only according to teachers, not parents.

On the other hand, some investigators report higher levels of hyperactive–impulsive symptoms (Rucklidge & Tannock, 2001) or total ADHD symptoms (Seidman et al., 2005) in diagnosed girls than in boys. Others do not find significant gender differences in hyperactive–impulsive symptom levels (Graetz et al., 2005; Owens, Pfiffner, & Hinshaw, 2013; Yang, Jong, Chung, & Chen, 2004), total symptom levels (Elkins et al., 2011, Graetz et al., 2005; Owens et al., 2013), or inattentive symptoms, whether objectively measured (Hasson & Fine, 2012; Newcorn et al., 2001; Yang et al., 2004) or according to parent and/or teacher report (Arcia & Conners, 1998; Brown, Madan-Swain, & Baldwin, 1991; Elkins et al., 2011; Graetz et al., 2005; Hartung et al., 2002 [parent report only]; Owens et al., 2013; Yang et al., 2004). In addition, the gender differences in reported symptom levels are usually small. Although boys with ADHD *may* typically have slightly higher levels of hyperactivity–impulsivity than girls, most evidence suggests that levels of inattention and total symptoms are quite similar between genders. This conclusion is somewhat different from earlier meta-analyses (Gaub & Carlson, 1997; Gershon, 2002) relying mostly on clinically referred samples, which suggest that girls have lower levels of most symptoms. More recent, large, community-based studies suggest that this is not the case.

Among adults, ADHD symptom levels appear to be comparable between men and women (Biederman, Faraone, Monuteaux, Bober, & Cadogen, 2004) or higher among women (Arcia & Conners, 1998; Fedele, Lefler, Hartung, & Canu, 2012; Robinson et al., 2008). It is important to remember that these reports of increased symptoms in women with ADHD may be due to a change from parent and teacher reports of children's symptoms to self-reports among adults. Women may have lower thresholds for what they consider symptomatic behavior or may be more likely than men to admit their symptoms, rather than symptoms among females increasing from childhood to adulthood in comparison to males.

Consistent with these findings regarding ADHD symptoms, and consistent with the observations from longitudinal studies reported earlier, existing cross-sectional data suggest strongly that at a global level, the overall levels of impairment of girls and boys with ADHD are equivalent (Bauermeister et al., 2007; Biederman et al., 2005; Graetz et al., 2005; Rucklidge & Tannock 2001). Indeed, and consonant with findings on adults' symptom levels, there have been at least two reports of greater impairment among adult women with ADHD (Arcia & Conners, 1998; Fedele et al., 2012; Gjervan, Torgersen, Nordahl, & Rasmussen, 2012), although Biederman and colleagues (2004) report equivalent levels of overall impairment in men and women. We consider specific types of impairment (e.g., academic and social) below. All told, although during childhood boys with ADHD do outnumber girls, the gender ratio is much smaller than previously believed. Among adults, it may be close to equal. Similarly, previous misconceptions about symptom levels being higher among males are generally unfounded. And it is quite clear that at all ages, males and females with ADHD have equivalent impairment.

Comorbidities

As suggested in three previous reviews (Arnold, 1996; Gaub & Carlson, 1997; Gershon, 2002), some document that girls with ADHD appear to have fewer externalizing comorbidities than boys with ADHD (Bauermeister et al., 2007; Biederman et al., 2002). Some have reported the same gender discrepancy among adults (Biederman et al., 1994; Rasmussen & Levander, 2009). However, a number of studies suggest instead that rates of externalizing comorbidities and co-occurring behavior problems are equivalent between (1) boys and girls and (2) men and women with ADHD (Biederman et al., 1994, 2005; Brown et al., 1991; Gabel, Schmitz, & Fulker, 1996; Levy, Hay, Bennett, & McStephen, 2004). Although no direct comparison with boys was made, Hinshaw (2002) found high rates of ODD comorbidity (71% for girls with ADHD-C and 47% for girls with ADHD-PI) among young girls with ADHD. Rates during adolescence (51% of all girls with ADHD-C or ADHD-PI; Hinshaw et al., 2006) and young adulthood (49% of girls with childhood ADHD-PI and 41% of girls with ADHD-C had comorbid CD or ODD;

Hinshaw et al., 2012) were slightly lower but still quite high, as is typically found in samples of boys. Noteworthy, however, is that these reports of externalizing comorbidity pertained exclusively to parent-reported symptomatology. Rated by objective observational data during summer enrichment programs (Hinshaw, 2002), girls' levels of antisocial and aggressive behavior were far lower than those of comparable samples of boys attending parallel programs. It may be that parental report of externalizing symptoms in girls reflects particular parental stressors or "views" of the incorrigibility of their daughters' behavior. In short, the jury is still out regarding gender differences in rates of comorbid externalizing problems.

Most investigations find no reliable differences in rates of comorbid internalizing problems, both anxiety and depression, in boys versus girls or men versus women with ADHD (Bauermeister et al., 2007; Biederman et al., 1994, 2004, 2005; Brown et al., 1991; Friedrichs, Igl, Larsson, & Larsson, 2012; Gabel et al., 1996; Graetz et al., 2005; Greene et al., 2001; Hartung et al., 2002; Rucklidge, Brown, Crawford, & Kaplan, 2007), although there is at least one report of increased rates for boys (Biederman et al., 2002). This rate equivalence between genders is somewhat different than the heightened longitudinal risk for an internalizing outcome that girls generally experience (noted earlier). It seems that the higher risk of later internalizing problems for girls with ADHD, as for all girls, does not obtain until adolescence. Relatedly, Rasmussen and Levander (2009) and Katz, Goldstein, and Geckle (1998) reported more symptoms of anxiety and depression in women than in men with ADHD. Also of note, gender differences in comorbidities may be moderated by subtype. Bauermesiter and colleagues (2007) found that boys with ADHD-C were more likely to have a comorbid mood disorder than girls, and that girls with ADHD-PI were more likely to have comorbid anxiety than boys. Researchers should be more cognizant of subtype (or "current presentation") issues as more data become available in which children are classified by subtype.

As noted earlier, longitudinal investigations suggest that risk for substance use or abuse is equivalent for girls and boys. However, in cross-sectional work, Biederman and colleagues (1999, 2002) found that girls with ADHD, ages 6–17, have a much greater risk for a substance use disorder compared to boys with ADHD. This is noteworthy because the girls were also much less likely to have comorbid CD, which is often identified as a moderator of substance use among children with ADHD. Thus, despite longitudinal evidence that is equivocal regarding gender effects, there is reason to be cognizant of possibly increased risk for substance use problems specific to girls with ADHD.

School Functioning

On balance, evidence suggests that boys with ADHD may have more trouble at school than girls, especially with behavior (as opposed to objectively measured academic achievement), although the evidence is not uniform. Some investigations report more school problems, both academic and behavioral, for boys. Biederman and colleagues (2002) found that boys with ADHD have higher rates of learning disabilities and lower levels of reading achievement. Bauermeister and colleagues (2007) reported more grade failure and suspensions, and DuPaul and colleagues (2006) reported less academic motivation among boys than among girls with ADHD. Based on classroom observations, Abikoff and colleagues (2002) found that boys with ADHD demonstrate much more aggression, rule breaking, interference, and out-of-seat behavior than do girls with ADHD, even those with ADHD-C. However, there were no significant gender differences in off-task behavior, and DuPaul and colleagues reported no gender differences in observed classroom behavior. Furthermore, Brown and colleagues (1991), DuPaul and colleagues (2006), and Rucklidge and Tannock (2001) reported no significant gender-based differences in achievement among children with ADHD. These findings are consistent with a meta-analyses regarding ADHD and achievement (Frazier, Youngstrom, Glutting, & Watkins, 2007).

On the other hand, DuPaul and colleagues (2006) showed that the school-related differences between girls with and without ADHD are larger than for boys with and without ADHD. Despite the equivalence of boys and girls on most of their measures of school functioning, they suggested that school problems among girls might be considered more severe because they reflect functioning further from what is considered normative. Of note, Graetz and colleagues (2005) found that boys with ADHD-C had more trouble with schoolwork than girls with ADHD-C, a difference that was not found among those with ADHD-PI. Again, consideration of subtype differences might clarify the varied findings on school functioning and gender.

Social Functioning

Although it was initially suggested that girls with ADHD have lower levels of peer rejection than do boys with ADHD (Arnold, 1996), most subsequent studies and reviews suggest that the compromised social functioning of boys and girls with ADHD is equivalent (Gaub & Carlson, 1997; Greene et al., 2001; Hartung et al., 2002; Hoza et al., 2005, Mikami et al., 2013). The longitudinal observations reported earlier also support this conclusion. However, some have suggested poorer social functioning among girls (Ek, Westerlund, Holmberg, & Fernell, 2008) and women with ADHD (Fedele et al., 2012). ADHD subtype may be relevant. In community samples, Graetz and colleagues (2005) found that boys with ADHD-C had more social problems than girls with ADHD-C, whereas Elkins and colleagues (2007) found that girls, especially those with ADHD-PI, were more bullied and less popular. At a global level, girls and boys with ADHD may be equally impaired in the social domain. As more data become available regarding gender × subtype interactions, gender differences in the social and peer domains may be clarified.

Neuropsychological Functioning

Neuropsychological differences between girls and boys with ADHD have been reported, but they are few and far between and inconsistent across studies. The vast majority of studies indicate that poor performance of girls and boys with ADHD is equivalent across neuropsychological measures, mostly reflecting executive functioning (Arcia & Conners, 1998; Balint, Czobor, Meszaros, Simon, & Bitter, 2009; Hinshaw, Carte, Fan, Jassy, & Owens, 2007; Houghton et al., 1999; Rucklidge, 2006; Rucklidge & Tannock, 2002; Seidman et al., 2005; Uebel et al., 2010; Wodka et al., 2008; Yang et al., 2004). In terms of overall intellectual performance, the Gaub and Carlson (1997) and Gershon (2002) reviews concluded that girls with ADHD might have somewhat lower IQs than boys with ADHD. Yet additional investigations have revealed no significant overall IQ differences (Arcia & Conners, 1998; Biederman et al., 1999, 2005; Gross-Tur et al., 2006; Hartung et al., 2002; Rucklidge & Tannock, 2001; Seidman et al., 1997; Yang et al., 2004). An exception was Biederman and colleagues (2002), who found that girls with ADHD have lower IQs than boys with ADHD.

Some of the isolated differences on neuropsychological tests include the following: higher scores on a design replication test for boys versus girls with ADHD (Brown et al., 1991; Yang et al. 2004); more impaired inhibition among boys (Rucklidge, 2006); the seemingly contradictory findings of poorer response inhibition and better planning by boys compared to girls (O'Brien et al., 2010); and slower processing speed for boys (Rucklidge & Tannock, 2001), although this finding was not replicated in Rucklidge (2006). Rucklidge (2010) suggests that type I error (i.e., incorrectly identifying associations that are in fact due to chance) accounts for these varied and isolated findings. It is also possible that the substantial variability in neuropsychological functioning found in children with ADHD is implicated. Alternatively, or additionally, it may be that gender interacts with subtype, so that analyses in which children with ADHD-C and ADHD-PI are grouped together may produce conflicting results. In support of this idea, Wodka and colleagues (2008) found a gender × subtype interaction on a measure of verbal fluency: Boys with ADHD-C outperformed girls with ADHD-C, whereas girls with ADHD-PI outperformed boys with ADHD-PI (although performance of girls and boys with ADHD was equivalent on measures of executive functioning at an overall level).

Gender comparisons in adults with ADHD are sparse, with the bulk of empirical evidence concerning neuropsychological differences between adults with ADHD, in general, and comparisons. However, in a meta-analysis of 25 studies that used 12 different neuropsychological measures, Balint and colleagues (2009) did find one possible gender difference among adults with ADHD. In studies with larger percentages of male participants, the ADHD–comparison difference on the Stroop interference task was larger than it was in studies with smaller percentages of male participants. In summary, although isolated neuropsychological differences between girls and boys, and men and women with ADHD are reported, no consistent intellectual or executive functioning difference has been found across samples.

Treatment History and Response

It is commonly assumed that the increased ratio of boys to girls in clinically referred samples is because boys may be more likely to have disruptive behavior

problems that motivate their parents and teachers to seek help. If, in fact, at least some of the gender differences in ADHD prevalence across clinical and community samples are due to such referral bias, one might expect to find differences in treatment history across community samples of girls and boys with ADHD. Bauermeister and colleagues (2007) showed this to be the case, with boys more likely to be referred for all types of treatment than girls. The likelihood of treatment with medication was especially large for boys compared to girls (odds ratio = 10.6). Bussing and colleagues (2005) found boys with ADHD to be more than twice as likely as girls to receive medication. Derks, Hudziak, and Boomsma (2007) also found far higher rates of treatment referral in boys than in girls with ADHD, which they attributed to teacher complaints about the children's behavior, rather than to parent perceptions of ADHD and behavior problem severity. However, not all investigations have shown gender differences in treatment history among nonreferred samples (Biederman et al., 2005; Visser et al., 2013), and some studies of adults also report no gender differences in treatment history (Biederman et al., 2004).

Not surprisingly, among girls and boys with ADHD referred for treatment, differences in treatment history are not found. Even though the ratio of boys to girls who present for treatment in psychiatric clinics is large, those girls and boys who do come in have similar treatment histories (Biederman et al., 2002; Rucklidge & Tannock, 2001). Furthermore, when girls and boys are treated for ADHD, they respond similarly. In the MTA, gender did not moderate response to treatment (MTA Cooperative Group, 1999; Owens et al., 2003). Girls and boys did not differ significantly in terms of response to behavioral treatment, to treatment with medication, and to combined treatment. Mikami and colleagues (2009) and Sharp and colleagues (1999) also found no gender differences in response to stimulant medications. We know of only two reports of gender-based differential response to treatment. First, Sonuga-Barke and colleagues (2007) found that within a single day, girls have a better response to stimulants earlier and a worse response later. If this finding were replicated there would be implications for adjusting dosing schedules based on gender. Second, Mikami and colleagues (2013) found that the beneficial effects of a novel classroom intervention encouraging peer inclusion were obtained predominantly for boys relative to girls.

SUMMARY AND FUTURE DIRECTIONS

Decades of longitudinal research have clearly documented the persistence of ADHD for many, if not most, children across developmental periods, even into middle adulthood. Serious consequences across many domains of symptomatology and impairment, for both boys and girls, are also clear. At the same time, as clinicians and researchers finally have begun to recognize the reality of ADHD in girls and women, longitudinal and cross-sectional evidence for gender differences in manifestations of ADHD is not compelling. However, rather than arguing that ADHD in girls is important *even though* it generally manifests as it does in boys, the take-home message regarding gender differences is that ADHD in girls is important *because* it manifests as it does in boys. Although gender differences might be interesting, the fact that girls generally do not show unique correlates or outcomes is important news because it means the condition is serious and debilitating for both genders. At the same time, the condition, over the long term, is not debilitating for every individual with ADHD. Despite ADHD persistence and increased risk for poor outcome in many domains, some children do not suffer over the long term. Future work needs to focus on explaining who will continue to be affected by ADHD and who will experience positive adjustment despite the initial challenge of ADHD. Identification of moderators on which ADHD persistence and outcome depend, and of mediators by which they are explained, is especially important for clinicians, educators, and parents trying to meet the needs of children with ADHD as they grow.

KEY CLINICAL POINTS

- ✓ Despite the earlier belief that ADHD is outgrown by adolescence, modern follow-up studies demonstrate a relatively high rate of persistence of ADHD from childhood to adolescence (50–80%) and into adulthood (35–65%).
- ✓ Differences in rates of persistence are substantially (four to nine times) lower if self-report is used rather than parent or other reports.
- ✓ Symptoms of hyperactivity (and perhaps impulsivity) decline more steeply with age than do symptoms of inattention.

- ✓ Childhood ADHD increases the risk for concurrent and later ODD and CD. But this risk may be partially or entirely due to childhood-associated externalizing disorders rather than to ADHD specifically. These disorders in turn increase the risk for adolescent and adult substance use and abuse, as well as antisocial activities and antisocial personality disorder.
- ✓ It is less clear that childhood ADHD predisposes children to later internalizing disorders. Comorbidity with other disorders may be more of a determining factor in this risk.
- ✓ Children with ADHD are more likely to experience academic impairment, driving problems, social impairment, and overall impairment by adolescence and adulthood than are typically developing children. They are also more likely to experience problems and adverse outcomes associated with driving and risky sexual behavior.
- ✓ Childhood ADHD is related to an increased risk of nicotine use by adolescence. Far less clear is whether ADHD in childhood predisposes individuals to adolescent alcohol use or abuse. Should comorbid ODD or CD be present, this increases the risk for adolescent and adult use and abuse of other substances.
- ✓ Children with ADHD are more likely to have problems with occupational functioning by adulthood than are typically developing children.
- ✓ Girls with ADHD are at risk for all of the aforementioned comorbid disorders and impairments, and often to the same extent as are boys with ADHD, but may be at higher risk for later internalizing disorders than boys, who may show a higher risk for externalizing disorders, substance use and abuse, and other risk-taking behavior. Yet these gender differences are those seen between girls and boys in population samples and may therefore not be specific to ADHD. Nor are they consistently evident across studies.
- ✓ Girls with ADHD as children may by adolescence be more prone than boys with ADHD and control girls to eating pathology, binge eating, and bulimia, but such differences attenuate by young adulthood.
- ✓ Although in childhood ADHD is somewhat more prevalent in boys than in girls, perhaps by a ratio of 3:1, this difference attenuates such that by adulthood, prevalence is nearly the same.
- ✓ Few if any gender differences in people with ADHD are evident in neuropsychological deficits or treatment response.

NOTES

1. A variable measured at baseline that is associated with outcome for all children (in this case, both those with ADHD and a comparison group) is called a "predictor," whereas a baseline variable differentially associated with outcome across groups is called a "moderator." Also, as subsequently described in the text, factors or variables that exist during initial evaluations and that differentially influence outcomes are called "moderators," whereas factors or variables that transpire during intermediate periods of development (between baseline and follow-up) and help to explain the genesis of relevant outcomes are termed "mediators" (see Kraemer, Wilson, Fairburn, & Agras, 2002).
2. There is debate about whether differences between males and females should be termed "sex differences" (in which "sex" refers to biological males and biological females) or "gender differences" (in which "gender" refers to a broader pattern of gendered expectations and roles, over and above biological sex). We choose the broader term "gender differences," realizing that there is inconsistent use of terms across the vast literature on this topic.
3. Note that in DSM-5 (American Psychiatric Association, 2013), the designation of types of ADHD has been softened to "current presentations," given extensive evidence that the supposed subtypes of ADHD-PI, ADHD-C, and ADHD-HI are not particularly stable over time.

CHAPTER 10

Executive Function Deficits in Adults with ADHD

Mary V. Solanto

Adults with attention-deficit/hyperactivity disorder (ADHD) have difficulty in self-management, including organization, planning, initiating and completing tasks on a timely basis, tracking and shifting tasks, self-monitoring, and self-inhibition. In the aggregate, these are termed "executive functions" (EFs) which, according to a recent definition, can be viewed as "those self-directed actions needed to choose goals and to create, enact, and sustain actions toward those goals (Barkley, 2012b, p. 60). This difficulty in self-regulation typically results in reduced productivity, inefficiency, missed deadlines, poor planning, "careless" errors, and losing and forgetting things as a result of disorganization. In some (particularly those with the combined form of ADHD), reduced inhibitory control may also lead to emotional dysregulation and inappropriate verbal and/or physical behavior in interpersonal interactions. Over the lifetime of the individual, these difficulties contribute to failure to achieve goals—personally, academically, and occupationally. These failures in turn likely contribute to the high rates of anxiety and depression in adults with ADHD (Kessler et al., 2006; also see Chapter 13).

Although not listed as a symptom of ADHD in the DSM-5 (American Psychiatric Association, 2013) or any previous edition of the DSM, executive dysfunction has in recent years come to be regarded by many in the field as a defining characteristic of ADHD in both children and adults (Barkley & Murphy, 2011; Barkley, Murphy, & Fischer, 2008; Brown, 2013).

MEASUREMENT OF EF ON NEUROPSYCHOLOGICAL TESTS

Executive dysfunction has traditionally been measured by neuropsychological tests. However, research over the last decade has called into question whether these tests capture the scope of executive dysfunction in ADHD and other disorders. Most notably, the effect sizes (i.e., difference between groups in mean scores, expressed in standard deviation [*SD*] units) reported in meta-analytic studies of the neuropsychological tests commonly used to assess EF have largely been between 0.5 and 0.65 (i.e., moderate) for differences between groups with ADHD and normal adult groups (Boonstra, Oosterlaan, Sergeant, & Buitelaar, 2005; Hervey, Epstein, & Curry, 2004; Schoechlin & Engel, 2005). In addition, effect sizes for non-EFs such as attention, verbal memory, and processing speed have generally been equivalent to those reported for EFs (Boonstra et al., 2005; Hervey et al., 2004). Similar results, showing only moderate effect sizes and lack of universality, were reported in a pivotal meta-analysis of studies of chil-

dren with ADHD (Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005).

The diagnostic efficiency of neuropsychological tests with respect to ADHD appears to be quite limited both in adults and children. Biederman and colleagues (2008) reported that neuropsychological tests identified only 14% of a sample of 194 adults with ADHD. Similar results were found in the study by Barkley and Murphy (2011) and the follow-up study by Barkley and Fischer (2011). In contrast, more than twice that number (34.4%) were identified as impaired in the Biederman and colleagues study on the basis of self- ratings of EF on the Current Behavior Scale, a precursor of the Barkley Deficits in Executive Function Scale (BDEFS), described further below. In another study, 89–98% of adults with ADHD were in the clinically impaired range (i.e., more than 1.5 *SD* from the normal mean or 7th percentile) on a prototype of the BDEFS (Barkley & Fischer, 2011; Barkley & Murphy, 2011).

In children, Doyle, Biederman, Seidman, Weber, and Faraone (2000) reported that scores in the impaired range on tests of EF had good positive predictive validity with respect to identifying boys with ADHD (i.e., few false positives) but only moderate negative predictive validity (i.e., a higher rate of false negatives). Biederman and colleagues (2004) reported that, based on a neuropsychological test battery, only 33% of a sample of 259 children and adolescents with ADHD had EF deficits. Moreover, numerous studies find little or no significant correlations between tests of EF and rating scales of this same construct (Toplak, West & Stanovich, 2013). In addition, rating scales appear to be more predictive of impairments in major domains of life activities than are tests of EF (Barkley & Fischer, 2011; Barkley & Murphy, 2010). Neuropsychological testing is therefore not appropriate to rule in or rule out a diagnosis of ADHD. Such testing may be useful, however, in assessing an individual's profile of cognitive strengths and weaknesses, including possible reading or other learning deficits, for educational or occupational purposes, and may be required to document the need for academic accommodations.

COMPONENT EXECUTIVE FUNCTIONS

Although not useful for clinical diagnostic purposes, the measurement of specific EFs via testing has nonetheless yielded insights into core components of executive dysfunction that affect at least a subgroup of those with ADHD. In the following, I describe the EFs that most consistently differentiate adults with and without ADHD in the meta-analytic studies: response inhibition, working memory, and set shifting. It should be noted that since the three meta-analyses with adults were published close together in time, there is considerable overlap in the studies they include.

Response Inhibition

"Response inhibition" refers to the ability to withhold a cognitive or behavioral impulse that may be inaccurate or maladaptive. Impulsivity–hyperactivity is one of two core symptom dimensions of ADHD in the DSM-5 (American Psychiatric Association, 2013). In ADHD, poor response inhibition may occur cognitively, behaviorally, or emotionally (see Chapter 3), as reflected in (1) responding before a question is completed or before instructions are reviewed; (2) responding without first considering all response options; (c) failing to withhold a behavioral or cognitive response to an irrelevant or inappropriate stimulus; (4) acting before considering the consequences of a socially offensive or aggressive behavior; and (5) being easily excited, overly aroused, and impatient or easily frustrated.

The continuous-performance test (CPT), of which there are numerous variants, has been widely used for clinical and research purposes as a measure of both response inhibition and attention/vigilance. On the visual CPT, the examinee views a series of stimuli (e.g., letters, numbers, or shapes) presented sequentially on a computer screen, with an interstimulus interval on the order of 1–4 seconds, and is instructed to respond whenever a predesignated target stimulus (e.g., a given letter or sequence of two letters) appears. CPTs with infrequent targets primarily tax attention processes as indexed by errors of omission, as, for example, on the integrated visual and auditory CPT (IVA; Sandford & Turner, 1995), whereas CPTs on which target stimuli predominate create a "set" to respond, thereby primarily taxing inhibitory control, as indexed by errors of commission on the Conners CPT-II (Conners, 2000). The frequency of CPT commission errors discriminated between groups with a moderately large effect size of 0.65 in five studies reported in the meta-analyses (Boonstra et al., 2005; Hervey et al., 2004; Schoechlin & Engel, 2005) and is one of the larger and most consistently demonstrated differences across studies in both children (Willcutt et al., 2005) and adults with ADHD.

The stop-signal task, a measure of response inhibition, is widely used in research on ADHD and other conditions. On this task, the individual performs a visual choice reaction time task (the primary task). On a proportion of trials, randomly selected, a tone (the "stop-signal") is presented immediately *after* the primary task stimulus ("go-signal") and is the cue to *inhibit* the response to the go-signal on that trial. The reaction time (RT) to the stop-signal ("stop-signal RT") is the critical index of inhibitory control and has been used in numerous studies with adults (Hervey et al., 2004; Schecklmann et al., 2013) and children (Alderson, Rapport, & Kofler, 2007; Willcutt et al., 2005) to differentiate groups with and without ADHD.

Working Memory

"Working memory" is a system that actively holds multiple bits of transitory verbal or nonverbal information in mind while they are manipulated (Cowan, 2008). An example of a cognitive activity that depends on working memory is mental arithmetic, in which numbers are held in memory while some operation (e.g., addition, multiplication) is performed on them and the result also is sustained in memory. Difficulties in working memory may underlie diverse difficulties in ADHD, such as keeping track of time; tracking conversations in order to be able to generate appropriate responses; keeping track of the location of one's belongings; and expressive writing, in which there is a need simultaneously to maintain both one's own and the reader's perspective in order to maximize cohesiveness.

Baddeley and Hitch (1994) delineated three main components of working memory: (1) the visual–spatial sketchpad and (2) the phonological loop (for temporary storage of nonverbal and verbally based information, respectively), and (3) the central executive, which is the controlling component responsible for the allocation of attention between these two "slave" components. Alderson, Kasper, Hudec, and Patros (2013) conducted a meta-analysis of 38 studies comparing working memory in adults with and without ADHD that yielded an effect size of 0.49 for the visual–spatial sketchpad and 0.55 for the phonological loop. A separate study conducted by the authors (Alderson, Hudec, Patros, & Kasper, 2013) also documented involvement of the central executive, but with smaller group differences than in previous studies of children with ADHD, which the authors interpreted to suggest maturation in this function over time.

Among the frequently used *verbal* tests of working memory in the studies included in the meta-analysis is the Paced Auditory Serial Attention Task (PASAT), on which the examinee hears a new number every 3 seconds and is asked to add that number to the one heard just before it. The Digit Span Backward subtest of the Wechsler Adult Intelligence Scale (WAIS) also differentiated groups. This subtest makes more demands on working memory than Digit Span Forward subtest, in that it requires a manipulation (reversal of order) to be performed on the number string held in memory. Rohlf and colleagues (2012) recently demonstrated that the *difference* between the highest number of digits repeated in the forward direction and the backward direction significantly differentiated groups, with an effect size of 0.51.

Among the visual–spatial tests that figured in the meta-analysis were the Spatial Working Memory subtest of the Cambridge Neuropsychological Test Automated Battery (CANTAB) and the Rey-Osterrieth Complex Figure Test (in which the examinee is asked to copy a complex figure, draw it from memory after a brief delay, then draw it again after a longer delay). Interestingly, the Wisconsin Card Sorting Test (WCST), widely used to index working memory, set formation, and set shifting, did not discriminate between groups in virtually any study with adults (Hervey et al., 2004), although it has been shown to do so in children with ADHD (Romine et al., 2004).

Set Shifting

"Set-shifting" has been defined as the ability to move back and forth between multiple tasks, operations, and mental sets (Miyake et al., 2000). Examples relevant to ADHD include shifting between tasks that have different cognitive demands (e.g., making business calls vs. writing a memo; cooking dinner while supervising children; watching videos vs. studying for a test). The last example may also make heavier demands on response inhibition given that one must first inhibit an activity that presumably provides much more immediate gratification.

The Stroop Color–Word Test is variably considered a measure of cognitive inhibitory control, resistance to interference, and set shifting. On the traditional version of this task, the individual is asked to read, as quickly as possible, a list of color words printed in black ink, then to name the color in which each of a list of XXXX's are printed; and finally to name the *color* in

which color names are printed while ignoring the incongruent word itself (e.g., the word "blue" printed in red ink). The "interference" score, which is calculated from the word reading, color naming, and color–word naming scores, reflects the individual's ability to inhibit the interference from reading the word while naming the colors.

Despite its intuitive appeal as a measure of set shifting, the meta-analyses indicated that the Stroop interference score does *not* differentiate between groups (Boonstra, Kooij, Oosterlaan, Sergeant, & Buitelaar, 2010; Hervey et al., 2004). This finding emerged as well in a more recent study of a similar task from the Delis–Kaplan Executive Function System's Color–Word Interference Task (CWIT), in which the difference between groups in interference score was reduced to nonsignificance after controlling for IQ and working memory (Halleland, Haavik, & Lundervold, 2012). In this study, however, a significant difference between groups did emerge on the final condition within the CWIT (not present on the Stroop), which requires the examinee to alternate between inhibiting and reading the color word if it is framed, This condition may be considered to be a more rigorous test of set shifting that is not confounded by speed of word or color naming, or by response inhibition. Thus, while interference control or response inhibition, as measured by the Stroop, does not appear to differentiate groups, set shifting, particularly on more complex tasks, may still be a discriminating variable.

The Trail-Making Test (TMT) is divided into two parts. On Part A the examinee is given a sheet of paper with the numbers 1 to 25 randomly scattered on the page, and is asked to draw lines connecting the numbers in order, as quickly as possible. On Part B, the subject is given a similar sheet of paper with the numbers 1 to 12 and the letters A to L randomly placed on the page, and is required to draw the connecting lines as quickly as possible, alternating between numbers and letters, in order (A, 1, B, 2, C, 3, etc.). Both parts of the TMT measure visual scanning and psychomotor speed. The TMT-B measures, in addition, set shifting (between numbers and letters). The meta-analyses each found moderate effect sizes. In the study by Boonstra and colleagues (2005), the effect sizes, based on six studies, were 0.46 for TMT-A and 0.65 for TMT-B. However, in order to isolate an effect of set shifting, the score on TMT-B must be adjusted for the score on TMT-A, which was not done in the meta-analyses. This was accomplished in a recent study by Rohlf and colleagues (2012), in which the total time to complete TMT-B was divided by total time to complete TMT-A. This "shifting score" did significantly discriminate between adults with (n = 37) and without (n = 32) ADHD, again providing support for differences in set-shifting adults with and without ADHD.

PLANNING AND EXECUTING FOR THE FUTURE: THE ROLE OF TEMPORAL DISCOUNTING

Adults with ADHD have difficulty planning for the future and successfully executing those plans. Notably, they are less likely than others to engage in positive behaviors in the present that will yield greater benefits in the future. Examples in the daily life of individuals with ADHD abound: going to bed at an hour that will allow sufficient sleep time; beginning and continuing work on academic and occupational assignments and projects within a time frame that allows for successful completion before deadlines; putting things away immediately after use to prevent inefficient searching; practicing healthful eating and exercise habits; and saving money for future needs. All of these activities require that the individual forgo some measure of current pleasurable activities in order to achieve larger rewards in the near-term or more distant future. Reluctance to forgo immediate rewards makes it less likely that adults with ADHD will sustain effort to pursue and achieve the larger, more significant goals of life, such as higher academic degrees, job advancement, and accumulation of savings for significant purchases.

Research suggests that this behavioral characteristic reflects the phenomenon known as "temporal discounting," wherein future rewards are discounted in value relative to immediately available rewards (Scheres, De Water, & Mies, 2013). It is hypothesized that the value of delayed rewards decreases *more* steeply as a function of the delay interval in individuals with ADHD than in typical individuals. Support for this hypothesis has been generated in multiple studies using experimental tasks in children with ADHD (Antrop et al., 2006; Kuntsi, Oosterlaan, & Stevenson, 2001; Scheres, Tontsch, Thoeny, & Kaczkurkin, 2010). Temporal discounting was also increased in adolescents with ADHD (plus oppositional defiant disorder [ODD]), relative to those without (Barkley, Edwards, Laneri, Fletcher, & Metevia, 2001), and greater temporal discounting was associated with reduced academic achievement in typical college students (Lee et al., 2012).

In adults, temporal discounting has been shown to occur more steeply in groups with less impulse control, including substance abusers and those with neuropsychiatric disorders (Wittmann & Paulus, 2008). Research with adults with ADHD is limited thus far to two studies: preference for smaller, sooner rewards in adults with ADHD was reported as a trend in a small imaging study (Plichta et al., 2009) and was a robust finding in a larger sample studied by Hoogman and colleagues (2011). Research in this area is actively continuing. A recently developed cognitive-behavioral intervention for adults with ADHD includes a component designed to offset temporal discounting by enhancing the salience—and therefore the motivating power—of distant rewards (Solanto, 2011, pp. 149–151).

NON-EFs

As mentioned, effect sizes in the meta-analyses were similar for EF and non-EF functions, suggesting that ADHD involves deficits in the latter as much as the former abilities (Boonstra et al., 2005; Hervey et al., 2004).

Attention

Given that an attention deficit has long been viewed as the defining feature of the disorder, it is not surprising that tests of attention have been widely used to assess patients with ADHD. Prominent among these, for both clinical and research purposes, is the visual CPT, on which the errors of omission (failures to respond to the target stimulus) are considered to index selective attention and sustained attention over time. Frequency of omission errors did discriminate between adult groups with a moderately large effect size in all three meta-analyses (Boonstra et al., 2005; Hervey et al., 2004; Schoechlin & Engel, 2005), as was also true for children (Willcutt et al., 2005). Simple RT to the target stimuli on the CPT and on other tasks (e.g., the go RT on the stop-signal task) did *not* distinguish the groups. However, the *variability* (standard error) in the CPT RT score did consistently differentiate groups in adults (Boonstra et al., 2005; Hervey et al., 2004), as well as children (Castellanos & Tannock, 2002), suggesting that variability of attention to task may be a critical feature of ADHD (Gonzalez-Gadea et al., 2013).

Memory

There is much interest in memory functions in adults with ADHD, who frequently report that they have trouble retaining material they have just learned or to which they have been exposed. Two prior meta-analyses have shown moderate deficits on verbal memory tasks, whereas visual memory was not affected (Hervey et al., 2004; Schoechlin & Engel, 2005). An important question, therefore, is whether adults with ADHD have fundamental problems with learning and/or memory. Skodzik, Holling, and Pedersen (in press) recently sought to address this problem by determining the extent to which problems of memory are explainable by difficulties in acquisition, and whether adults with ADHD have an additional retrieval deficit. Their meta-analysis of studies of verbal memory (including the California Verbal Learning Test, the Logical Memory subtest of the Wechsler Memory Scale (WMS), and the Rey Auditory Verbal Learning Test), revealed that adults with ADHD showed deficits in both delayed (e.g., 20 minutes) Free Recall (effect size = 0.49) and Acquisition (effect size = 0.58). Nearly all the variance (95%) in memory, however, was explained by differences in memory acquisition, suggesting that memory deficits in ADHD reflect a learning difference at the stage of encoding. The latter may result from problems of attention or learning strategies, including those affected by working memory and other EFs. There were no significant differences between groups in visual memory (tested via the Rey-Osterrieth Complex Figure Test, the Visual Reproduction subtest of the WMS, and a modified version of the Visual Learning and Memory Test for Neuropsychological Assessment). The lack of differences in visual memory is interesting and consistent with the results of previous meta-analyses, which found that tests of verbal fluency, but not spatial–figural fluency, distinguished adults with and without ADHD (Hervey et al., 2004). Skodzik and colleagues also reported that there was no additional deficit in retrieval processes in adults with ADHD. This suggests that patients with ADHD should be encouraged to use visual–spatial prompts and aids when attempting to learn new material.

NORMED RATING SCALES OF EFs

There are three widely available self-ratings of EFs in adults, one of which was developed specifically for use

in the assessment of ADHD: the Brown Attention-Deficit Disorder Scales (BADDS; Brown, 1996). The other two rating scales, the Behavior Rating Inventory of Executive Function—Adult Version (BRIEF-A; Roth, Isquith, & Gioia, 2005), and more recently, the BDEFS (Barkley, 2011), were developed to assess EFs across various conditions and disorders.

The BADDS scale was developed on the basis of clinical studies and observations and comprises 40 items, divided into five subscales: Activation (initiation of tasks, time estimation, and prioritization), Attention (focused, sustained, and shifting), Memory (working and short-term), Effort (regulation of alertness, sustaining effort), and Affect (managing and modulating emotions). The scale was normed on 142 adults diagnosed in clinical interviews on the basis of DSM criteria, and 143 controls matched for age and socioeconomic status (SES). The scale demonstrated significant differences between the ADHD and control groups, and includes a helpful index of likelihood that the individual meets diagnostic criteria for ADHD. Problematic with the scale is the very limited sample of normal or typical adults that is not representative of the U.S. population and the construction of the subscales based on the developer's view of each EF domain rather than empirical or statistical analyses, such as factor analysis, that are typically used to guide the constructions of dimensions in rating scale development.

The BDEFS was developed in three stages (Barkley, 2011). First, items were constructed for the scale based on existing theories of EF and its components, as well as on chart reviews of several hundred cases of adults with ADHD. Second, this 91-item prototype scale (P-DEFS) was then given to three groups of adults (Barkley et al., 2008): 146 adults with ADHD participating in the author's University of Massachusetts (UMASS) Study of Adult ADHD; 97 community controls presenting with possible ADHD but ultimately diagnosed with other conditions; and 109 volunteers from the community. Factor analysis that included all participants yielded five scales (Barkley & Murphy, 2011): Self-Management to Time (prepared on time for work or assigned tasks, time estimation, prioritization, punctuality, planning ahead); Self-Organization/Problem Solving (organization of thinking, action, and writing; overcoming obstacles to goals); Self-Restraint (considering consequences before commenting, deciding, or acting); Self-Motivation (sustaining effort, quality, and output in work; choosing larger more delayed rewards over immediate rewards); and Self-Activation/Concentration (distractibility, sustaining alertness and concentration while working). This same scale was also given to a group of children with ADHD followed for 20 years to young adulthood and a control group in the Milwaukee longitudinal study (Barkley et al., 2008). Factor analysis of the scale for these participants revealed the same five-factor structure (Barkley & Fischer, 2011). Finally, the scale was administered to 1,249 adults drawn from the general U.S. population (Barkley, 2011). It was factor-analyzed again with this sample. The results did not perfectly replicate the earlier analyses because the factor of Self-Activation/Concentration did not emerge and was therefore removed from the final scale. Also, since the original scale lacked content for an important domain of EF, the self-regulation of emotions, a new subscale was created for that domain. The final scale contains 89-items including this new scale, Self-Regulation of Emotions (Barkley, 2011). The scale demonstrates considerable differentiation of adults with ADHD from those who have sluggish cognitive tempo and from adults in a general population sample who have neither condition (Barkley, 2012a).

There is some overlap in the content of the BADDS scales and those from the final BDEFS. For instance, the Effort scale (BAADS) has some item overlap with the Self-Motivation scale (BDEFS); likewise, there is overlap on the Affect scale (BAADS) and Self-Restraint (BDEFS) and Self-Regulation of Emotions scales (BDEFS). Items that reflect Activation on the BADDS scale are included in Self-Management to Time on the BDEFS. Attention and Memory on the BADDS scale are variously represented on the BDEFS Self-Management to Time and Self-Organization. Items found on the BDEFS Organization/Problem Solving (BDEFS) do not appear to be represented on the BAADS.

The BRIEF-A was developed to assess EFs across a wide array of neurological and cognitive disorders, and was normed in a sample of 1,136 adults drawn from the general population after exclusion of adults with various disorders and medical conditions. It was then further evaluated on 1,050 adults with a range of impairments (Gioia, Isquith Guy, & Kenworthy., 2000). The BRIEF-A comprises nine conceptually developed subscales that place on two dimensions (indices) when factor-analyzed. The Behavioral Regulation Index (BRI) includes the Inhibit, Shift, Emotional Control, and Self-Monitor scales. The Metacognitive Index

(MCI) includes Initiate, Working Memory, Plan/Organize, Task Monitor, and Organization of Materials. A Global Executive Composite is generated from the BRI and MCI. Although the BRIEF-A has been used as an outcome measure in several studies of executive dysfunction in adult ADHD, there is as yet no research to indicate how well it differentiates or classifies individuals with and without ADHD, or the extent to which scores on this measure are correlated with functional impairment in ADHD. Nevertheless, given the overlap of its item content with the BDEFS and BADDS, one would expect it to perform similarly to those scales in differentiating groups of ADHD and control adults.

COMPARISON BETWEEN EF TESTS AND EF RATINGS

In two studies of adults with and without ADHD, Barkley and colleagues compared self-ratings of EF on the P-DEFS with a battery of EF tests with respect to their predictive utility vis-à-vis overall functional impairment. They reported that whereas the ratings accounted for more than half of the variation in impairment, the best combination of EF tests explained less than 10% of the variance (Barkley & Fischer, 2011; Barkley & Murphy, 2010). In addition, the P-DEFS was significantly more predictive of occupational functioning than was the neuropsychological test battery in both studies (Barkley & Fischer, 2011; Barkley & Murphy, 2010).

EF tests and EF ratings also appear to identify different subgroups of individuals with ADHD having different correlates of impairment. In a study of 194 adults with ADHD, those who performed poorly on the psychometric tests (n = 28, 14%) had lower IQ and academic achievement, whereas those identified as impaired in EF ratings (n = 67, 34.4%) had more severe ADHD symptoms, worse social adjustment, more comorbid conditions, and lower overall functioning. Twenty-eight adults (14%) in the sample were impaired on both, whereas 71 (37%) were impaired on neither. Parallel differences with respect to academic functioning have been shown for children with ADHD with and without tested executive dysfunction (Biederman et al., 2004).

Disparity between performance on EF tests and EF ratings is not limited to ADHD. A recent meta-analysis examined correlations between performance-based measures and ratings of EF in a total of 20 studies (13 child and 7 adult) across a variety of clinical disorders. The results revealed an overall median correlation of only .19 (Toplak et al., 2013). The authors concluded that these two approaches to the measurement of EF are not assessing the same construct.

This challenge to the role of EF tests in assessing EF in ADHD and various other disorders has been based on arguments that psychological tests in current use are not sufficient or comprehensive measures of EF (Barkley, 2012b; see also Chapter 16). This may be the case in part because they are highly structured, focus on "cool" purely cognitive (as opposed to "hot" affective) aspects of EF, and thus overlook emotional and social features of EF, and involve a time frame on the order of minutes, whereas real-world executive control requires self-regulation in the absence of external structure, and involves social and emotional contexts over much longer periods, extending to days, weeks, months, and years.

HETEROGENEITY IN EXECUTIVE DYSFUNCTION

Variability in the expression of EFs suggests the possibility of subtypes within the pool of adults who are diagnosed as having ADHD. This variability may in part correspond to differences between the combined and inattentive presentations/subtypes of ADHD (American Psychiatric Association, 2013) or between individuals with and without sluggish cognitive tempo (Barkley, 2012a; see Chapter 17), but these factors have been largely unexamined in studies to date.

Barkley has propounded a developmental hierarchy of EFs, in which elemental component functions (e.g., working memory, inhibitory control) are organized into progressively higher and more complex levels of functioning over the course of development (Barkley, 2012b; see Chapter 16). The model delineates six levels: At the lowest level are *preexecutive* functions, such as arousal, attention, and memory, essentially reflecting largely automatic brain functions shared with other primates. This is followed by the *instrumental* level of self-directed, moment-to-moment, largely mental actions used for self-control (e.g., inhibition, verbal and nonverbal working memory, emotional self-regulation, timing, planning). The third level, the *adaptive* level, uses the instrumental EFs for meeting daily needs of survival and self-care. The fourth level is the *tactical* level, which uses lower EF levels for self-regulation across daily activities occurring in reciprocal social relationships with others and is manifested in self-management

to time, self-organization, self-motivation, self-restraint, and self-regulation of emotions. The fifth level, the *strategic* level, uses the tactical and lower EF levels to achieve midterm to longer-term goals involving cooperation with others and as reflected in educational, occupational, economic, and social pursuits. Likely contained within that level is one that Barkley calls *principled,* which uses all earlier EF levels to achieve long-term, highly abstract goals related to one's longer-term welfare and happiness, as well as one's contribution to society. An implication of this model is that individuals with deficits at the lowest level of EF may be expected to have difficulties at all subsequent levels, whereas some individuals may experience deficits only at higher levels that do not radiate downward to impact lower levels adversely. This may account in part for the heterogeneity in expression of executive dysfunction in adults with ADHD, in that only the more severely affected are likely to show deficits at the instrumental level, such as those assessed on EF tests in current use. Others may experience difficulty only later in development when encountering demands for higher and more complex levels of EF at work or in higher education.

TREATMENT OF EXECUTIVE DYSFUNCTION

Recent reviews and integration of the literature on the effects of stimulants on cognitive tests, largely in children, indicate that improvement is more likely seen on non-EF tasks (e.g., delayed match-to-sample complex RT, spatial recognition RT) rather than on tasks with an EF component (e.g., inhibitory control, organization, set-shifting, planning; Swanson, Baler, & Volkow, 2011). In adults, whereas stimulant and nonstimulant medications reduce or ameliorate core symptoms of ADHD, there is little evidence from clinical observation that they substantially improve EF as it is employed in daily life. In a randomized controlled study, Biederman and colleagues (2011) found no effects of oral osmotic release drug delivery system (OROS)-methylphenidate on EF, whether ascertained on the basis of neuropsychological tests or the BRIEF-A. However, positive changes in EF, as measured on EF rating scales, have been shown following treatment with Vyvanse (Adler et al., 2013; Brown, Brams, Gao, Gasior, & Childress, 2010), mixed amphetamine salts (Brown & Landgraf, 2010) and atomoxetine (Durell et al., 2013). Continued research is needed to resolve discrepancies among the stimulant studies, and to ascertain the clinical significance of rated changes in EF over time across medications.

Cognitive-behavioral interventions designed to improve EFs as used in daily life activities in adults with ADHD have been shown to be effective in two randomized controlled double-blind trials (Safren et al., 2010; Solanto et al., 2010; see also Chapter 31). Further research is needed to delineate the relative benefits and mechanisms of action of cognitive-behavioral therapy (CBT) and pharmacotherapy for improving EF, and to identify clinical predictors of differential response to treatments.

SUMMARY

Adults with ADHD are impaired in numerous aspects of EF, including response inhibition, verbal and nonverbal working memory, set shifting, and possibly temporal discounting, as reflected in cognitive tests of these EFs. On rating scales, their deficits are manifested in poor time management, self-organization and problem solving, self-restraint (inhibition), self-motivation, and self-regulation of emotions.

Neuropsychological tests in common use do not fully capture the wide range of EF deficits and are associated with a high rate of false negatives when used to diagnose ADHD. Standardized self-report rating scales of EF have greater predictive utility with respect to identifying adults with ADHD and are far more highly correlated with functional impairment in general, and occupational impairment in particular. A recently proposed developmental hierarchy of EFs may help to account for heterogeneity of EF deficits in ADHD. This model suggests that the elemental EFs (e.g., working memory, inhibitory control), which operate on a time scale of minutes to hours, are organized into progressively higher and more complex levels of functioning that operate over broader time spans and ultimately involve longer term educational, occupational, economic, and social goals. Whereas some more severely affected individuals may be impaired at the instrumental EF level, such as that typically assessed on EF tests, others may experience difficulty only when they encounter demands for higher and more complex levels of EF at work or at advanced levels of education. The development of treatments to enhance EFs in adult ADHD is at an early stage, but it holds promise, particularly with respect to the utility of cognitive-behavioral interventions (see Chapter 32).

KEY CLINICAL POINTS

- ✓ Adults with ADHD are impaired in numerous aspects of EF, including response inhibition, verbal and nonverbal working memory, and set shifting, as reflected in cognitive tests of these EFs.
- ✓ They are also deficient in time management, planning and problem solving, self-organization, self-motivation, self-restraint, and emotional self-regulation, as reflected in rating scales of EF in everyday life.
- ✓ Neuropsychological tests in common use do not fully capture the wide range of EF deficits and are associated with a high rate of false negatives when used to diagnose ADHD.
- ✓ Standardized self-report rating scales of EF have greater predictive utility with respect to identifying adults with ADHD and are far more highly correlated with functional impairment in general, and occupational impairment in particular.
- ✓ A recently proposed developmental hierarchy of EFs (Chapter 16) may help to account for heterogeneity of EF deficits in ADHD. This model suggests that the elemental EFs (e.g., working memory, inhibitory control), which operate on a time scale of minutes to hours, are organized into progressively higher and more complex levels of functioning that operate over broader time spans and ultimately involve longer-term educational, occupational, economic, and social goals. Whereas some more severely affected individuals may be impaired at the instrumental EF level, such as that typically assessed on EF tests, others may experience difficulty only when they encounter demands for higher and more complex levels of EF at work or at advanced levels of education.
- ✓ The development of treatments to enhance EFs in adult ADHD is at an early stage, but it holds promise, particularly with respect to the utility of cognitive-behavioral interventions (see Chapter 32).

CHAPTER 11

Health Problems and Related Impairments in Children and Adults with ADHD

Russell A. Barkley

As the authors of the previous chapters have attested, attention-deficit/hyperactivity disorder (ADHD) is associated with a variety of difficulties other than the central problems with inattention, impulsivity, and overactivity. Such children and adults have a higher likelihood of having other cognitive, developmental, academic, and social difficulties. This chapter focuses instead on the health problems and related domains of impairment not addressed in prior chapters. Not all children and adults with ADHD display all these risk factors. But as a group, they are more likely to do so and to display them to a degree that is greater than expected in typical people. Because the health-related problems are not considered to be the core or essence of the disorder, they are not diagnostic of the disorder when present, nor do they rule out the diagnosis when absent.

GENERAL HEALTH STATUS AND CHRONIC ILLNESS

ADHD appears to be associated with a number of health risks as well as increased use of medical services and resultant expenses (Cuffe, Moore, & McKeown, 2009; Nigg, 2013). Research indicates that children with externalizing disorders, including ADHD, appear to be at risk for a several chronic physical conditions, including obesity, atopic eczema, epilepsy, and asthma (Goodwin et al., 2009). But what of ADHD specifically? Several early studies found that children with ADHD have more problems with general health than do normal children. Nearly 30 years ago, Hartsough and Lambert (1985) found that 50.9% of hyperactive children were described as having been in *poor health during infancy,* whereas Stewart, Pitts, Craig, and Dieruf (1966) found that this prevalence described 24% of their sample. Both figures are greater than those for control children (29.2 and 2.7%, respectively).

A small body of evidence also suggests that both children with ADHD (Giacobo, Jane, Bonillo, Arrufat, & Araujo, in press) and children with ADHD followed to adulthood (Barkley, Murphy, & Fischer, 2008) voice more complaints about functional somatic symptoms (e.g., headaches, stomachaches, and vague bodily concerns) that may have little if any medical origins. The number of such complaints was related to the extent to which ADHD had persisted to the adult follow-up (Barkley et al., 2008). The degree of such complaints seems to be linked to the degree of anxiety in both children and adults (Barkley et al., 2008; Giacobo et al., in press), as well as the degree of parental over-

protection of children (Giacobo et al., in press). Longitudinal studies (Barkley et al., 2008; Brook, Brook, Zhang, Seltzer, & Finch, in press) likewise reveal an elevated risk for impaired general health in teens with ADHD followed to adulthood (ages 27–36).

Health concerns across a variety of domains also appear to afflict adults diagnosed with ADHD at adulthood. In our study of large samples of adults with ADHD compared to a clinical and a community control group (Barkley et al., 2008), we used the Skinner Health and Lifestyle Interview (Skinner, 1994), a self-administered computerized survey of health-related behavior that expresses results in a figural form, with each domain coded as a strength, concern, or risk. The results for this lifestyle assessment appear in Figure 11.1 for those domains in which significant group differences were evident. The groups did not differ in the percentage scored as having a concern or risk in the lifestyle domains of nutrition, eating habits, caffeine use, physical activity, or body weight. However, the ADHD group had a higher percentage of individuals reporting problems in nine out of 16 areas assessed than did the community control group. These areas included sleep, social relationships, family interactions, tobacco use, nonmedical drug use, medical/dental care, motor vehicle safety, work and leisure, and emotional health. The ADHD group had more members with concerns/risks in nonmedical drug use, motor vehicle safety, and emotional health than did the clinical control group. Obviously, lifestyles of adults with ADHD pose greater concerns/risks for more of them across many more lifestyle domains than do the lifestyles of community adults. But illicit drug use, driving, and emotional health are areas in which adults with ADHD differ specifically from clinic-referred adults who do not have ADHD.

The presence of chronic health problems, such as recurring *upper respiratory infections and allergies*, were also noted more often in hyperactive children than in normal children (39–44% vs. 8–25%) (Hartsough & Lambert, 1985; Mitchell, Aman, Turbott, & Manku, 1987; Szatmari, Offord, & Boyle, 1989). Likewise, Trites, Tryphonas, and Ferguson (1980) noted more

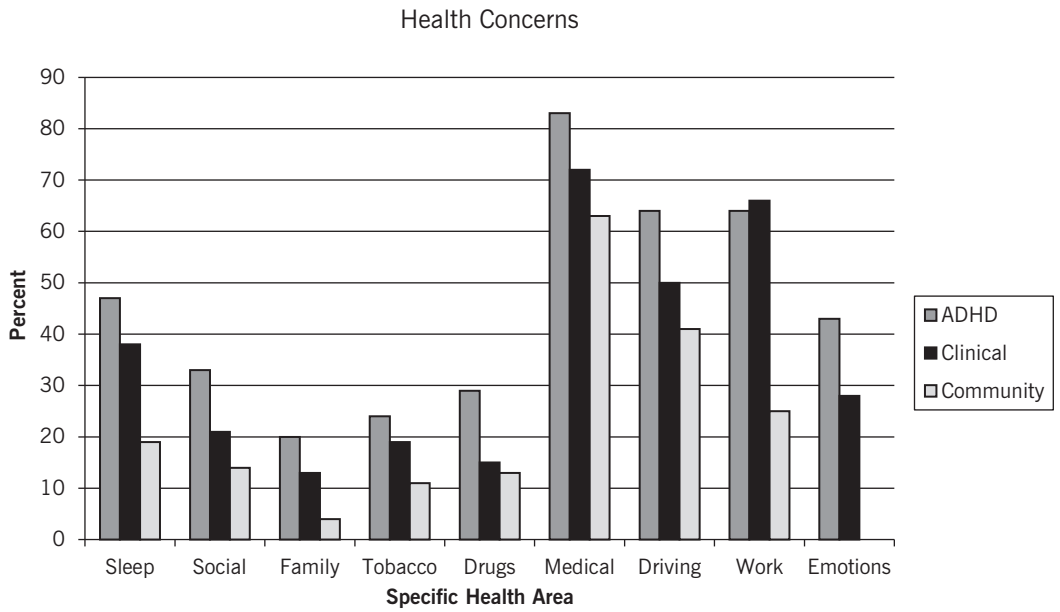

FIGURE 11.1. Percent of each group scoring in the risk or concern range on the Skinner Health and Lifestyle Interview from the UMASS Study. The figure depicts those health and lifestyle areas on which the ADHD group differed from the community control group. From Barkley, Murphy, and Fischer (2008). Copyright 2008 by The Guilford Press. Reprinted by permission.

allergies in hyperactive children than in normal children, and others have noted the inverse, that is, more ADHD symptoms in children with atopic (allergic) disorders (Roth, Beyreiss, Schlenzka, & Beyer, 1991). A recent prospective, 10-year follow-up of a large sample of preschool children with atopic eczema found that degree of early eczema was significantly associated with risk for early- but not late-onset ADHD (Genuneit et al., 2014). In one study, only children with hyperactivity not associated with conduct problems were more likely to have allergies (Blank & Remschmidt, 1993). But others have not found an association between ADHD and allergies (McGee, Stanton, & Sears, 1993; Mitchell et al., 1987); the association between the specific allergy of atopic rhinitis (hay fever) and ADHD has shown mixed results (Hart, Lahey, Hynd, Loeber, & McBurnett, 1995; Genuneit et al., 2014; Yang et al., in press). Yang and colleagues (in press) also reported that children with allergic rhinitis were more likely to have elevated symptoms of ADHD. Thus, the nature of any association between ADHD and allergies remains unclear as of this writing.

One large-scale study suggests that individuals suffering from *acne* may be 2.5 times more likely to have ADHD than do those without this skin condition (Gupta, Gupta, & Vujcic, 2014). Although this was a very large population-based study, further research in this area is warranted.

Otitis media, or middle ear infection, has been noted to be more common and more recurrent in children with ADHD (Adesman, Altschuler, Lipkin, & Walco, 1990). Also, early-onset and recurrent otitis media has been linked to greater severity of ADHD symptoms (Padolsky, 2008). Even so, two studies are inadequate for rendering any definitive conclusions about this association, though current evidence is suggestive of one.

Several early studies examined whether children with ADHD were more likely to suffer from *asthma*. An initial report by Hartsough and Lambert (1985) suggested such an increased risk for asthma among children considered to be hyperactive. Yet several subsequent studies using larger samples (n = 140) did not find this to be the case when clinical diagnostic criteria for ADHD were used to identify the children (Biederman, Milberger, Faraone, Guite, & Warburton, 1994; Biederman, Milberger, et al., 1995). Nevertheless, several more recent population-based studies have resurrected this small but significant risk. For instance, in one study involving a birth cohort of 4,119 children, those who met criteria for ADHD (about 7.5%) had a significantly increased risk of asthma (22 vs. 13%) (Leibson, Katusic, Barbaresi, Ransom, & O'Brien, 2001). This assertion that asthma is twice as common in children with ADHD was evident in a more recent U.S. population-based study (Cuffe et al., 2009). The reverse relationship is also evident: Children with asthma are slightly but significantly more likely to have ADHD (odds ratio = 1.31) than are children without asthma (7 vs. 4.6%, respectively) (Chen et al., 2013). Therefore, a small relationship of risk is shared between ADHD and asthma.

In contrast to the findings for asthma, there appears to be no association between ADHD and a higher risk for *diabetes* or *hypertension* (Nigg, 2013) despite the association between ADHD and obesity, discussed below. However, a small emerging body of evidence suggests an association between ADHD and risk for *coronary heart* and *lung disease,* which, if not a consequence of obesity, may well be related to other risky lifestyle factors, such as a greater use of alcohol, tobacco, and other drugs (Barkley et al., 2008). In the Milwaukee follow-up study of children with ADHD, Barkley and colleagues (2008) conducted complete physical and laboratory examinations of their children with ADHD and control children years later at a mean age of 27 years. By that time, the hyperactive children were beginning to show some significant signs of risk for coronary heart disease, as assessed through several risk rating methods and their lipid profiles. Likewise, a recent population-based study of older adults in The Netherlands found that elevated ADHD symptoms were positively associated with the presence of nonspecific chronic lung diseases and cardiovascular diseases, and the number of chronic diseases, while being negatively associated with self-perceived health status (Semeijn et al., 2013). Those relationships were not found to be mediated by lifestyle variables, implying a more direct linkage between ADHD and these health risks. Such findings are consistent with observations in another study of 1,122 men followed for 12 years, in which degree of self-regulation was negatively predictive of risk for various types of coronary heart disease (CHD), even after researchers controlled for levels of anxiety, depression, and anger (Kubzansky, Park, Peterson, Vokonas, & Sparrow, 2011). Conscientiousness, the personality trait, is clearly related to self-regulation and is also repeatedly associated with adult health and well-being (Hampson, 2008). Given that children and adults with ADHD place toward the lowest end of the spectrum of self-regulation or Conscientiousness in the population, one should not be surprised to see an el-

evated risk of CHD associated with the disorder, as well as lower levels of adult health and well-being more generally. Obviously there is a need here for more research into the link between ADHD and CHD given that the latter is one of the major causes of mortality in the U.S. adult population.

The little evidence that is available on the subject suggests that ADHD is not associated with difficulties with vision, such as refractive errors (Fabian et al., 2013; Hartsough & Lambert, 1985).

DENTAL HEALTH

Only a few studies have examined the relationship of ADHD to dental health, but their findings consistently indicate that children with ADHD are at increased risk for various dental problems. The earliest study I was able to locate on this topic was conducted in New Zealand by Broadbent, Ayers, and Thomson (2004), who found that children with ADHD were 12 times more likely to have diseased, missing, or filed teeth (DMFT) even after they controlled for fluoride history, medical problems, diet, and oral hygiene habits. A subsequent study likewise documented a greater number of caries in the primary and secondary dentition of children with ADHD (Grooms, Keels, Roberts, & McIver, 2005). Several studies were conducted by Blomqvist and colleagues in Sweden. In the initial report, they found that children with ADHD had significantly more DMFT, as well as more behavior management problems during the office examination, than did control children (Blomqvist, Holmberg, Fernell, Ek, & Dahllof, 2006). The results of these earlier studies were subsequently replicated by Chandra, Anandakrishna, and Rey (2009), who found that children with ADHD not only had more dental caries, but they also were not likely to engage in proper dental hygiene as often as control children, and they ate more sugary substances—both of which likely contributed to their higher rate of caries. However, as Broadbent and colleagues (2004) noted, even after researchers control for factors such as diet and hygiene, a significant risk for DMFT problems remains. A separate study also revealed that adolescents with ADHD had lower rates of caries-free teeth and higher rates of decay or filed surfaces, as well as higher rates of gingivitis that caused their gums to bleed when probed, than did control teens (Blomqvist, Ahadi, Fernell, Ek, & Dahllof, 2011). Besides DMFT problems, some research indicates that children with ADHD have more problems with toothache, bruxism, bleeding gums, poorer hygiene, and oral trauma histories than do typical children (Atmetlla, Burgos, Carillo, & Chaska, 2006; Bimstein, Wilson, Guelmann, & Primosch, 2008; Katz-Sagi, Redlich, Brinsky-Rapoport, Matot, & Ram, 2010; Pessah, Montluc, Bailleul-Forestier, & Decosse, 2009), with a five times greater risk for oral trauma than control children (Katz-Sagi et al., 2010). The reverse has also been found in a study in which children presenting with dental trauma were more hyperactive and impulsive than control children (Thikkurissy, McTigue, & Coury, 2012). One study in Israel did not find higher rates of DMFT or any differences in diet or oral hygiene between children and adults with ADHD and control cases, but sample sizes were small (n = 31 and 30, respectively) limiting its statistical power to detect such differences (Hidas et al., 2011). It did find that rates of unstimulated saliva flow were reduced in children with ADHD, whether medicated or not, and that children with ADHD had more plaque. Other research has not found evidence of reduced salivary flow, however (e.g., Grooms et al., 2005). Later research in Germany, using far larger samples, found that hyperactivity and inattention were significantly associated with the extent of lesions of noncavitated caries and molar–incisor hypermineralization (Kohlboeck et al., 2013).

Not surprisingly, office behavior problems are more common in children with ADHD, as noted earlier in that they may show not only more behavior problems, as noted here and in other research (Atmetlla et al., 2006; Pessah et al., 2009). Children with ADHD may also demonstrate lower stress reactivity to the dental examination, as manifested in lower salivary cortisol levels after the examination than levels in comparison children (Blomqvist et al., 2007). They may also demonstrate poorer quality communication with the dentist at the time of examination (Blomqvist et al., 2005).

No studies have yet examined the role of parental ADHD, which is likely to be present in a sizable minority of parents of children with ADHD, in the problems with diet and oral hygiene noted earlier. And while the greater risk for oral trauma is consistent with the larger body of evidence on risk for accidental injuries linked to ADHD (see below), I found no studies that have investigated this issue of shared liability across types of dental and nondental accidents.

Far less research has been conducted on the oral health of adults with ADHD. A recent study indicated that adult ADHD is more common (16%) in adults referred for treatment of dental anxiety than would be

expected from population prevalence estimates (Carlsson, Hakeberg, Blomkvist, & Boman, 2013). Such adults with ADHD had higher levels of dental anxiety and self-reported poorer oral health than did dentally anxious adults without ADHD, but clinical evidence of poorer oral health did not differ significantly between these groups. Far more research on the dental health and problems that may be associated with ADHD in adults is needed given the more abundant literature demonstrating the many dental risks evident in children with ADHD.

It is now reasonably well established that ADHD in children and teens is associated with a substantially greater risk of dental caries specifically and DMFT more generally, as well as an increased risk for oral trauma. There is also some evidence of poorer dental hygiene and possibly even poorer diet associated with the disorder, but these factors have been less well studied and do not seem to account for the heightened risk for caries. As one might expect, children with ADHD may be more difficult to manage during the office dental examination. Far less is known about the dental problems associated with ADHD in adults. Clearly, there is a need not only to make primary care pediatric dentists aware of these heightened risks but also to develop interventions that promote better hygiene and diet in families of youth with ADHD, as well as greater preventive utilization of dental care. A number of common-sense recommendations for dental care can be found in the review by Murray, Naysmith, Liu, and Drummond (2012).

SUBSTANCE USE

As discussed in the chapters on comorbidity (Chapters 5 and 13), teens and adults with ADHD are more likely to qualify for a diagnosis of substance use disorder. This is especially the case for those who already have comorbid conduct disorder (CD). But apart from being more likely to have a diagnosis of a substance dependence or abuse disorder, teens and adults with ADHD use both legal (alcohol, tobacco) and illegal (marijuana) substances more often than do controls, even if they do not have CD (Barkley et al., 2008).

Much of the research on drug use in adults with ADHD comes from longitudinal studies of children with ADHD followed to adulthood (Weiss & Hechtman, 1993). That youth with ADHD are at higher risk for increased tobacco use as adolescents and young adults has been demonstrated in several studies (see Tercyak, Peshkin, Walker, & Stein, 2002, for a review; Barkley, Fischer, Edelbrock, & Smallish, 1990; Barkley, Fischer, Smallish, & Fletcher, 2004; Borland & Heckman, 1976). For instance, Milberger, Biederman, Faraone, Chen, and Jones (1996) followed 6- 17-year-olds with and without ADHD for 4 years and found that ADHD was specifically associated with a higher risk for initiating cigarette smoking, even after they controlled for social class, psychiatric comorbidity, and intelligence. Stable smoking by adolescence has also been found to be linked to childhood ADHD (Wilens et al., 2011). Molina, Smith, and Pelham (1999), in a study of 202 adolescents, reported that ADHD is associated with increased use of all substances, including nicotine, but only when it is associated with comorbid CD. Yet they also found that it was the hyperactive–impulsive (HI) dimension of ADHD within this comorbid group that was most closely associated with this elevated risk of substance use. In partial agreement with these results, Burke, Loeber, and Lahey (2001) followed 177 clinic-referred boys with ADHD to age 15 years and found that 51% of these teens reported tobacco use, but that this risk was only elevated in the group with comorbid ADHD and CD. Unlike Molina and colleagues, these authors found that it was the inattention dimension that was specifically associated with a 2.2 times greater risk for tobacco use by adolescence, even after they controlled for other factors known to be associated with such use (CD, poor parental communication, ethnicity, etc.). Tercyak, Lerman, and Audrain (2002) also confirmed this link between not just ADHD but specifically its inattention symptoms and the risk for cigarette use by adolescence. Even mild levels of ADHD symptoms appear to elevate this risk for smoking (Whalen, Jamner, Henker, Delfino, & Lozano, 2002). The risk of smoking by adolescence may be accentuated in youth with ADHD whose school adjustment is poor (Flory, Malone, & Lamis, 2011). Later research also indicated that adults with ADHD are more likely to have smoked tobacco in their lives and are more likely to be current smokers than individuals in a community control group, but not more than those in a clinical control group (Barkley et al., 2008).

A study (Kollins, McClernon, & Fuemmeler, 2005) further cements the relationship between ADHD symptoms and increased risk of nicotine use. Kollins and colleagues (2005) used the National Longitudinal Study of Adolescent Health, a nationally representative sample, to examine whether ADHD symptoms were associated with increased smoking risk. They followed 15,197 ado-

lescents into young adulthood. Analyses showed a linear relationship between inattentive and HI ADHD symptoms and lifetime likelihood of being a regular smoker (having smoked at least 1 cigarette per day for at least 30 days). Even when they controlled for CD symptoms, each additional ADHD symptom significantly increased the risk for regular smoking. For those who did smoke, more symptoms were associated with an earlier age of smoking onset. ADHD symptoms are therefore a useful predictor of risk for smoking, and for an earlier onset of smoking, even outside of a clinical setting. Given the stimulant-like action of nicotine on the dopamine transporter in the striatum of the brain and its similarity to the effects of methylphenidate on that site (Krause et al., 2002), these findings suggest that greater nicotine use in those with ADHD could be a form of self-medication in an effort to treat their own symptoms. However, other mechanisms that possibly account for this link between ADHD and nicotine use (social, cognitive, psychological) need to be explored more fully (Glass & Flory, 2010), such as recent evidence that behavioral disinhibition, novelty seeking, and risk taking may contribute to the risk for smoking as much as self-medication (Sousa et al., 2011). Some studies also have indicated that certain risk genes for ADHD may also increase nicotine use, and that severity of ADHD interacts with these risk genes to further promote risk for nicotine use (Bidwell et al., 2012; McClernon, Fuemmeler, Kollins, Kail, & Ashley-Koch, 2008; Thakur, Sengupta, Grizenko, Choudhry, & Joober, 2013).

Concerning alcohol use, the picture from research studies had been initially mixed. Blouin, Bornstein, and Trites (1978), in a retrospective study, were among the first to report that children with hyperactivity may be more at risk than control children for adolescent alcohol use (57% of hyperactive children vs. 20% of the controls). Larger, more recent epidemiological studies have also suggested that ADHD increases the likelihood of both nicotine *and* alcohol use by adolescence (Gudjonsson, Sigurdsson, Sigfusdottir, & Young, 2012). Weiss and Hechtman (1993) found that as teenagers, somewhat more of their hyperactive participants used alcohol than did their control group, but this was not found at the adult follow-up. Hartsough and Lambert (1985) also did not find increased alcohol use at their adolescent follow-up. More recent longitudinal studies may help to clarify these inconsistent results. Some large studies indicate that ADHD may increase the risk for later teen alcohol use, but only in those children who engages in deviant peer relationships and whose parental monitoring is low (Molina et al., 2012). Some research (Knop et al., 2009) and two meta-analyses found that childhood ADHD does not necessarily increase the risk for alcohol and drug use disorders in adolescence, but it does so eventually by adulthood (Charach, Yeung, Climans, & Lillie, 2011; Lee, Humphreys, Flory, Liu, & Glass, 2011). By contrast, childhood ADHD is more strongly associated at adolescence with nicotine use (Charach et al., 2011; Lee et al., 2011). Moreover, family association studies suggest that the liability for alcohol use disorders in families of children with ADHD may be specifically transmitted, separate from any liability conferred by ADHD, rather than being a general risk associated with ADHD liability in the family, as are other drug use disorders (Biederman, Petty, et al., 2008).

These and other studies have also documented greater frequency of use of other substances, especially marijuana, in adolescents with ADHD (Barkley et al., 2008; Chilcoat & Breslau, 1999). Given the well-known association between CD and risk of drug use, Barkley and colleagues (2004) subdivided their hyperactive group into those who did and did not have lifetime CD by young adulthood (self-reported) and compared their frequency of use of various drugs to that of the control group. Results indicated significant group differences for nine of the 11 drug use activities surveyed. In all cases, it was the hyperactive group with CD that accounted for these differences, with no significant differences between the hyperactive-alone and control groups in any form of drug use.

Most studies concur with the Milwaukee study in finding that the elevated risk for substance use and abuse in adolescence is mostly, but not entirely, accounted for by comorbidity with conduct problems in childhood or a frank diagnosis of CD (August, Stewart, & Holmes, 1983; Barkley, Fischer, et al., 1990; Biederman et al., 1997; Chilcoat & Breslau, 1999; Claude & Firestone, 1995; Flory, Lynam, Milich, Leukefeld, & Clayton, 2001; Gittelman, Mannuzza, Shenker, & Bonagura, 1985; Kuperman et al., 2001; Lynskey & Fergusson, 1995; Mannuzza, Gittelman-Klein, Bessler, Malloy, & LaPadula, 1993; Molina et al., 1999; Realmuto et al., 2009; Wilson & Marcotte, 1996). Likewise, youth diagnosed with alcohol dependence have a markedly higher incidence of ADHD and CD, with a developmental sequence that is a progression from initial alcohol or tobacco use to marijuana, and finally to other street drugs (Kuperman et al., 2001). Such findings are quite consistent with studies of community samples in show-

ing that primarily CD, more than ADHD, is associated with greater risk for substance use, dependence, and abuse (Armstrong & Costello, 2002). But ADHD and its symptoms continue to contribute to a child's future risk for illicit substance use even after researchers control for conduct problems (Knop et al., 2009; Malone, Van Eck, Flory, & Lamis, 2010; Sihvola et al., 2011). Once again, it may be the attention deficit symptoms in ADHD that are most predictive of later tobacco and other substance use problems (Tapert, Baratta, Abrantes, & Brown, 2002). This greater use of drugs among youth with comorbid ADHD and CD may contribute to further problems with learning, memory retention, and attention (Tapert, Granholm, Leedy, & Brown, 2002). What recent studies do suggest is that there is a shared familial–genetic liability between ADHD and substance use disorders that may arise from a shared genetic network (Arcos-Burgos, Velez, Solomon, & Muenke, 2012; Biederman, Petty, et al., 2008). For a fine discussion of the possible mechanisms by which ADHD contributes to an increased risk for substance use disorders over the course of development, such as CD, school failure, deviant peer relationships, and risk-taking behavior, see the review by Eme (in press).

In one early study authors asserted that childhood treatment with stimulant medication increased the risk for substance use in adolescence, particularly for other stimulants (Lambert & Hartsough, 1998). More than 17 studies have since examined this issue, and all have failed to find that such childhood treatment with stimulant medication increased the later risk for excessive use of abuse of other substances, such as illegal use of stimulants (Barkley, Fischer, Smallish, & Fletcher, 2003; Barkley et al., 2008; Chang et al., in press; Wilens, Faraone, Biederman, & Gunawardene, 2003) and a few even found a small potentially protective effect if medication use was sustained into adolescence (Chang et al., in press; Wilens et al., 2003).

Studies of the drug use patterns of clinic-referred adults with ADHD have been far fewer in number and less consistent in their findings. Generally they indicate a significant two-way risk relationship between ADHD and substance abuse (Kalbag & Levin, 2005). Adults with ADHD are more prone to be diagnosed as having drug dependence or abuse disorders, particularly for alcohol and marijuana (Barkley et al., 2008). ADHD in adults in that study was specifically associated with a greater number of cocaine and LSD (lysergic acid diethylamide) users, as well as users of illegal prescription drugs, compared to both of our control groups. While the presence of a history of CD accounted for the elevated use of cocaine, it did not explain the greater likelihood of adults with ADHD using other substances. Other studies using self-reported information also found that adults with ADHD rate themselves as more likely to use or abuse drugs (De Quiros & Kinsbourne, 2001; Murphy & Barkley, 1996), primarily marijuana, cocaine, and psychedelics (Murphy & Barkley, 1996) as well as illegal prescription drugs (Barkley et al., 2008). Not only are substance use disorders more common in adults with ADHD, but adult ADHD symptoms are more common in drug users, and ADHD cast as a disorder may be three to seven times more likely (11–35%) to be present in adults with various substance use disorders (Carpentier, van Gogh, Knapen, Buitelaar, & De Jong, 2011; de los Cobos et al., 2011; Fergusson & Boden, 2008; Kalbag & Levin, 2005; Parrott et al., 2012; Romo, Kern, Mille, & Dubertret, 2012). The presence of ADHD in these cases appears to be associated with worse psychopathology and drug use (Arias et al., 2009; Carpentier et al., 2011). Such drug use may further worsen the attentional problems and ADHD symptoms over time (Fergusson & Boden, 2008; Tapert, Granholm, et al., 2002; Wilens et al., 2011).

The specific risk of excessive alcohol use or abuse by adults with ADHD has previously presented a mixed picture. In two small studies, Barkley, Murphy, and Kwasnik (1996) and De Quiros and Kinsbourne (2001) did not find a greater frequency of alcohol use or bouts of intoxication in their ADHD groups than in their control groups. But in later, larger studies, the ADHD group reported consuming significantly more alcoholic drinks per week, and getting drunk and using illegal drugs significantly more often in the previous 3 months than had the members of our control group (Barkley, Murphy, DuPaul, & Bush, 2002; Barkley et al., 2008). One study of Norwegian adults with ADHD also found higher rates of alcohol use disorders, as well as use of cannabis, amphetamines, and opiates (Torgersen, Gjervan, & Rasmussen, 2006). Therefore, while the relationship of adult ADHD to excessive alcohol use was not consistently corroborated in past research, more recent, larger studies confirm such a relationship.

GROWTH, HEIGHT, WEIGHT, AND EATING PATHOLOGY

For years, ADHD was not thought to be associated with problems with height, weight, or physical growth.

Indeed, if there were an association with weight, it was speculated to be a negative one due to the increased activity levels of children with ADHD, which one would expect to result in a lower body mass index (BMI). One earlier study examined a sample of 124 children and adolescents with ADHD for the presence of growth deficits in height and weight (Spencer et al., 1996). No evidence of weight deficits was found in the children with ADHD, even though 89% of the sample had been treated with stimulant medications, drugs thought to result in reductions in weight. There were small but significant deficits in height in the children with ADHD compared to their control group, but not between the adolescents with ADHD and their control group, implying that any growth delay may be time limited to childhood. These height deficits were not related to treatment with stimulant medications. The authors concluded that ADHD-associated temporary deficits in growth in height in childhood through midadolescence may no longer be evident by late adolescence. In contrast, a subsequent study of more than 7,000 children in France suggested that medication-naive children with ADHD were somewhat taller and heavier than were typical children, but no such differences were evident in adolescents (Faraone, Lecendreux, & Konofal, 2012). The authors speculated that this might reflect a problem with growth regulation in children with the disorder that is no longer evident by adolescents.

However, a study in the United States revealed a link between ADHD and greater body mass or frank obesity in the current generation of children with ADHD (Holtkamp et al., 2004). The authors found that nearly 20% of children with ADHD had a BMI at or greater than the 90th percentile, and more than 7% were at or above the 97th percentile. This difference between more recent and older research findings may reflect an interaction of personality traits (ADHD symptoms, especially impulsivity), with greater ecological availability of "junk" food for current as opposed to prior generations of children. Subsequently, Waring and Lapane (2008) surveyed more than 62,800 U.S. children and found that those with a prior history of a professional diagnosis of ADHD who had not received stimulant treatment for their disorder were 1.5 times more likely to be overweight. In contrast, those with ADHD who were being treated were 1.6 times more likely than typically developing children to be underweight. Recent research has also shown that boys diagnosed as hyperactive (ADHD) in childhood were twice as likely to be obese in midlife at a 33-year follow-up as boys in a control group followed for the same period of time (41 vs. 21%; Cortese et al., in press). Additional analyses showed that it did not matter whether the individual's ADHD had persisted at follow-up or remitted because these groups' rates of obesity did not differ from each other, but both had higher obesity rates than the control group. In my own follow-up study with Mariellen Fischer (analyzed for this chapter), in which we followed hyperactive boys to a mean age of 27 years, we found precisely the same results, with boys whose ADHD did or did not persist to that age having twice the rate of obesity (BMI ≥ 30) as boys in the control group (40% in each ADHD group vs. 20% for controls; see Barkley et al., 2008, for study details). Note that the rates of obesity are nearly identical in these two large-scale follow-up studies. In a study that documented the reverse association of ADHD and obesity, more than 57% of children hospitalized for obesity (BMI ≥ 85th percentile) were subsequently diagnosed with ADHD (Agranat-Meged et al., 2005).

Several recent studies have explored which symptoms of ADHD and other variables may account for children's risk of being overweight or obese. In a recent study of more than 11,600 German children, results indicated that the HI symptoms in particular showed a negative correlation with nutritional quality, and positive associations with greater high-energy food intake and greater exposure to television (van Egmond-Fröhlich, Weghuber, & de Zwaan, 2012). These findings suggest that these may be the variables that increase the risk for being overweight in children, especially girls, with ADHD. In a subsequent study, van Egmond-Frölich, Widhalm, and de Zwaan (2012) evaluated more than 17,600 German children and once again noted a relationship between HI symptoms and overweight and obesity in both sexes of children. But after controlling for possible confounding variables, such as socioeconomic status, parental BMI, and parental smoking, only the relationship between HI symptoms and being overweight for girls remained significant. Still to be disentangled, however, is the extent to which the obesity is related to comorbid disorders, such as anxiety and depression, that often coexists in a significant minority of patients with ADHD (Nigg, 2013). For instance, the recent report from the Ontario Child Health Survey follow-up study noted that although ADHD symptoms in childhood were significantly associated with greater BMI and obesity in adulthood, this risk was explained entirely by comorbidity with CD (Korczak, Lipman, Morrison, Duku, & Szatmari, 2014).

Though less studied, the relationship between ADHD and risk for being overweight or obese appears to hold true for adults. For instance, Barkley and colleagues (2008) documented significantly greater BMI in children whose ADHD had persisted to the young adult follow-up (mean age 27 years) in comparison to those whose ADHD had not persisted and the control group. Apart from such clinical samples, population-based studies in adults have likewise demonstrated what was found for children (discussed earlier): ADHD symptoms are significantly associated with risk for being overweight. Pagoto and colleagues (2009) assessed 6,735 U. S. adults ages 18–44 years. Those who had sufficient symptoms to warrant a diagnosis of adult ADHD were significantly more likely to be overweight (odds ratio = 1.58) or obese (OR = 1.81) compared to those with no history of ADHD symptoms. These relationships remained significant despite controls for demographic variables and degree of depression. Further analyses suggested that it may have been the link between ADHD and binge-eating disorder (BED) that mediated this risk for excess weight. As with children, the inverse relationship seems to hold true as well, with ADHD being overrepresented (28–32%) in patients being seeking treatment for obesity (Cortese, Comencini, Vincenzi, Speranza, & Angriman, 2013; Levy, Fleming, & Klar, 2009; Nazar et al., 2012), a prevalence far higher than that seen in the typical adult population (approximately 4–5%). Both the ADHD symptoms directly and the more general deficits in executive functioning may contribute to eating pathology and obesity and also foster unsuccessful efforts at weight loss (Cortese et al., 2013).

The link between ADHD and obesity may arise from several possible pathways as discussed by Nigg (2013) and earlier by Cortese and Penalver (2010; Cortese & Vincenzi, 2012). It is possible that the pathway is from obesity to ADHD or at least its attention problems as a function of sleep deprivation that can arise from disordered breathing or frank airway obstruction during sleep that may be more common in obese children. Nigg (2013) discounts this explanation due to the fact that ADHD often arises earlier than does obesity. Moreover, ADHD is not merely daytime inattention; thus, it is unclear whether the clinically complex disorder of ADHD is more likely to occur in children with such disrupted sleep. It is also possible that there exists some underlying shared genetic mechanism between ADHD and obesity, such as microdeletions in chromosome 11p14.1 that occur in both disorders (Shinawi et al., 2011). Another possibility may be shared intergenerational transmission of risk for both disorders perhaps through fetal programming effects. Most likely, as Nigg (2013) and others (Cortese et al., 2013) have noted, is that ADHD symptoms and related executive function (EF) deficits increase the likelihood of poor eating, more limited exercise, and more engagement with visual media, all of which may limit physical activity (discussed earlier), therefore leading to excessive weight. So people with ADHD should be evaluated for obesity and whether treatment of ADHD, as with medications, may reduce this risk, which seems to be the case (Waring & Lapane, 2008). This seems especially likely in view of the well-known anorectic effects of these medications, especially the stimulants (see also Chapter 27). Moreover, children and adults who are obese should be screened for ADHD because it is possible that treatment of their ADHD (e.g., with medication), may reduce their weight and future obesity risk, as has been the case with adult obese patients (Cortese et al., 2013; Levy et al., 2009). Moreover, stimulants such as methylphenidate have been found to reduce fat and carbohydrate intake in obese adolescents and may well do the same for obese teens with ADHD (Danilovich, Mastrandrea, & Quattrin, 2014).

As suggested earlier, ADHD seems to be linked not only to risk for being overweight or obese but also, at least in females, to a growing risk for eating pathology, particularly binge eating (BE), to more severe BE, and to its more extreme form, bulimia nervosa (BN; Nazar et al., 2012). Studies of children and adolescents, as well as adults, who have such eating pathologies likewise have long documented that impulsivity, as well as comorbid anxiety and depression, and parental obesity and eating pathology, are overrepresented and are likely risk factors that predispose individuals toward BE and BN (Nazar et al., 2012, 2014; von Ranson & Wallace, in press). In fact, some research indicates that 21% of those patients treated for BN had ADHD in childhood and were four times more likely to have a current diagnosis of adult ADHD (Seitz et al., 2013). The presence of ADHD was associated with more severe eating pathology and more symptoms of general psychopathology (Nazar et al., 2014; Seitz et al., 2013). Yates, Lund, Johnson, Mitchell, and McKee (2009), however, did not find such an overrepresentation, although they did report elevated symptoms of ADHD in at least 21% of women seeking treatment for an eating disorder. Problematic in such studies was the use of outdated DSM-IV criteria designed for children, which may have set too

high a symptom threshold to detect cases of ADHD in adults (Barkley et al., 2008; McGough & Barkley, 2004), leading to the lower threshold for diagnosing adult ADHD in DSM-5. But consistent with earlier studies that found such a link, in a large study of 12,366 twin pairs in Sweden, Råstam and colleagues (2013) found that children who rated high on eating problems scales had a higher prevalence of ADHD and/or autistic spectrum disorders (ASDs; 40%) in comparison to children without such eating problems. In girls, social interaction problems predicted risk for eating problems while in boys, impulsivity and activity level did so.

Some authors believe that it is not just the contribution of impulsivity to BE and BN that occurs in cases with ADHD. Such patients with comorbid ADHD symptoms may also demonstrate an increased reward sensitivity that may interact with impulsivity and inattention to heighten the likelihood of BE and BN eating pathology (Appelhans et al., 2011; Pagoto, Curtin, Appelhans, & Alonso, 2012; Seitz et al., 2013). Besides being linked to eating pathology, the presence of ADHD symptoms in people seeking treatment for obesity is also associated with more prior attempts to lose weight and less weight loss in those attempts (Pagoto et al., 2010). For these reasons, clinical researchers believe that ADHD may serve both as a marker for more severe eating pathology and comorbidity, and an obstacle to clinical management of eating pathology in patients who need treatment to improve their responsiveness (Levy et al., 2009; Nazar et al., 2014; Pagoto et al., 2012).

Given the totality of the evidence discussed earlier, it seems reasonable that the inverse would also be the case: People with ADHD, particularly those with elevated HI symptoms, are at risk for such eating pathologies. Only a limited amount of research has addressed this issue, but such risks became evident in large studies of girls with ADHD followed up in adolescence. Biederman and colleagues (2007) followed 140 girls with ADHD (ages 6–18) in Massachusetts for a period of 5 years and contrasted them with a control group of girls on measures of eating pathology. At follow-up, 16% of the ADHD girls met criteria for a current or past eating disorder (30% for anorexia, 50% for bulimia, and 20% for both AN and BN). The girls with ADHD were 3.6 times more likely to be diagnosed with any eating disorder and 5.6 times more likely to have BN specifically. Those with such eating disorders also had higher levels of depression, anxiety, and other disruptive behavior disorders, as well as earlier onset of menarche than girls with ADHD without eating disorders, consistent with previously discussed studies of girls with eating disorders. Similarly, in California, Mikami, Hinshaw, Patterson, and Lee (2008) followed 140 girls with ADHD and a control group of 88 girls over a 5-year period, evaluating them for body image dissatisfaction, eating pathology generally, and bulimic symptoms specifically. Girls with ADHD had larger BMIs than comparison girls; girls with the combined type of ADHD had significantly more eating pathology than did control girls, whereas girls with mainly the inattentive form of ADHD placed between these two groups. Consistent with earlier research, degree of impulsivity was a major predictor of risk for eating pathology by follow-up, as was degree of peer rejection and parent–child relationship problems (particularly punitive parenting). Sobanski and colleagues (2008) reported that 10–21% of their adults with ADHD, depending on subtype, had an eating disorder, compared to 0% of their control group. A recent review of the literature found eight studies of this issue of ADHD and eating pathology, five of which found a clear association (Curtin, Pagoto, & Mick, 2013). The authors concluded that youth with ADHD had a three to six times greater risk of developing an eating disorder and were significantly more likely than control groups to have eating pathology. Thus, the limited evidence to date suggests that ADHD in adolescent and adults, especially in females, may predispose to eating pathology generally and to binge-eating disorders specifically. Likewise, adults with BED or BN are more likely to have ADHD or significant problems with impulse control. Many of the researchers in these initial studies have recommended that clinicians specializing in the evaluation and treatment of either ADHD or obesity/eating pathology be aware of this comorbidity and screen for the overlap during their evaluations.

ELIMINATION DISORDERS

Enuresis, particularly nighttime bedwetting, was noted in early studies of hyperactive children to occur in as many as 43% of children, compared to 28% of normal children (Stewart et al., 1966). Two subsequent studies, however, did not find this to be the case (Barkley, DuPaul, & McMurray, 1990; Kaplan, McNichol, Conte, & Moghadam, 1987). But more recent studies do seem to suggest an overrepresentation of enuresis, at least in a minority of children with ADHD (11–30%) (Baeyens et al., 2006; Biederman, Santangelo, et al., 1995; Duric

& Elgin, 2011; Ghanizadeh, Mohammadi, & Moini, 2008). Enuresis seems to be 3.4 times more likely to occur in children diagnoses with ADHD (Baeyens et al., 2006). A study of Norwegian children seen in an outpatient clinic found that enuresis or encopresis was present in 15% of children with ADHD versus 3% of comparison children (Duric & Elgin, 2011). Among those children with both ADHD and enuresis, rates of oppositional defiant disorder (ODD) are significantly higher than in children with ADHD without enuresis (Baeyens et al., 2006; Ghanizadeh, 2010).

Hartsough and Lambert (1985) reported that children with ADHD are more likely to have difficulties with *bowel training* compared to normal children (10.1 vs. 4.5%), whereas Munir, Biederman, and Knee (1987) found that 18% had functional *encopresis*. As noted earlier, Duric and Elgin (2011) found that children with ADHD had a higher risk for encopresis–enuresis (15%) than did comparison children, but they did not report the rate for encopresis specifically. My colleagues and I were unable to replicate either of these findings, but our sample size was relatively small and therefore had limited power to detect such a small association (Barkley, DuPaul, et al., 1990). A recent population-based study using more than 735,000 children did find a small but significant relationship between children with ADHD and risk for constipation (4.1%) compared to children without ADHD (1.5%), as well as a more modest relationship of ADHD and fecal incontinence (0.9 vs. 0.15%) (McKeown, Hisle-Gorman, Eide, Gorman, & Nylund, 2013). Thus, children with ADHD are only slightly but significantly (statistically) more likely to have problems with constipation and encopresis, and this risk applies to a very small minority of cases.

SEIZURES, EPILEPSY, BRAIN ELECTRICAL ABNORMALITIES, AND NEUROFEEDBACK

A population-based study in Iceland employing a case–control design demonstrated a significant association between child ADHD and risk for *epilepsy and unprovoked seizures* (Hesdorffer et al., 2004). In this study, children with ADHD were 2.5 times more likely to have epilepsy or unprovoked seizures, particularly if they had the predominantly inattentive type of the disorder. The inverse relationship also held true; a history of ADHD (predominantly inattentive type) was found to be 2.5 times more common among children with epilepsy or unprovoked seizures. The finding of a link between epilepsy and ADHD was also replicated in Norway in a large study of children with ADHD (n = 607). Socanski, Aurlien, Herigstad, Thomsen, and Larsen (2013) noted a risk of 2.3% for epilepsy in this sample, which is more than four times the population prevalence for children of this age (0.5%). No research on adults with ADHD could be located on this issue, so it is unclear whether this same relationship holds for that age group.

Apart from this small but elevated risk for frank seizure disorders or epilepsy in children with ADHD, there is abundant evidence of abnormal electroencephalographic (EEG) patterns in children with this disorder (Hastings & Barkley, 1978; Loo & Makieg, 2012). While such findings are pertinent to the neurobiological etiology of ADHD, they also speak to the poorer neurological health and developmental status of children with the disorder. The most common finding in children and adults with the disorder is increased frontal–central theta band activity, believed to be associated with reduced arousal (Loo & Makieg, 2012). A meta-analysis of EEG studies (Snyder & Hall, 2006) found an effect size difference between ADHD and control groups of 1.31, which is substantial, with an average of 32% excess theta band power in the ADHD group. Not surprisingly, then, because the ratio of theta-to-beta band power is also substantially higher in ADHD cases than in controls, with an effect size greater than 3.0 (Loo & Makieg, 2012; Snyder & Hall, 2006), these two EEG measures are of great interest to clinicians and researchers seeking a laboratory measure that might prove useful in the diagnosis of ADHD (Snyder et al., 2008). Results of research examining the predictive accuracy of this ratio for the diagnosis of ADHD generally find an 84–95% accuracy rate, but with 16–18% of ADHD cases being misclassified as normal due to normal ratios (Loo & Makieg, 2012; Loo & Barkley, 2005; Snyder et al., 2008). Other researchers have found an accuracy rate considerably lower (58%) (Magee, Clarke, Barry, McCarthy, & Selikowitz, 2005), and in a recent meta-analysis, Arns, Conners, and Kraemer (2013) found much lower effect sizes for group differences on these measures and significant heterogeneity across studies, which argues against the use of these measures diagnostically. Such a mixed pattern of results and an elevated rate of false negatives in even the most supportive studies should reduce one's enthusiasm for using EEG alone as a diagnostic tool. Moreover, Loo and Makieg (2012) and others (e.g., Snyder et al., 2008) have cautioned that increased theta band

activity has also been associated with other disorders, such as bipolar and substance use disorders; it is therefore not specific just to ADHD. Moreover, theta–beta ratios cannot identify comorbidities in people with ADHD, which makes them poor stand-alone measures for diagnosis.

The findings of increased theta band activity and a higher theta-to-beta ratio on EEG led earlier clinical investigators, such as Joel Lubar (e.g., Lubar & Shouse, 1976) to speculate that operant conditioning of brain electrical activity might be a means of improving the symptoms of ADHD. A number of early studies indeed reported some promise for this intervention, leading to claims among practitioners that such neurofeedback treatment (NF) was as effective as medication, had no side effects, and produced permanent improvements in ADHD symptoms that lasted into adulthood in up to 80% of treated children. But these studies were not scientifically rigorous, often amounting to simply pre- versus posttreatment comparisons of treated children using various behavior rating scales and psychological tests, such as IQ tests or continuous performance tests. None of these early studies used sham, placebo, or alternative treatment comparisons groups, or employed blinded assessments of the children. More recently, better controlled studies have led to rather mixed results; some have found benefits in comparison to alternative or sham treatments, while others have not. Loo and Makieg (2012), among others, recently reviewed the literature on NF treatment for ADHD.

The reviewers found four studies that employed sham or placebo control treatments for comparison to children who received the NF protocol. These were the most rigorous studies included in their review. All kept parents blinded to the treatment conditions their children were receiving and three of the four studies kept therapists blinded as well. Results for all four studies found that both groups improved as a result of treatment, with no differences in improvement between them, which means that there was no specific treatment effect for NF. Of import in these studies is that there were no significant changes in the EEG and no differences in neuropsychological test performance, as well as no differences in parent or teacher ratings. This indicates that the very mechanism by which NF is argued to work—improving EEG activity in critical frequency bands—did not change in the NF and sham feedback groups. The fact that earlier studies using just waiting-list control groups and unblinded evaluations of NF effectiveness found apparent improvements as a result of NF, while placebo–sham-controlled, blinded and hence more rigorous studies do not, strongly suggests that much, if not all, of the improvement attributed to NF is actually nonspecific (therapist contact time, parental expectancy effects, participant motivation, etc.) (Loo & Makieg, 2012).

The reviewers located five additional studies in which NF was compared to another active treatment condition, such as another form of cognitive training software. Although some of these studies found that ADHD inattention significantly improved with each treatment, as rated by parents, the statistical analyses were questionable because they were biased toward finding a treatment effect (use of one-tailed tests), but none directly compared posttreatment scores between the groups. None of the studies found any improvements in teacher-rated ADHD symptoms in the school setting, and three of the four studies that used neuropsychological testing found no improvement in EF (Loo & Makieg, 2012). These results, coupled with those from the earlier placebo–sham-controlled studies are not especially supportive of a specific NF effect on ADHD symptoms, leading the reviewers to conclude that "studies reviewed herein do not support NF training as a first-line, stand alone treatment for ADHD" (p. 583). Moriyama and colleagues (2012) also reviewed this same literature, reaching similar though more optimistic conclusions and acknowledging that the more rigorous studies found little if any improvements in ADHD symptoms, yet continuing to view NF as a valid treatment option based largely on the more poorly conducted studies. In contrast, yet another review of this literature found that the promising results seen in randomized trials in which assessments were not blinded did not carry forward into subsequent studies using blinded evaluations and sham–placebo control groups (Lofthouse, Arnold, & Hurt, 2012). More recently, Sonuga-Barke and colleagues (2013) conducted a meta-analysis of various nonmedical interventions for ADHD, including NF. They only examined studies in which participants had been randomized to NF-treated and comparison groups (placebo, sham, active treatments). Their results indicated that studies using nonblinded ratings from people closest to the training setting (e.g., parents or therapists) produced significant results, but these comparisons became nonsignificant in better studies using blinded evaluations and examining treatment effects further from the treatment setting (e.g., school). Since these reviews were published, an additional study of NF involving a sham–placebo treat-

ment control group with blinded evaluations has been reported. It found that both groups improved significantly with their being no differences between them (van Dongen-Boomsma, Vollebregt, Slaats-Willemse, & Buitelaar, 2013). Despite promising results from uncontrolled or nonblinded studies of NF, more rigorous studies to date have not demonstrated that NF offers specific treatment effects beyond what can be attributable to various nonspecific factors. Thus, as Loo and Makieg (2012) concluded, NF is not established as a valid front-line, stand-alone intervention for ADHD at this time.

SLEEP PROBLEMS

Several early studies found that children with ADHD are more likely to have *sleeping problems* than are normal children. Difficulties with time taken to fall asleep may be seen in as many as 56% of children with ADHD compared to 23% of normal children, and up to 39% of children with ADHD may have problems with frequent night waking (see Corkum, Tannock, & Moldofsky, 1998, for a review; Greenhill, Anich, Goetz, Hanton, & Davies, 1983; Kaplan et al., 1987; Stein, 1999; Stewart et al., 1966; Trommer, Hoeppner, Rosenberg, Armstrong, & Rothstein, 1988). For example, Ball, Tiernan, Janusz, and Furr (1997) found that 53–64% of their ADHD group had sleep problems, as reported by parents, and that whether or not the children were taking stimulant medication did not seem to influence these results. Later studies have continued to support an association between ADHD and parent-reported sleeping disturbances (Hvolby, Jorgensen, & Bilenberg, 2009). This higher incidence of sleep difficulties may appear as early as infancy in children with ADHD (Stewart et al., 1966; Trommer et al., 1988), with as many as 52% described as such in infancy, compared to 21% of normally developing children. Resistance to going to bed, frequent night wakenings, and fewer total sleep hours may be the most obvious sleep difficulties that children with ADHD experience, as reported by parents (Hvolby et al., 2009; Stein, 1999; Wilens, Biederman, & Spencer, 1994). But difficulties with sleep onset and night waking are believed to characterize an unstable sleep pattern that has been shown to have a significant association with ADHD (Gruber, Sadeh, & Raviv, 2000). More than 55% of children with ADHD also have been described by parents as being tired on awakening, compared to 27% of normal children (Trommer et al., 1988). And children with ADHD manifest more frequent episodes of sleepiness during the day (Lecendreux, Konofal, Bouvard, Falissard, & Mouren-Simeoni, 2000).

Studies using objective measures of sleep, such as polysomnograms during overnight sleep, have not documented any difficulties in the physiological nature of sleep itself associated with this disorder (Ball & Koloian, 1995; Corkum et al., 1998; Cortese, Faraone, Konofal, & Lecendreaux, 2009; Lecendreaux et al., 2000). Sleep quality (objectively or electrically measured) does not seem to account for these parental reports of daytime tiredness and sleepiness, delayed sleep onset at nighttime, and disrupted sleep. Two meta-analyses of objective sleep measures (Cortese, Konofal, Yateman, Mouren, & Lecendreaux, 2006; Sadeh, Pergamin, & Bar-Haim, 2006) did find objective evidence that children with ADHD are more active during sleep, and have more daytime sleepiness and a greater Apnea–Hypopnea Index (AHI), despite their inability to find any evidence of electrical abnormalities on overnight polysomnograms. In a subsequent meta-analysis of 16 studies that also included subjective measures of sleep difficulties along with additional studies using objective measures, Cortese, Faraone, and colleagues (2009) found substantial evidence of ADHD-associated sleeping difficulties in parent reports of greater bedtime resistance, delayed sleep onset, more night awakenings, difficulties with morning awakening, and sleep-disordered breathing. Compared with controls, no differences were found for parasomnias, restless sleep, or sleep duration in children with ADHD. Objective measures also revealed greater sleep-onset latency, more frequent shifts in sleep stage per hour of sleep, and a higher AHI (disordered breathing) associated with ADHD. They also had lower sleep efficiency and less true sleep time, as assessed by various laboratory measures. But in the percentage of time spent in various sleep stages and other measures, such as night awakenings (assessed by actigraphy), children with ADHD did not differ from controls. Some of these results partially replicate the reports of parents concerning some of these sleep parameters while others do not. More recently, in a meta-analysis of 18 studies in which sleep-disordered breathing (SDB) was examined, Sedky, Bennett, and Carvalho (in press) found a significant association between ADHD and SDB. The total portrait here is one of considerable difficulties, with bedtime resistance, sleep onset, sleep efficiency, SDB/AHI, and daytime tiredness being linked to ADHD.

It seems likely, as noted by Cortese, Faraone, and colleagues (2009), that four other factors may operate here to contribute to the larger number of parent reports. Some of the parent-reported difficulties with bedtime resistance may be part and parcel of the difficult behavior and oppositionality often observed in children with ADHD rather than a reflection of true sleeping difficulties or disorders. Moreover, some research suggests that parents of children with ADHD may be more likely to have inappropriate sleep habits having to do with environmental management around bedtime, scheduling of bedtimes, and other factors that could impact bedtime difficulties (Owens, 2008). Parents may also overreport their children's bedtime problems due to the high level of behavior problems such children may manifest throughout the day; parents' impressions of these may carry over to late day/bedtime difficulties. However, some of the significant group differences on the objective measures noted earlier would suggest that this explanation cannot account entirely for the more numerous parental reports of sleep-related problems in children with ADHD because such children do have some sleeping abnormalities (onset, sleep stage changes, AHI, daytime sleepiness, etc.). Nor can the use of stimulant medication to treat ADHD and well known for producing insomnia account for these difficulties because children on medication were excluded from the Cortese, Faraone, and colleagues meta-analysis.

But it appears that some of these parent-reported behavioral difficulties surrounding children's bedtime are more a function of disorders that often are comorbid with ADHD (ODD, anxiety disorders) than of ADHD (Corkum, Beig, Tannock, & Moldofsky, 1997; Corkum, Moldofsky, Hogg-Johnson, Humphries, & Tannock, 1999). Or they may be nonspecific to ADHD, in that they characterize other behavior problems or learning disorders as well (Gregory & O'Connor, 2002; Marcotte et al., 1998). One such candidate is ODD, which is evident in a majority of children with ADHD. Another is anxiety/depression, which also exists in a substantial subset of children with ADHD. Mayes and colleagues (2009) studied the extent to which comorbidity accounts for sleep problems and found that only children with the combined type of ADHD had more parental reports of sleeping difficulties relative to controls and those with the inattentive type of ADHD. Interestingly, the inattentive type of ADHD was associated with sleeping more, not less, than controls. The presence of comorbid anxiety/depression increased the frequency of sleep problems, whereas ODD did not. Likewise, Hvolby and colleagues (2009) did not find ODD to be associated with parent-reported sleeping difficulties beyond those attributable to ADHD alone. Consistent with these results are other studies showing that anxiety in children can be associated with sleeping difficulties, especially night waking, whether or not it is associated with ADHD (Hansen, Skirbekk, Oerbeck, Richter, & Kristensen, 2011). A recent study also found that children with ASDs had elevated levels of sleeping difficulties that did not differ from the elevated rates in children with ADHD, although both groups had more sleep problems than did children with epilepsy or typical controls (Tsai et al., 2012). So comorbid conditions, such as anxiety/depression and ASD more than ODD, may well make some contribution to bedtime behavioral and sleeping difficulties apart from those attributable specifically to ADHD (Corkum et al., 1999; Gregory & O'Connor, 2002; Marcotte et al., 1998). This in fact also proved to be the case in a study by Willoughby, Angold, and Egger (2008), in which preschool children with ADHD, without regard to comorbidity, showed elevated levels of sleep assistance, parasomnias, and dyssomnias related to their level of HI symptoms. But once researchers controlled for comorbid disorders, these relationships became nonsignificant. Only the inattention symptoms of ADHD remained significantly associated with daytime sleepiness in these children, implying that need for sleep assistance, parasomnias, and dyssomnias seen in conjunction with ADHD are related to comorbidity.

A possible mechanism for some of the sleep-related difficulties evident in ADHD is the recent finding that children with ADHD have a more elevated level of certain polymorphisms of *CLOCK* genes than that seen in the typical population (Cao, Cui, Tang, & Chang, 2012; Dueck, Thome, & Haessler, 2012). Chinese children with ADHD were noted to have a more elevated incidence of the *T3111C* polymorphism of this *CLOCK* gene that was even more prevalent in children whose parent reported sleep disturbances than in those whose parent did not (Cao et al., 2012). The normal circadian rhythm is known to be affected by these *CLOCK* genes that also affect the sleep–wake cycle and release of hormones such as melatonin and cortisol (Dueck et al., 2012). Thus, there seems to be some promise in exploring in future research this relationship of genetic predispositions to sleep problems in ADHD.

One finding that may be characteristic of the sleep of ADHD children is greater movement during sleep (Corkum et al., 1998, 1999; Cortese, Faraone, Kono-

fal, & Lecendreux, 2009; Cortese et al., 2006; Porrino et al., 1983). While not evident in their meta-analysis, Cortese, Faraone, and colleagues (2009) note that the sample of such studies was limited, as was the reliability of objective measurement of movement, thus limiting their conclusions on this issue. Such findings of greater periodic limb movements during sleep in some studies using both parent report and objective measurement (Sadeh et al., 2006) have suggested a possible connection between ADHD and restless legs syndrome (RLS; Pichietti et al., 1999). That connection needs to be explored more fully, though one recent study also noted support for this relationship (Jesus et al., 2013). The authors found that such abnormal sleep movements, as well as difficulty transitioning to sleep, were related to low serum ferritin levels (iron) in children with ADHD (Cortese, Konofal, Bernardina, Mouren, & Lecendreux, 2009). However, other research indicates that low ferritin levels are more likely to be related to comorbid disorders than to ADHD generally (Oner & Oner, 2008), suggesting that it may be comorbid behavioral problems that mediate the findings of the Cortese, Konofal, and colleagues (2009) study.

Miano, Parisi, and Villa (2012) have hypothesized that the sleeping difficulties associated with ADHD may be subdivided into five phenotypes: "(i) a sleep phenotype characterized mainly by a hypo-arousal state, resembling narcolepsy, which may be considered a "primary" form of ADHD (i.e., without the interference of other sleep disorders); (ii) a phenotype associated with delayed sleep onset latency and with a higher risk of bipolar disorder; (iii) a phenotype associated with sleep disordered breathing (SDB); (iv) another phenotype related to restless legs syndrome (RLS) and/or periodic limb movements; (v) lastly, a phenotype related to epilepsy/or EEG interictal discharges" (p. 147). The management of the sleeping difficulties in these cases would be different and target the possible origin of the sleep problem, such as bipolar disorder, SDB, RLS, epilepsy, and so forth, rather than treating all ADHD-related sleeping difficulties the same. While both sensible and intriguing, to my knowledge, no research has examined either empirical evidence for such phenotyping (e.g., cluster analysis) or the benefits of these management ideas in any controlled fashion.

The quantity of sleep a child receives, as well as elevated symptoms of disordered breathing during sleep, are associated with teacher ratings of externalizing behavioral problems, particularly inattention (Aronen, Paavonen, Fjallberg, Soininen, & Torronen, 2000; Cortese, Konofal, et al., 2009). One study examined the relationship between different dimensions of children's psychopathology and different dimensions of sleeping problems (Stein, Mendelsohn, Obermeyer, Amromin, & Benca, 2001). Insomnia was the only sleep problem related to ratings of inattention, whereas noisy sleep was related to ratings of aggression, and parasomnias (sleep walking, nightmares, night terrors, head banging) were related to anxiety/depression, thought problems, and social problems. The latter finding may explain why past meta-analyses have not found consistent evidence that links parasomnias to ADHD; it is more likely a function of comorbidity. Some authors have argued that this means that sleep problems may be contributing to psychopathology in children (Aronen et al., 2000). But the direction of effect in these studies is unclear given the correlational nature of these findings. Is limited sleep (insomnia) a direct contributor to school behavioral problems and inattention, or is it that children who are more likely to misbehave and be inattentive are also more likely to have difficulties getting to sleep at night and with other facets of sleep? These correlation-based results simply do not provide an answer.

One study, however, did manipulate sleep quantity, while examining its impact on daytime behavioral problems in normal healthy children (Fallone, Acebo, Arnedt, Seifer, & Carskadon, 2001). Children whose sleep had been restricted to 4 hours on one occasion were found the next day to have increased inattention but not increased hyperactive or impulsive behavior. Nor did they have impaired performance on a laboratory measure of inattention and impulsiveness. The study suggests that limited sleep may well increase inattentiveness in children, but the short duration of the sleep manipulation may have limited the researchers' ability to test this relationship between sleep and other behavioral indicators. Sadeh, Gruber, and Raviv (2003) restricted the sleep of normal children by 1 hour over three consecutive nights and did find an effect on laboratory measures of neurobehavioral functioning (attention, inhibition, etc.). Also of interest is the recent finding that whereas reduced sleep may well be associated with inattentiveness in healthy normally developing children, it is not related to the behavioral symptoms in children with ADHD (Gruber & Sadeh, 2004). These results suggest that the likely causal connection between disrupted sleep and inattention that may be evident in normal children does not arise from the same mechanism(s) as what may exist between

ADHD and its associated sleep problems. Indeed, some research suggests that the pattern of objectively assessed sleeping difficulties that is evident in ADHD is not the same as that in children with sleeping problems, and that when ADHD and sleep problems are comorbid, the pattern of findings is also distinct from that for either condition alone (Sawyer et al., 2009). The authors concluded that the neurological difficulties that may be contributing to sleep difficulties are not the same as those associated with ADHD, or with ADHD plus sleeping disturbances. This should give some pause to clinicians considering the widespread use of tonsillectomies or other interventions for improving disordered breathing during sleep as a means of addressing the daytime inattention of children with clinically diagnosed ADHD. Both clinical data and a recent meta-analysis of adenotonsillectomy for SDB (Sedky et al., in press) suggest that improvement in ADHD may be seen within a year after such surgery (Chervin et al., 2006). Sedky and colleagues (in press) recommended screening all children with ADHD for possible SDB given its greater frequency in children with ADHD. If SDB is present, they suggest that surgical intervention be considered. More rigorous randomized trials of this treatment have not been done, yet clearly they are necessary before considering surgical intervention in children with ADHD and SDB.

One intervention for delayed sleep onset in ADHD that has been studied is the use of sublingual melatonin (Van der Heijden, Smits, Van Someren, Ridderinkhof, & Gunning, 2007) prior to bedtime. Improvement in sleep onset was reported (averaging nearly half an hour earlier) in children with ADHD receiving the melatonin compared to placebo, in which the sleep onset actually lengthened during the study period. However, no improvement in bedtime behavior, cognition, or quality of life was associated with the intervention condition. A recent review of the literature on medication interventions for sleep problems in children with ADHD concluded that clonidine and L-theanine also improved sleep, as did melatonin, while zolpidem was not effective and had substantial side effects associated with its use (Barrett, Tracy, & Giaroli, 2013).

In a recent study, Jesus and colleagues (2013) found results that suggest ADHD medications may result in reduced sleep problems in children with ADHD. But the study was purely a naturalistic one and did not involve randomization to treated and untreated groups, so the conclusion that treating ADHD with medication improves sleep problems needs to be studied fully.

Another type of intervention for bedtime problems was evaluated in a study by Sciberras and colleagues (Sciberras, Fulton, Efron, Oberklaid, & Hiscock, 2011) who invented a behavioral sleep training program to help parents reduce the sleeping difficulties of children with ADHD. In a pilot study using a randomized trial of small samples, they compared two groups of families whose children with ADHD had sleep problems. Families received either one session of counseling on behavioral strategies to employ at bedtime and overnight (n = 13) or two to three sessions (n = 14). At posttreatment most parents, regardless of treatment group, reported the strategies to be useful, and at 5 months postrandomization, 67% of parents in both groups stated that their children's sleeping problems had resolved. There were also improvements in children's quality of life and daily functioning, and parental anxiety, but there was little change in children's ADHD symptoms.

To date, very few studies have specifically examined sleeping difficulties in adolescents with ADHD; they are typically lumped in with younger children in prior research. But one study that did so found no greater frequencies of various sleep difficulties in a teen group with ADHD than in a control group (Stein et al., 2002). Only stimulant medication status was associated with elevated sleep difficulties in the ADHD teen group. However, depression was significantly associated with sleeping difficulties in these adolescents, a finding that is consistent with other results suggesting that, with age, it is depression, not ADHD, that is more predictive of sleeping difficulties from adolescence to adulthood (Gregory & O'Connor, 2002).

Likewise, only a few studies have evaluated the sleeping difficulties associated with ADHD in adults. Surman and colleagues (2009) compared large samples of both adults with ADHD and adults in a control group. They found that adults with ADHD went to bed later; had a wider range of bedtimes; were more likely to take over an hour to fall asleep; and reported more difficulties going to sleep, sleeping restfully, and waking in the morning. They also reported more daytime sleepiness than did control adults. These differences remained despite researchers'controls for use of ADHD medications (which can induce insomnia), age, and comorbidity with other psychiatric disorders. Similar results were reported in a population-based survey of a large sample of adults in Romania, in which severity of ADHD symptoms was associated with greater insomnia, longer latencies to sleep onset, shorter sleep duration, and more frequent (unwanted) awakenings during sleep, as well

as an evening orientation to their circadian rhythm (Voinescu, Szentagotai, & David, 2012). These difficulties are similar to those seen in the studies of children with ADHD discussed earlier. Two studies suggest that the sleep quality in adults with ADHD is associated with the HI symptom dimension (especially impulsivity) and not with the inattentive dimension (Mahajan, Hong, Wigal, & Gehricke, 2010; Voinescu et al., 2012). It is possible that the longer latencies to sleep and greater insomnia associated with adult ADHD is linked to delayed circadian rhythm, in which these adults show a strong evening over morning preference (41 vs. 18%; Rybak, McNeely, Mackenzie, Jain, & Levitan, 2007).

INTERNET USE AND ADDICTION

The increasing availability of computers, computer games, and the Internet and Web-based gaming networks has opened up the possibility for a new domain of health- (and mental health)-related difficulties for people, such that, on average, 9% of youth may qualify as Internet or video game addicts or as having problematic Internet usage (Gentile et al., 2011). Those with ADHD may be especially prone to such addictions—a risk that was not available to prior generations of children with ADHD. It can be easily reasoned that individuals who have difficulties with impulse control and self-regulation, such as those with ADHD, may find that the opportunities the Internet affords for stimulation seeking and risk taking can lead to a new source of "addictive behavior" (Gentile et al., 2011; Weiss, Baer, Allan, Saran, & Schibuk, 2011). Moreover, people who have difficulties with face-to-face interpersonal behavior, such as occurs in ADHD, may find the greater anonymity of the Internet and the opportunity to create an alternate persona, to provide an alternative means of socializing. In the past 5 years, more than 58 studies have been done on internet addiction (IA) in general (Kuss & Griffiths, 2012) with more than 21 studies examining the role of ADHD, among other psychiatric symptoms, in the risk for addiction (Carli et al., 2013; Ko, Yen, Yen, Chen, & Chen, 2012).

Among the first articles to appear on this topic relative to ADHD was a U.S. study in which 72 teens and their parents were interviewed about Internet and computer video game use in relation to symptoms of ADHD. The study found significant associations between gaming more than 1 hour per day and elevated symptoms of ADHD, particularly inattention (Chan & Rabinowitz, 2006). Later, in a study in France, Bioulac, Arfi, and Bouvard (2008) rated a small sample of children with ADHD and control children, ages 6–16, on the Problem Video Game Playing Questionnaire (PVP), which can be used to define addictive video game playing. The symptoms of such addiction were adapted from DSM-IV criteria for substance dependence and for gambling addiction. The findings did not show any differences in the frequency or duration of play between the two samples. Control children often played less than once a week, whereas one-third of the children with ADHD played between one and three times a week, but the groups did not differ statistically in that respect. The time spent per session also did not differ, with most children spending between 1 and 2 hours (65% for ADHD, 50% for controls). The authors also reported that the two groups did not differ with regard to the type of video game, since both groups played action and reflection games (adventure games, role playing games, logic games). However, they did find that, according to the parents, the children with ADHD were less likely than controls to stop playing of their own accord (59% of the ADHD group vs. 90% of the control group). About three times as many children with ADHD reacted to such parental restrictions on game use with refusal, anger, violence, or tears (59 vs. 19%). On the PVP, 34% of children with ADHD had scores of 5 or more problematic symptoms, which is sufficient to be considered addicted to video games, compared to none of the control children. Children with ADHD meeting such criteria differed from those who did not in that they had more severe hyperactivity/ADHD symptoms and higher parent ratings of aggression and conduct problems. In a subsequent study, Bioulac and colleagues (in press) examined the nature of video game performance between small samples of children with ADHD and control children, and reported no evident differences across three types of games despite the groups' differing performances on a continuous-performance test. The small sample sizes, however, greatly limited the power of this study to detect less than large effect sizes. Thus, problematic video game playing or addiction may be significant problems for children with ADHD, even if the quality of their play does not differ from that of control children.

But what of Internet use and the forms of gaming it permits? Studies on this topic have mostly been done in Asia, and they repeatedly support an association between ADHD and some of its comorbid conditions and IA (Carli et al., 2013; Ko et al., 2012). For instance,

Yen, Ko, Yen, Wu, and Yang (2007), in a sample of 2,114 students, found that in males and females, both ADHD symptoms and depression were associated with hostility, making an additional contribution to risk in males. In a subsequent large study surveying 2,293 students across 10 different junior high schools in Taiwan, using the Chen Internet Addiction Scale, Ko, Yen, Chen, Yeh, and Yen (2009) evaluated their sample across four time periods (upon entry, 6 months, 12 months, and 24 months later). IA symptoms, such as preoccupation with the Internet, uncontrolled impulses to use it, usage more than intended, tolerance, withdrawal, impairment of control, excessive time and effort spent, and impairment in decision-making ability were captured by the Chen scale using 26 items rated on a 4-point Likert scale. Scores of 64 or higher were defined as representing addiction. The authors found that ADHD symptoms and hostility were the most significant predictors of IA in both males and females. Although ADHD was the most important predictor among females with IA, depression and social phobia were lesser but also significant predictors. By the 2-year follow-up, ADHD, depression, social phobia, and hostility were predictive of IA. Similar results were more recently observed in Turkish university students where degree of ADHD symptoms, especially HI, was significantly associated with degree of IA even after researchers controlled for anxiety, depression, and personality traits (although these factors were also linked to IA after they controlled for ADHD as well) (Dalbudak & Evren, 2014).

Ko and colleagues (2009) reasoned that ADHD may be an important determinant of IA for various reasons, including subjects' poor impulse control; impaired interpersonal socializing; penchant for greater hostility, which can be expressed through Internet war gaming; and the fact that for those with social phobia, the Internet may be a less threatening form of socializing than are face-to-face encounters. Also, Internet gaming may increase the release of dopamine into the brain, which may temporarily compensate for the dopamine deficiency believed to be involved in some cases of ADHD (Koepp et al., 1998) and may therefore be a form of self-medication. The authors further speculated that the screening and treatment of ADHD and these related predictors may be needed as part of any effective intervention for IA, and that those studying patients with ADHD and these other conditions must be aware of their increased risk for such addiction.

Computer game addiction appears to share some similar risk factors with other forms of addiction, such as substance use and gambling, in a recent study of 16- to 25-year-old German youth (Walther, Morgenstern, & Hanewinkel, 2012). In particular, problem gaming appears to link up with cannabis use rather than tobacco or alcohol use. The most common personality trait linked to five forms of addictive behavior, including gaming, was high impulsivity, perhaps explaining why those with ADHD may be more prone than others to various forms of addiction, including gaming. But computer game addiction was also associated with irritability/aggression, social anxiety, and low self-esteem, in agreement with the study by Ko and colleagues (2009) on the importance of these factors in predicting Internet and video game addiction. In a small study of adults diagnosed with IA, Bernardi and Pallanti (2009) found a higher than expected prevalence of ADHD, along with other disorders, including anxiety, obsessive–compulsive disorder (OCD), dysthymia, and personality disorders. These findings were largely replicated in a sizable study of IA in Taiwanese college students (n = 2,793), in which ADHD was the most significant predictor of IA, followed by general impulsivity (Yen, Yen, Chen, Tang, & Ko, 2009). A recent review of 20 studies on the topic of problematic Internet use (PIU) likewise identified ADHD as the most consistent predictor across these studies (100% of studies), followed by depression (75% of studies), hostility/aggression (66%), obsessive–compulsive symptoms (60%), and anxiety (57%), with males being more prone to this form of problematic behavior than females (Carli et al., 2013). The review concludes that symptoms of depression and ADHD have the most significant and consistent correlations with PIU. A similar conclusion was reached in the review of much of this same literature by Ko and colleagues (2012). Several longitudinal studies suggest that while greater amounts of gaming, high impulsivity, and low social competence may be precedents to and risk factors for pathological gaming, depression, suicidality, anxiety, social phobia, and low school achievement might well be the consequences of such gaming (Gentile et al., 2011; Messias, Castro, Saini, Usman, & Peeples, 2011). One study suggests that methylphenidate treatment of children with ADHD who play video games may decrease their symptoms and game usage (Han et al., 2009). And while not specifically targeting IA or gaming addicts with ADHD, literature reviews suggest that cognitive-behavioral therapy combined with family therapy, as well as psychopharmacology, might be the most efficacious intervention for youth who are IA or video game addicts (King, Delfabbro, & Griffiths, 2012; Liu, Liao, & Smith, 2012; Winkler,

Dorsing, Rief, Shen, & Glombiewski, 2013), approaching the disorder as one would other, more established forms of addiction.

Given that children with ADHD are more likely to be aggressive and hostile than other children, and that these factors increase the use of video gaming, including violent games, one might ask whether playing violent video games feeds back to increase such aggressive behavior. In a study of 377 children with elevated ADHD and depression symptom scores, however, those who play such games were not more likely to engage in delinquent behavior or bullying than those who do not play these violent games (Ferguson & Olson, 2014). This lack of association also seems to be the case for typical youth, in whom longitudinal data do not support an adverse effect of video game violence on either violent behavior or academic abilities (Ferguson, 2011; Ferguson, Garza, Jerabeck, Ramos, & Galindo, 2013). Instead, depression and antisocial behavior in youth are better prospective predictors of later violence than exposure to violent video games or violent media (Ferguson, 2011). In contrast to this, in a study in Pakistan that surveyed the opinions of teachers on the role of exposure to violent media and behavior problems in children with ADHD, the vast majority of teachers believed that media violence has an adverse affect on these children (Kazimi, Sadruddin, & Zehra, 2013). Of course, this study provides no evidence that teachers are correct in holding such opinions, only that they believe this relationship holds true. Thus, the results of the limited research to date do not support the belief that exposure to violent gaming specifically and violent media more generally has an adverse impact on children with ADHD, although teachers (in Pakistan) seem to hold such an opinion.

In conclusion, Internet and video game use and addiction are problematic for a substantial proportion of both children and adults with ADHD, and those who engage in the excess use of such media are more likely to have elevated symptoms of ADHD, among other disorders. More research is needed on treatments for these difficulties, but at least one study suggests that ADHD medications may help to reduce the time people spend in these media.

ACCIDENTAL INJURIES

Children with ADHD are considerably more likely to experience a variety of physical injuries due to accidents than are normal children (for reviews, see Barkley, 2001; Nigg, 2013). Early researchers found that up to 57% of children with ADHD are described as accident prone, and 15% have had at least four or more serious accidental injuries, such as broken bones, lacerations, head injuries, severe bruises, lost teeth, or accidental poisonings (Hartsough & Lambert, 1985; Mitchell et al., 1987; Reebye, 1997; Stewart et al., 1966). Results for the comparison or normal groups of children in these early studies were 11 and 4.8%, respectively. Stewart, Thach, and Friedin (1970) found that 21% of hyperactive children had experienced at least one accidental poisoning compared to 7.7% for typically developing children. In a much larger study of more than 2,600 children, Szatmari and colleagues (1989) found that 7.3% of children with ADHD children had experienced an accidental poisoning and 23.2% had suffered bone fractures compared to 2.6 and 15.1%, respectively, in the control group. Leibson and colleagues (2001) reported an elevated risk for major injuries among children with ADHD (59 vs. 49%) using a large birth cohort. Consistent with this finding, Swensen and colleagues (2004) also found a higher incidence of accident claims among children (28 vs. 18%) and adolescents (32 vs. 23%) with ADHD when they examined medical claims for a large population of employees of national manufacturers.

The injuries sustained by children with ADHD may also be more severe and occur more frequently. For instance, Mangus, Bergman, Zieger, and Coleman (2004) examined children admitted over a 7-year period to a regional pediatric burn unit and found that those with ADHD had a greater likelihood of a thermal rather than a flame burn, more extensive burn injuries, and a greater length of stay in the unit. Hoare and Beattie (2003) compared children with ADHD and control children who had attended an accident and emergency department in Edinburgh, Scotland, and noted that children with ADHD were more likely to attend because of injury, and that they had a greater frequency of injury, as well as differences in type of injury (head, wound–laceration, poisoning). It seems clear, then, that children with ADHD have an elevated risk of physical injury, of more frequent injuries, and of more severe injuries than do normal children. More recent studies continue to bear out the significant association between childhood ADHD and physical injuries (Badger, Anderson, & Kagan, 2008; Marcus, Wan, Zhang, & Olfson, 2008; Merrill, Lyon, Baker, & Gren, 2009; Pastor & Reuben, 2006). Population-based surveys of parents indicate that children with ADHD are 1.8 times more likely to experience a physical injury each

year than are control children (20.4 vs. 11.5% per year; Pastor & Reuben, 2006).

Some early retrospective and prospective studies generally found a relationship between degree of aggressiveness, not the degree of overactivity, and the likelihood of accidental injury in preschoolers (Davidson, Hughes, & O'Connor, 1988; Langley, McGee, Silva, & Williams, 1983). Because children with ADHD are more likely to be aggressive or oppositional, it may be that this characteristic increases their accident proneness rather than their higher rates of activity level or impulsivity (Langley et al., 1983). Yet a large population study of 10,394 British children found that both overactivity and aggression contributed independently to the prediction of accidents (Bijur, Golding, Haslum, & Kurzon, 1988). The linkage between childhood aggression and injury risk also has been demonstrated in more recent large population studies (Carlson et al., 2009). In a different study, Lalloo, Sheiham, and Nazroo (2003) examined 6,000 children in England and found that only hyperactivity was predictive of an increase in accidental injury, once they controlled for demographic and socioeconomic factors. Since the latter factors are more likely to be related to childhood aggressiveness, controlling for them may explain why aggressiveness itself was no longer predictive of accident risk in this study. Rowe, Maughan, and Goodman (2004), in a study of injuries among more than 10,000 children in Britain, found that ADHD was most likely to be related to fractures, while ODD was more related to burns and poisonings. Recent research shows that the risk of injury may be five times higher in children diagnosed with ADHD than in those without the disorder (van den Ban et al., 2014). Thus, both ADHD and aggression or ODD are linked to accidental injuries but of different forms in most studies. Yet the relationship to child psychopathology generally and ADHD specifically is not always evident (Dudani, Macpherson, & Tamin, 2010). In summary, the totality of evidence indicates that there is likely to be a direct association of ADHD specifically and externalizing behavior more generally with increased physical injuries that is independent of comorbidity for other disorders. Perhaps this is why children placing in the upper quartile of externalizing behavior problems are more than twice as likely to die by age 46 as children in the lowest quartile (Jokela, Ferrie, & Kivimaki, 2008).

Adults with ADHD also demonstrate an increased risk of physical injuries apart from those that may be associated with driving accidents (discussed below; Merrill, Lyon, Baker, & Gren, 2009; Swensen, Allen, Kruesi, Buesching, & Goldberg, 2004). The few studies of this issue indicate that such adults are more likely to file claims for accidental injury and poisoning, and to exhibit a greater rate of injury.

And what of the inverse relationship? Do children who experience more accidental injuries show an elevated level of ADHD? More than 40 years ago, research suggested that children experiencing accidents are more likely to be overactive, impulsive, and defiant (Cataldo et al., 1992; Rosen & Peterson, 1990; Stewart et al., 1970). Pless, Taylor, and Arsenault (1995) found that children injured as pedestrians or bicycle riders in traffic accidents performed more poorly on tests of vigilance and impulse control, and received higher parent and teacher ratings of hyperactive–aggressive behavior. More recent research has continued to show that a substantial minority (28.6%) of children admitted to hospitals as a consequence of physical injury related to falls, auto–bicycle, auto–pedestrian, or bicycle accidents are likely to have ADHD (Maxson, Lawson, Pop, Yuma-Guerrero, & Johnson, 2009). These studies suggest that a high percentage of those experiencing such serious accidents may have ADHD or greater-than-normal ADHD symptoms. In short, children admitted to hospitals for injuries are three times more likely to have ADHD than those admitted for other reasons, such as appendicitis (Nigg, 2013). And among children with ADHD who may suffer a traumatic brain injury (TBI) specifically, they are more likely to be disabled and more severely disabled following the injury than are children without ADHD who experience TBI, even after researchers control for other possible mediating variables (Bonfield, Lam, Lin, & Greene, 2013).

Why do those with ADHD apparently have a greater risk for accidents, accidental injuries (non-head), and accidental poisonings than those without the disorder? Obviously, the symptoms of the disorder contribute to such risk and may explain the greater risk of injury to males than females given the greater preponderance of ADHD symptoms in male children (Karazsia, Guilfoyle, & Wildman, 2011). Parents report that their children with ADHD are inattentive while engaging in risky activities and are more heedless or thoughtless of the consequences of their actions (impulsive), thus placing themselves in situations or engaging in activities that are more likely than usual to result in physical harm. In population-based studies, hyperactivity (Junger, Japel, Cote, Xu, Bolvin, & Tremblay, 2012) and impulsivity are specifically associated with injury risk

(Rowe, Simonoff, & Silberg, 2007). But there may be other reasons as well that deserve consideration, such as the following:

- *Motor incoordination.* As discussed in other chapters, children with ADHD demonstrate greater motor clumsiness, awkwardness, and more rapid and ill-timed motor movements than other children. They also demonstrate slower reaction times than typically developing children. It is not hard to see how such clumsiness or even developmental coordination disorder (DCD) might contribute to accident risk, particularly in an already impulsive group of children (Rowe et al., 2007).

- *Comorbid ODD and CD.* Another, more important contributor may be comorbidity for ODD and CD. As I have repeatedly noted, children experiencing accidents are frequently more aggressive, defiant, and oppositional than other children, or at least they pose more discipline problems for parents. And children with externalizing symptoms such as aggression and antisocial behavior are more likely to experience injuries across their lifetimes into adult midlife (Jokela, Power, & Kivimaki, 2009). ODD and CD, as stated earlier, are far more common in children with ADHD and may contribute to even greater risk for accidents and injuries than would be the case in children with ADHD alone. Indeed, some have argued that this pattern of defiant and aggressive behavior is far more contributory to accident risk than is hyperactivity, although other studies indicate that each makes an independent contribution to injury risk, as noted earlier.

- *Comorbid anxiety and depression.* Cross-sectional and longitudinal research have repeatedly indicated a link between internalizing symptoms (anxiety and depression) and increased risk for unintentional injury (Carlson et al., 2009; Marcus et al., 2008; Rowe et al., 2007), and that the internalizing symptoms are not the consequence of such injuries (Rowe et al., 2007). Since ADHD is associated with a higher likelihood of anxiety and depression (see Chapters 5 and 13), it is possible that ADHD remains the mediator in this relationship. However, researchers who control for comorbidity continue to find anxiety and depression to be factors in injury risk (Carlson et al., 2009; Rowe et al., 2007). It is unclear why higher levels of anxiety or depression would increase injury risk, but one proposed mechanism is that, like ADHD, psychopathology more generally is associated with greater motor clumsiness and, as noted earlier, this may increase the risk for injury (Rowe et al., 2007). Anxious or depressed children may also be more inattentive and mentally preoccupied, which might create higher risk for injury, though this remains conjectural. However, other longitudinal research has indicated a reduced risk of accidental injuries, particularly in sports, traffic, and home settings, in children with higher internalizing symptoms (Jokela et al., 2009), so further research on the nature and direction of this relationship seems to be in order.

- *Diminished EF.* Children and adults with ADHD demonstrate substantial and varied deficits in the various components of EF, as discussed in other chapters in this volume. Indeed, on rating scales of EF in daily life, the vast majority of children and adults with ADHD demonstrate substantial deficits in the components of EF (Barkley, 2012; Barkley & Murphy, 2011). Research using simulated pedestrian–automobile situations indicates that children with low behavioral control more generally (Barton & Schwebel, 2007) and ADHD specifically are more likely to choose riskier environments (smaller traffic gaps) in which to cross streets and are therefore more susceptible to pedestrian–auto accidents than other children, despite demonstrating normal curbside behavior (waiting, looking both ways before crossing, etc.; Stavrinos et al., 2011). The latter study also found that deficits in EF (decision making) were associated with this risk, in that children with ADHD did not evaluate the information in the immediate crossing situations as posing as much risk to them as did control children, perhaps due to greater distractibility or because they were delay averse or less patient. Clarifying the nature of this relationship of child EF factors and injury risk, research indicates that both risk taking and errors in judgment, perhaps due to inattention, are both contributors to injury risk and mediate the link between conduct problems and hyperactivity with injury risk (Rowe & Maughan, 2009).

- *Parental characteristics.* A few studies of children's accidents, particularly those taking place out of doors, suggest that parents of these children may supervise their children's play activities less than other parents. Accident proneness is therefore moderated by certain parental characteristics, such as degree of monitoring of child behavior, low maternal conscientiousness, maternal neuroticism, maternal antisocial behavior, and low paternal self-control (van Aken, Junger, Verhoeven, van Aken, & Dekovic, 2007; Davidson et al., 1988; Davidson, Taylor, Sandberg, & Thorley, 1992; Junger et al., 2012). Other researchers using a controlled "hazard

room" situation observed that mothers of children with behavior disorders monitored their children less often in such hazard-prone environments than did mothers of control children (Schwebel, Hodgens, & Sterling, 2006). Parents of hyperactive or injury-prone children play less often with them, allow their children out of their homes for longer periods of time, and let their children go to school alone more often than do parents of control children. For instance, Schwebel, Brezausek, Ramey, and Ramey (2004) found that among children at high risk for injury (males, hyperactive children, families in poverty), positive parenting and greater availability of time to be with children were protective of risk for injuries. Though far more research remains to be done on the issue of parental supervision and its quality in relation to accident risk, current evidence suggests that parental characteristics, particularly low monitoring, may be risk or protective factors, and that such monitoring may be less adequate in parents of children with ADHD, probably because more such parents have ADHD and other psychopathology themselves (see Chapter 7).

Worth considering here is that current research also suggests that predictors of single unintentional injuries in children may differ from those for repeated unintentional injuries (Junger et al., 2012), such that mother's antisocial behavior and older age at first birth, as well as child sex (male) and being hyperactive, are associated with single unintentional injuries. In contrast, maternal smoking during pregnancy, nonmedical prescription drug use, single motherhood, and possibly self-efficacy, as well as an interaction between child sex and temperament (male with negative temperament) predicted repeated unintentional injury. Other research shows that living with a single parent or no parent likewise increases injury risk over time (Dudani et al., 2010).

These and other factors are worth the consideration of clinicians in efforts to reduce the injury risk to children with ADHD. Available evidence is quite limited, but it implies that ADHD medications do not completely reduce such injury risks even though nonsignificant reductions are evident (van den Ban et al., 2014; Marcus et al., 2008; Merrill et al., 2009). The previously discussed factors that accentuate accident risks may explain why ADHD medications are unlikely to completely reduce that risk given that those medications do not influence factors such as comorbidities for internalizing disorders or parental characteristics that may contribute to injury risk beyond child ADHD. Thus, other interventions may be needed, beyond simply medicating patients with ADHD so as to reduce symptoms, then assuming, wrongly, that such symptom reduction translates into a normalization of injury risk.

CHILD ABUSE

Only minimal research has examined the extent to which children with ADHD are abused. That they are abused should not be surprising given that increased aggression, externalizing disorders, impulsivity, and other common characteristics associated with ADHD are linked to risk for abuse (Margolin & Gordis, 2000). Moreover, the parents of children with ADHD are more likely to have ADHD themselves and problems with parenting, to report more parenting stress and less parenting competence, and to experience marital distress or divorce, and more depression than other adults (see Chapter 7), all of which can heighten the risk of such parents abusing a child. In an early study of this issue, Wozniak and colleagues (1999) did not report a link among ADHD, child abuse, and posttraumatic stress disorder (PTSD), but examination of the results indicates that their ADHD group had suffered more exposure to traumatic events, including sexual abuse, physical abuse, and witnessing domestic violence, than did the control group (7.0 vs. 0.1%, respectively). The lack of any significant difference here may be due to the fact that the authors did not disaggregate the types of possible abuse to which the children may have been exposed (Briscoe-Smith & Hinshaw, 2006).

Ford and associates (1999) examined a large sample (n = 165) of children seen in an outpatient psychiatric clinic for trauma exposure (both victimized and nonvictimized events). While they found an initial association of both ADHD and ODD to having been exposed to victimization trauma, they found no relationship between ADHD and trauma exposure after appropriately controlling for various child and family factors that could potentially confound this relationship. However, ODD remained significantly associated with likelihood of victimization trauma events, regardless of whether it coexisted with ADHD. This makes sense given the frequent association of ODD with disrupted parenting, family social adversities, and parent psychopathology (see earlier discussion of ODD/CD). Indeed, Ford and colleagues found that family psychopathology was a significant predictor of victim-

ization in the study samples. Traumatic victimization was found to contribute uniquely to the child's risk for ODD, but not for ADHD. The percentage of children exposed to any traumatic events was 63% for ADHD, 62% for ODD, 91% for ADHD + ODD, and 48% for the adjustment disorder group, with only the comorbid ADHD + ODD group differing significantly from the control group. This difference was entirely accounted for by experiences of victimization trauma rather than nonvictimization events, such as accidents, injuries, illness exposure. In further analyses of these samples, the authors found that 6% of children with ADHD were likely to have PTSD, whereas 24% of children with ODD and 22% of children with ADHD + ODD qualified for the PTSD diagnosis (Ford et al., 2000). Only the two groups with ODD differed significantly from the control group of children diagnosed with adjustment disorders (0% occurrence of PTSD) and showed significantly elevated PTSD-specific symptoms (hyperarousal, sleep disturbance, generalized arousal, and startle response). Since ODD may have a substantial overlap in clinical presentation with borderline personality disorder (BPD), it is not clear from this study whether it is actually childhood BPD within the ODD group that accounts for this relationship. Even so, ODD is the more common disorder among outpatient referrals and, for now at least, should be considered to be a significant risk factor for victimization trauma.

In a study of girls with ADHD, Briscoe-Smith and Hinshaw (2006) found that they were three times more likely to have been abused than comparison girls without ADHD (14.3 vs. 4.5%). The subgroup of girls with ADHD who were abused manifested higher rates of externalizing behaviors, such as aggression, and more peer rejection (owing in large part to their aggressive behavior).

While no definitive conclusions can be drawn from such a limited a number of studies on this topic, it does appear that only a minority of children with ADHD may be exposed to any form of child abuse, and that this risk is greatest among those who may have ODD specifically or other externalizing symptoms more generally.

DRIVING RISKS

Until 20 years ago, the one domain of major life activity for teens and adults that had not been well explored in research on ADHD was driving, or the independent operation of a motor vehicle. Driving is often an underappreciated domain of self-sufficiency and major life activity for teens and adults because it is such a commonplace and therefore ordinary life activity. Yet it is a domain that facilitates most other adaptive domains (including employment, family care, responsibilities, overall functioning, education, social engagements, shopping, and entertainment, among others), all of which would suffer extreme curtailment if an adult were to be deprived of this privilege, especially in the United States. In all of these other domains of major life activity, driving permits greater independence from others, exposure to more numerous opportunities, and greater efficiency in accomplishing various goals. It also, however, opens up greater exposure to harm to oneself, to others, and to property, by providing access to a 1–2 ton projectile that is often used at speeds in excess of 50–60 miles per hour. Like the domain of unintentional injuries discussed earlier, driving is a domain that can markedly increase morbidity and mortality. Thus, any disorder that may adversely impact driving also would be expected to have a pervasive, albeit secondary, impact on many other domains of daily adaptive functioning in other major life activities, while simultaneously exposing the individual to greater liability for the various harms noted earlier. ADHD is just such a disorder that should have some impact on operation of a motor vehicle.

Probably the first to document driving risk in ADHD was an early longitudinal study of hyperactive children followed to adulthood. Weiss, Hechtman, Perlman, Hopkins, and Wener (1979) found that as adolescents and as young adults, individuals with ADHD, as drivers, were more likely to be involved in traffic accidents than their normal peers. They were also more likely to incur greater damage to their vehicles relative to normal controls (Hechtman, Weiss, Perlman, & Tuck, 1981). As interesting as the results were concerning a likely relationship of ADHD and poor driving, these risks were largely determined through self-reports and not corroborated through the official driving records of the participants. Nor was the basis for these driving-related adverse outcomes evident in this early study. Was it the attention deficits associated with ADHD that led to such risks, the impulsiveness, both, or some third set of attributes linked to ADHD? Or were these risks the result of comorbid disorders, especially CD, and therefore one more manifestation of antisocial conduct?

These various lines of reasoning led my colleagues and myself to undertake a series of studies on the driving

problems associated with ADHD. Others also followed suit, generating what is today a substantial literature on this topic. The essence of these results is summarized here (for more detailed reviews, see Barkley, 2004; Barkley & Cox, 2007; Jerome, Habinski, & Segal, 2006; Vaa, 2014). In comparison to control groups of typical people, the following is true of clinic-referred teens and adults with a diagnosis of ADHD, or those derived from population samples with elevated symptoms of ADHD:

- They are more likely to have driven an automobile illegally prior to the time they became eligible as licensed drivers (Barkley, Guevremont, Anastopoulos, DuPaul, & Shelton, 1993; Barkley et al., 2002) or to have driven at other times without a valid license (Barkley et al., 2008).
- They are more impaired on predriving basic cognitive tests and on driving simulator measures of driving performance (e.g., visual field deficits, motor incoordination, erratic steering); they have reduced or more erratic reaction times to critical events, greater distractibility, and more impulsiveness; and they are less rule-governed, more prone to errors, and have more speeding and accidents (scrapes and crashes) (Barkley et al., 1996; Classen, Monahan, & Brown, 2014; Fischer, Barkley, Smallish, & Fletcher, 2007; Narad et al., 2013), but not in all studies (Barkley et al., 2002). They may be more prone to distractions while driving in simulators than controls in the context of engagement in low-stimulation or boring secondary tasks than when doing higher demand tasks (Reimer, Mehler, D'Ambrosio, & Fried, 2009).
- They are more impulsive, take more risks, and are more distracted in behind-the-wheel driving observations in natural settings either by observers (Fischer et al., 2007) or in-vehicle cameras (Merkel et al., in press), and they experience more crashes, minor adverse events, and rapid acceleration or deceleration events during actual driving, as monitored by in-vehicle cameras (Merkel et al., in press).
- They are less likely to employ sound driving habits in their current driving performance, as reported by themselves and others (Barkley et al., 1993, 1996; Fischer et al., 2007; Fried et al., 2006; Garner et al., 2012; Reimer et al., 2005; Richards, Deffenbacher, Rosén, Barkley, & Rodricks, 2006; Rosenbloom & Wultz, 2011). Such ratings are predictive of actual adverse events in the driving histories of participants in these studies (Barkley et al., 1993).
- They display greater levels of anger, hostility, and aggression while driving (road rage; Richards, Deffenbacher, & Rosén, 2002; Richards et al., 2006).
- They are more likely to have had their licenses suspended or revoked (Barkley et al., 1993, 2002, 2008; Fischer et al., 2007).
- They are more likely to have received traffic citations, and have received more such citations, often repeatedly for the same infractions, most notably for speeding and reckless driving (Barkley et al., 1993, 1996, 2002, 2008; DeQuiros & Kinsbourne, 2001; Fischer et al., 2007; Fried et al., 2006; Garner et al., 2012; Lambert, 1995; Murphy & Barkley, 1996; Nada-Raja et al., 1997; Narad et al., 2013; Thompson, Molina, Pelham, & Gnagy, 2007; Woodward, Fergusson, & Horwood, 2000).
- They are more likely to have had a crash or to have had more such crashes while driving a vehicle (Barkley et al., 1993, 1996, 2008; Fischer et al., 2007; Garner et al., 2012; Murphy & Barkley, 1996; Nada-Raja et al., 1997; Thompson et al., 2007; Woodward et al., 2000). This link between ADHD and accident risk also includes motorcycle delivery drivers (Kieling et al., 2011).
- They are more likely to be held as being at fault in such crashes (Barkley et al., 2002, 2008).
- They are more likely to have had crashes involving injuries (Barkley et al., 1996; Woodward et al., 2000).
- They have more severe crashes, as reflected in dollar damage (e.g., $4221 vs. $1665) (Barkley et al., 2002; Fischer et al., 2007).
- They are more likely to have their driving performance adversely affected by alcohol (Barkley, Murphy, O'Connell, Anderson, & Connor, 2006).
- They are unlikely to differ in some of their basic cognitive abilities essential for driving (e.g., capacity for visual discrimination; Barkley et al., 2002), yet they are inferior in others (e.g.,more difficulties with tasks requiring visual scanning and rule-governed behavior; Barkley et al., 2002).
- They are not likely to differ in their driving knowledge in terms of perceptual skills, traffic risk situations, and driving procedures (Barkley et al., 1996, 2002), but they may be less knowledgeable about driving laws and rules of the road, at least during rapid decision making in high-risk situations (Barkley et al., 2002).
- They are not likely to view their driving performance as being that different from other, typical drivers even though it is, as noted earlier, signifi-

cantly worse (Knouse, Bagwell, Barkley, & Murphy, 2005).

Many of the adverse outcomes noted earlier (citations, crashes, suspensions, etc.) are also corroborated in official driving records (Barkley et al., 1996, 2002, 2008), and they appear to exist in not only clinic-referred adults with ADHD but also children with ADHD followed into adulthood (Barkley et al., 2008). It is likely that comorbid ODD and CD exacerbate the risk for these adverse outcomes and may even account for some of the differences between ADHD groups and control groups. For instance, in the recent meta-analysis by Vaa (2014), the relative risk (odds ratio) for accidents was 1.86 for drivers with ADHD, most of whom had these comorbidities, and 1.31 for those without them. The problem with making such comparisons is that ODD and CD are directly correlated with severity of ADHD and share much of the underlying genetic predispositions that influence all three disorders (see Chapter 14; also Tuvblad, Zheng, Raine, & Baker, 2009). Thus, ODD and CD are not confounding factors in such studies but are directly linked to the severity of ADHD. Differences found across groups of participants with ADHD who do and do not have these comorbidities are largely just comparisons of groups whose severity of ADHD varies or the shared liability for externalizing disorders more generally. Hence, efforts to remove them via statistical covariation methods or participant recruitment are actually removing a large part of the variance in the driving measures that is due to ADHD itself. Thus, it makes little sense to argue, as Vaa does, that it is largely these comorbid disorders that account for the elevation in crash risk, and that the crash risk associated with ADHD alone is only modestly elevated. Moreover, the number of studies of pure ADHD, uncomplicated by these comorbidities, is very small and therefore not as robust an indicator of crash risk in noncomorbid cases, as this study implies.

While the severity of current ADHD symptoms was significantly associated with driving risks, some risks were further associated with the severity of oppositional and conduct problems (Barkley et al., 1993, 2008; Thompson et al., 2007) or, at least in girls, were mediated by deviant peer affiliations in adolescence (Cardoos, Loya, & Hinshaw, 2013). The association between attention difficulties and risk for accidents involving injury, driving without a license, and traffic violations, however, holds up in general population samples not selected for ADHD (Nada-Raja et al., 1997; Woodward et al., 2000). The associations also withstand controls for subtype of ADHD, conduct problems, driving experience, and sex (Barkley et al., 2002, 2008; Woodward et al., 2000). Males with ADHD, however, are more likely than females with the disorder to experience license suspensions, to drive without a valid license, and to receive speeding citations (Barkley et al., 2008). When considering the fact that driver inattention is among the most common reasons given for vehicular crashes (Barkley et al., 2002), these adverse outcomes should not be surprising. It is now abundantly evident that ADHD is associated with various driving performance problems and associated adverse outcomes. Noteworthy as well is that in the general population, texting on cell phones while driving has become a major source of inattention (distraction), and that such texting adversely affects the driving of both teens with ADHD and controls (Narad et al., 2013). This would be expected to place teens with ADHD in even greater harm than control teens given that their driving is already significantly impaired, even when they are not texting.

While driving has been the most studied domain of vehicular use in teens and adults with ADHD, one recent study suggests that they are also more likely to engage in other motor sports. These sports pose high risks for injury, particularly if the individual has comorbid CD or antisocial personality disorder and engages in heavy drinking (Wymbs et al., 2013).

Various factors seem to improve the driving performance of teens and adults with ADHD. Among them may be the use of a standard rather than an automatic transmission (Cox et al., 2006). The reason for this may be that the manual transmission requires more mental and motor engagement in the task of driving than the automatic transmission, which may help drivers with ADHD sustain their attention better on driving. Cumulative evidence certainly indicates that ADHD medications can significantly improve the driving performance of teens and adults with ADHD (Barkley, Anderson, & Kruesi, 2007; Barkley & Cox, 2007; Biederman et al., 2012; Kay, Michaels, & Pakull, 2009; Sobanski et al., 2012), which, one hopes, would eventually translate into a reduction in the adverse driving outcomes noted earlier (crashes, injuries, citations, etc.).

RISKY SEXUAL BEHAVIOR

The sexual activities of teens and adults with ADHD have received some research attention since the previous edition of this book. Barkley and Fischer were the

first to report a pattern of early initiation (1 year earlier on average) and riskier sexual activity (more partners, less use of contraception) in their hyperactive (ADHD) group by the follow-up in young adulthood (age 21) of their Milwaukee longitudinal study (Barkley, 1998; Barkley, Fischer, Smallish, & Fletcher, 2006). This riskier pattern of conduct led to a markedly greater risk for teen pregnancy (38 vs. 4%) and sexually transmitted diseases (STDs; 17 vs. 4%) in the hyperactive group than in the control group. Others have demonstrated a similar pattern of sexual conduct in young male adults with a history of childhood ADHD (e.g., Flory, Molina, Pelham, Gnagy, & Smith, 2006), whose childhood ADHD was associated with earlier initiation of sexual activity and intercourse, more sexual partners, more casual sex, and more partner pregnancies. Both longitudinal studies found that these risks were further elevated by higher levels of conduct problems, but such problems did not account for the separate contribution made by ADHD. At the age 27 follow-up of the Milwaukee study, the hyperactive group had already engaged in far higher rates of risky sexual behavior and had more members who experienced teen parenthood and sexually transmitted disease (Barkley et al., 2008). The groups did not differ in the percentages experiencing any of the sexual problems reviewed with the participants using an interview format, such as premature ejaculation or impotence in males, or in inability to climax, exhibitionism, cross dressing, or voyeurism. But the children whose ADHD had persisted to the adult follow-up (persistent group) were twice as likely to experience low levels of sexual interest sometimes or more often than experienced in the nonpersistent or control groups (49 vs. 25 and 24%, respectively. The study also found that the two ADHD groups (persistent and nonpersistent) reported a higher the number of lifetime sex partners (means of 17 and 13, respectively) than the control group (mean = 8). As in the age 21 follow-up, members of both hyperactive groups were more than three times as likely either to have become pregnant, in the case of females, or to have gotten someone else pregnant, in the case of males, than was the case for the control group. Not surprisingly, this led to more of the hyperactive groups having biological offspring than was the case for the control group. While neither of these studies reported any link of ADHD to any type of sexual dysfunction, in a more recent article, Soydan and colleagues (2012) observed the reverse relationship, in that 42% of males experiencing premature ejaculation had clinically elevated symptoms of ADHD versus just 3.7% of males in a control group.

Both the Milwaukee study and the report by Flory and colleagues involved primarily (Barkley, Fischer, et al., 2006) if not exclusively males (Flory et al., 2006). Two later studies examined the relationship of ADHD in females to risky sexual behavior. One found that in a general community sample, level of ADHD symptoms was correlated with some risky sexual behaviors (Hosain, Berenson, Tennen, Bauer, & Wu, 2012). In the other study, in a small sample of college women, those with higher levels of ADHD reported having had more unprotected sex than did women with low ADHD symptoms or college men (Huggins, Rooney, & Chronis-Tuscano, 2012). No studies have examined women with a clinical diagnosis of ADHD. Interestingly, a recent study of a small sample (n = 50) of college men likewise found that elevated symptoms of ADHD along with low birthweight were linked to a more favorable attitude toward casual sex, and that such an attitude predicted a greater number of sex partners (Frederick, 2012). That author believes such findings may indicate an evolutionary adjustment, such that men experiencing reduced fitness in reproductive terms may offset this disadvantage by being more willing to engage in casual sex.

In the past 5 years, several much larger population-based studies have examined whether ADHD symptoms are linked to risky sexual activity. Galera and colleagues (2010) evaluated 1,148 adolescents in a follow-up study in France and noted that symptoms of CD were linked to an earlier age of first intercourse when associated with elevated HI symptoms. It was the combination of symptoms of both disorders that significantly elevated the risk for early sexual activity. Likewise, in a large study of 881 females in Quebec, Canada, mean age of 21 years, Fontaine and colleagues (2008) found that females with a joint risk factor (odds ratio of 2.31) of combined high levels of hyperactivity and physical aggression were more likely to experience early pregnancy than other females. In a study of 420 children followed for 14 years to age 18 in Rotterdam, The Netherlands, Timmermans, van Lier, and Koot (2008) similarly found that early physical aggression (as measured by the Child Behavior Checklist) was linked to risky sexual behavior (early age of first intercourse, more partners, lack of use of contraceptives, sexually transmitted disease, early pregnancy, possible HIV infection, etc.) by age 18 years. Surprisingly the authors did not evaluate the role of ADHD symptoms from this scale, but their results are consistent with those presented earlier, showing the link between early aggression and an elevated likelihood of risky sexual behavior.

A later and larger population-based study in Sweden that involved 2,388 twin pairs evaluated at ages 9, 12, and 15 years, examined the relationship of ADHD, ODD, and CD to likelihood of having had intercourse by age 15 years and the number of sex partners by that age (Donahue et al., 2013). The initial results showed that all three disorders were associated with an increased likelihood of intercourse and that furthermore, ADHD and ODD were associated significantly with an increased number of sex partners. Both findings confirm the results of the studies of clinically diagnosed cases of ADHD reported earlier. The authors further noted that these associations were slightly attenuated after they controlled for parental criminal history and limited education, but most remained significant. However, after the authors controlled for unmeasured family variables (shared environment and genetic effects), the associations were no longer significant. The latter analysis, however, would have removed the genetic contribution to these disorders in the probands, which is known to be substantial, especially for ADHD. The results suggest that there exists a shared familial–genetic risk for risky sexual behavior in teenagers with ADHD, ODD, and/or CD.

The evidence to date therefore clearly indicates an association between ADHD symptoms or disorder and risky sexual behavior, but this risk is often compounded by comorbidity with conduct problems and physical aggression, or frank ODD and CD. Moreover, there may be shared familial environmental and genetic predispositions to such an increase in the likelihood of risky sexual activities. Given the consistency of these results, further work in this area seems promising and warrants development of an early intervention program to reduce these risks. As for any relationship between ADHD and sexual dysfunctions, evidence to date is scant, with just one small study in which males experiencing premature ejaculation were 10 times more likely to have high ADHD symptoms than were males in a control sample.

SUICIDAL THINKING AND ACTIONS

There has been only limited research on the association between ADHD and suicidality but what evidence exists supports an increase in risk for both suicidal thoughts and especially suicide attempts (a combination known as "suicidality") in those with the disorder. Three reasons would lead one to expect suicidality to be higher in this those with ADHD than in a typical community sample. First, there is higher than expected comorbidity between ADHD and mood disorders, especially dysthymia and probably major depression, in clinic-referred children and particularly adults with ADHD (see Chapter 5; Barkley et al., 2008). This would automatically lead one to hypothesize a higher frequency of suicidality in those with ADHD who experience these additional comorbidities than in a normal population. Another is that suicide attempts and completions in particular have been shown to be linked in part to impulsivity (Kim et al., 2003), as discussed further below.

The third reason is that two follow-up studies of hyperactive (ADHD combined type) children into adulthood have found that their rate of suicidality is higher than expected compared to control groups followed contemporaneously.

Children with ADHD as Adults

In their excellent textbook *Hyperactive Children Grown Up*, Weiss and Hechtman (1993) briefly dealt with this issue in describing the results of their own longitudinal study of hyperactive children followed to adulthood. They indicated that the great majority of their hyperactive participants who made suicide attempts requiring psychiatric hospitalization were part of the approximately 10% who had significant psychiatric or antisocial disturbance at their 15-year follow-up (mean age of 25). However, they did not present an actual incidence rate. In reviewing the published reports of the New York (Mannuzza et al., 1993; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998) and Swedish (Rasmussen & Gillberg, 2001) longitudinal studies, no reference to such outcomes could be found.

Barkley and Fischer (2005) reported more detailed results about suicidality in their Milwaukee follow-up study of hyperactive children at their age 21 follow-up. At the young adulthood follow-up, they interviewed participants about 12 questions dealing with the topic of suicidality. During high school, members of the hyperactive group were somewhat more likely to have considered suicide than members of the control group (36 vs. 22%, respectively), but they were five times more likely to have attempted suicide if they had considered it (16 vs. 3%). And they were more likely to have been hospitalized for such an attempt (7 vs. 0%). After high school, the rate of suicidal thinking declined somewhat for both groups but remained significantly elevated in the hyperactive group (25 vs. 12%), while the likelihood of a suicide attempt declined substantially and was no

longer significantly different from that in the control group (6 vs. 3%). Nor was the rate of hospitalization following the attempt any greater for the hyperactive group (5 vs. 1%). It is in high school, therefore, that the greatest risk for suicidal ideation, attempts, and hospitalizations after such attempts appears likely to arise in the hyperactive group. Even so, an elevated risk of suicidal ideation remains in the hyperactive group after leaving high school up to age 21. Barkley and Fischer reported that the elevated risks for suicidal thinking and attempts were chiefly mediated by the presence of major depression, though the presence of CD and, to a lesser extent, the severity of ADHD in childhood, made significant additional contributions to risk for suicidality. By the age 27 follow-up of these same participants (Barkley et al., 2008), the authors asked two questions dealing with suicidality. Had the participant considered suicide or attempted suicide in the interim 6 years (on average) since they had last been evaluated? (*Note:* Such questions do not reflect lifetime risk, which we studied at the age 21 follow-up, but only interim risk or risk going forward from age 21 to 27.) They found that a significantly greater percentage of both hyperactive groups, once again, had considered suicide (persistent ADHD to age 27: 38%; nonpersistent ADHD: 24%) in comparison to the control group (8%). There were no group differences in the risk of suicide attempts in the interim (13, 9, and 3%, respectively). Such findings are consistent with the age 21 follow-up in showing that after high school, only the risk of ideation is greater in hyperactive children growing up, and it is not a function of whether ADHD has persisted to age 27. Risk for suicidal ideation since the age 21 follow-up was largely predicted by current mood disorder and, to a lesser extent, current anxiety disorder. Also, having any past mood disorder and severity of ADHD were associated with this risk.

Further corroboration of a link between childhood ADHD and risk for later suicide attempts was reported in a follow-up study of children diagnosed with ADHD at ages 4–6 years compared to control children by 9–18 years of age (Chronis-Tuscano et al., 2011). Young children with ADHD were 3.6 times more likely to attempt suicide during the follow-up period and 4.3 times more likely to experience a mood disorder during follow-up. Girls showed a greater risk for suicide attempts than boys. The authors found that maternal depression and, as in the Milwaukee study (discussed earlier), child comorbidity of emotional and behavior problems at study entry were predictive of later risk for suicidal behavior. In their larger follow-up study of girls with ADHD into early adulthood, Hinshaw and colleagues (2012) likewise found these women to have significantly higher rates of suicide attempts and self-injury than did control girls followed over the same time span, even after controlling for childhood demographic factors and comorbid disorders.

The converse relationship has also been identified, in which children and adolescents hospitalized for injuries are found to have a greater likelihood of having ADHD, as discussed earlier, but especially injury from assault or from suicide and self-harm (Lam, 2005). And those individuals who did have ADHD were likely to remain in the hospital longer than injured children without ADHD, suggesting that the injuries were more severe.

Adults Diagnosed with ADHD

In a study of clinic-referred adults with ADHD, Barkley and colleagues (2008) found that their ADHD group did not differ from either a clinical or community control group in either suicidal ideation or suicide attempts prior to 18 years of age, in contrast to the findings of the Milwaukee study. They reported that 15–16% of both control groups had considered suicide and 2–4% had made an attempt at suicide before age 18 years, in comparison to 25% of the ADHD group that had considered it and 6% that had attempted it. After age 18 years, however, they found that more of both the ADHD and clinical control groups had considered suicide (29 and 27%, respectively) than was the case for the community control group (6%). But these two groups did not differ from each other, implying that suicidal ideation at least was associated with outpatient psychopathology rather than specifically with ADHD in these adults. A significantly greater proportion of the ADHD group (8%), however, had also made a suicide attempt (1%) than that in the community control group since age 18. The clinical control group fell between both of these groups in this case and did not differ significantly from either of them. These results were corroborated in a study of ADHD in adults in Korea, which found a significant association between ADHD and adults with suicidality, among other comorbid disorders (Park et al., 2008). Likewise, in a population-based study, Agosti, Chen, and Levin (2011) reported a suicide attempt rate of 16% of adults with ADHD identified in their sample, whereas in a study of Turkish outpatient adults with ADHD, Duran, Fisticki, Keyvan, Bilici, and Caliskan (2013) reported that 38.5% had attempted suicide.

The risk for suicidality in the UMASS Study of Adults with ADHD was largely related to comorbidity for both major depressive disorder (MDD) and dysthymia (Barkley et al., 2008). Three times as many people who had thought of suicide before age 18 years had MDD compared to those who had not considered suicide. The same was true for those who had attempted suicide (73 vs. 25%). Dysthymia was somewhat less prevalent than MDD among those who had or had not considered or attempted suicide before age 18 years, but the pattern of risk associated with dysthymia was still similar, such that more than 2.5 times as many people who considered or attempted suicide had dysthymia compared to those who had not considered or attempted suicide. The results are even more striking for those who considered or attempted suicide after 18 years of age. Here more than four times as many people who considered or attempted suicide had MDD, and more than three times as many had dysthymia. CD was not related to suicidal thinking at this age, but it was related to attempts. More than twice as many attempters as nonattempters had CD. In a regression analysis, MDD, dysthymia, and ADHD severity (number of symptoms from interview) all significantly contributed to the prediction of suicidal thinking. Only MDD significantly predicted a suicide attempt after age 18 years.

These results corroborate the earlier findings of the Barkley and Fischer (2005) follow-up study, showing that the risk for suicidality among individuals with ADHD was mostly a function of their higher rate of comorbidity with MDD and dysthymia, and to a far lesser extent their severity of ADHD. CD was not predictive of these outcomes after researchers statistically controlled for these other disorders. Biederman and colleagues also found much the same mediational pathway of ADHD in females to their risk for suicidality via comorbidity with major depression (Biederman, Ball, et al., 2008). And the later study by Agosti and colleagues (2011) likewise found that although adult ADHD was a risk factor for suicide attempts, it was only weakly associated with that risk, in that comorbid disorders were a much stronger contributor.

ADHD as a Risk Factor in Other Clinical Populations

The inverse relationship of higher rates of ADHD in adolescent suicide attempters has also been suggested. In one study of admissions to an emergency room for suicide attempts (Manor et al., 2010), results indicated that 65% of these attempters qualified for a diagnosis of ADHD, although only five had received a prior diagnosis of the disorder. Approximately 43% qualified for a diagnosis of depression and 39% had a Cluster B personality disorder. Similarly, Kelly, Cornelius, and Clark (2004) studied adolescents with substance use disorders and their risk for suicide attempts, and found that the risk was a function of severity of ADHD and mood disorders, as did Arias and colleagues (2009). Kelly and colleagues found that ADHD was a risk factor mainly in males; in females, primarily mood disorders and alcohol use disorders were linked to risk of suicide. The same pattern seems to hold among incarcerated youth. Putnins (2005) found that risk of suicide attempt was a function of ADHD as well as mood disorders, substance use, and having a bad temper. Goodman, Gerstadt, Pfeffer, Stroh, and Valdez (2008) studied 43 psychiatrically hospitalized children for their level of assaultive and suicidal behavior, and found that children with a pattern of combined assaultive and suicidal behavior were more likely to be diagnosed with ADHD than those who were assaultive only. Aggression seemed to mediate the link between ADHD and suicidal behavior.

The Mediating Role of Comorbidity

The linkage of ADHD to suicide and the possible mediating role of depression and CD is also documented in both early (James, Lai, & Dahl, 2004) and later reviews (Impey & Heun, 2012) of this literature. It is evident not just in clinical samples, described earlier, but also in population-based studies, such as that by Cho and colleagues (2007) in Korea, who evaluated 788 high school girls. They noted that ADHD symptoms correlated with risk for suicidal ideation and that symptoms of depression partially mediated that link. Similarly, Galera, Bouvard, Encrenaz, Messiah, and Fombonne (2008) studied 917 French children and teens, ages 7–18 from the general population. They found that the HI symptom dimension of ADHD increased the lifetime and current risks for suicidal thoughts and attempts in males but not in females. They did not assess depression in this study, which may have been the link to suicidality in females, as suggested earlier.

Studies besides that of Galera and colleagues (2008) also suggest that psychomotor restlessness is a risk factor for suicidal behavior, beyond the risks posed by a mood disorder in youth with adjustment disorders (Pelkonnen, Marttunen, Henriksson, & Lonnqvist,

2005). It may be through its heightened HI that ADHD elevates this risk for suicidality in youth with comorbid depression. Research shows that in individuals with depression, degree of impulsivity specifically and ADHD symptoms more generally are significantly correlated with the likelihood of suicidal behavior, as well as the lethality of the attempt (Keilp, Gorlyn, Oquendo, Burke, & Mann, 2008; Patros et al., 2013). This may explain the earlier Milwaukee study finding that ADHD is linked more to risk for attempts than to suicidal ideation, which is more a function of comorbid depression. And once suicidal thinking or behavior has occurred, it serves as a predictor of increased risk for later suicidal ideation and attempts beyond the contribution made by major depression or substance use disorders (Fergusson, Horwood, Ridder, & Beautrais, 2005; Putnins, 2005).

Even further corroboration of this link between ADHD and suicidality and the meditational role of mood disorders comes from a recent, large-scale (n = 418) investigation of clinic-referred children and teens in Hungary (Balazs, Miklosi, Kereszteny, Dallos, & Gadoros, 2014). Of these, 211 met DSM criteria for ADHD and another 105 had sufficiently elevated symptoms to be considered subthreshold cases. All cases were treatment naive, so treatment, particularly with ADHD medications, is neither a beneficial nor a detrimental factor in these results. This issue is important given that some have claimed that these medications may increase the risk of suicide, although a recent meta-analysis has found this not to be the case (Bushe & Savill, 2013). In the study, 12.9% of children (age 12 and under) and 38.9% of teens reported either thinking about or attempting to end their own lives within the past month (current suicidality). Older age was associated with an increase risk for suicidality, as earlier research has shown. Gender was not. Mediational analyses clearly showed that ADHD does increase the risk for current suicidality, but that this relationship was entirely mediated by comorbidity and age. In children age 12 years and under, more severe ADHD symptoms were associated with greater comorbid anxiety symptoms, and the latter served to mediate the link between ADHD and current suicidality. Although more severe ADHD symptoms were also significantly associated with more symptoms of other, comorbid disorders (depression, ODD, CD, tics, OCD, etc.), those comorbidities did not mediate the link to suicidality. In contrast, in adolescents, the link between ADHD and current suicidality was a function of comorbidity with symptoms of major depression and dysthymia, as well as those of substance abuse/dependence. Once again, more severe ADHD symptoms increased the risk for symptoms of these mediating disorders, which then accounted for the link to current suicidality. Yet again, more severe ADHD symptoms increased the likelihood of other, comorbid symptoms but those comorbidities did not mediate this link to suicidality.

In summary, and hardly surprising, it is largely the existence of anxiety in children, and especially mood disorders in adolescents and adults, that elevates the suicidality risks in ADHD. Current ADHD severity (probably impulsivity) does seem to make a further though smaller contribution to risk, especially for suicide attempts, and probably more in males than in females.

HEALTH CARE COSTS

Early, small studies did not find that children with ADHD had more hospitalizations, length of hospital stays, or surgeries than normal children (Barkley, DuPaul, et al., 1990; Hartsough & Lambert, 1985; Stewart et al., 1966). But in view of their clearly elevated risks for various injuries, children with ADHD probably should use more medical care and generate greater medical costs. This has been observed in more recent studies over the past decade using larger samples and even populationwide databases. Children with ADHD have a significantly greater use of outpatient medical services, more hospitalizations, and are especially more likely to utilize emergency department services (Chan, Zhan, & Homer, 2002; Cuffe et al., 2009; Guevara, Lozano, Wickizer, Mell, & Gephart, 2001; Leibson & Long, 2003). This resulted in a doubling of the medical care cost associated with ADHD relative to control cases (Guevara et al., 2001; Leibson et al., 2001; Leibson & Long, 2003). The same findings of increased costs linked to ADHD have been recently reported in a longitudinal study in Australia, which found substantially higher costs linked to ADHD in children ages 4–9, with the excess costs amounting to $25–30 million AUS (Sciberras, Lucas, Efron, Gold, Hiscock, & Nicholson, in press). Swensen and colleagues (2004) studied a large population sample (more than 100,000) and also found that annual medical care costs for children with ADHD were three times greater than in control cases ($1,574 vs. $571). But they and others in The Netherlands (e.g., Le et al., in press) also found that

medical care cost claims were also greater among immediate family members of the children with ADHD as well ($2,728 vs. $1,440 in the study by Swensen et al., 2004), perhaps owing to the greater risk of psychopathology, substance dependence and abuse, stress, and depression among these family members. More recent studies bear out this substantial increase in health care costs (billions of dollars) associated with children with ADHD and their immediate family members (Birnbaum et al., 2006; Le et al., in press; Pelham, Foster, & Robb, 2007; van Roijen et al., 2007). Medical care costs are also found to be markedly higher in adults with ADHD (Secnik, Swensen, & Lage, 2005).

LIFE EXPECTANCY

The relationships between ADHD and increased (1) accident proneness in childhood, (2) speeding and auto accidents in adolescence and young adulthood, (3) crime (Satterfield, Hoppe, & Schell, 1982), (4) suicide attempts (Weiss & Hechtman, 1993), (5) substance use and abuse (alcohol and tobacco primarily) in adolescence and adulthood (Barkley et al., 2008), and (6) a general pattern of risk-taking behavior all intimate that ADHD might be expected to be associated with a *reduced life expectancy*. The diminished regard for the future consequences of one's behavior that characterizes many adolescents and adults with ADHD would also predict a reduced concern for health-conscious behavior, such as exercise, proper diet, and moderation in using legal substances (caffeine, tobacco, and alcohol) throughout life (Barkley et al., 2008; Milberger et al., 1996).

Further cause for concern arises from the follow-up study of Terman's original sample of highly intelligent children. Most of those subjects were in their 70s or older at follow-up, and half of them are deceased (Friedman et al., 1995). The follow-up study of that group indicated that the most significant childhood personality characteristic predictive of reduced life expectancy by all causes was related to impulsive, undercontrolled personality characteristics. Individuals classified as having this set of characteristics lived an average of 8 years less than those who did not (73 vs. 81 years). Subjects in this study were defined as impulsive by virtue of falling within the lowest 25% of the sample in impulse control. Given that subjects defined as having ADHD typically fall well below this threshold, in the lowest 5–7%, the risk for reduced longevity in those with ADHD would seem to be even greater than was found among Terman's subjects. That conclusion would seem to be further supported by the fact that Terman's subjects were intellectually gifted and came from families of above-average or higher economic backgrounds. Both of these factors probably would have conveyed a greater advantage toward longer life expectancy than would be the case for intellectually normal children with ADHD who tend to come from middle or lower economic backgrounds.

No follow-up studies of children with hyperactivity or ADHD have lasted long enough to document unequivocally such a reduction in life expectancy; the oldest subjects now appear to be entering their 40s (Klein et al., 2012; Weiss & Hechtman, 1993). Yet concern over life expectancy in ADHD is not unfounded. Swensen, Allen, and colleagues (2004) found that individuals with ADHD are more than twice as likely as controls to die prematurely from their misadventures. Results of the British National Child Development Study also indicate that children in the upper quartile of externalizing behavior were twice as likely to die by age 46 years as children in the lowest quartile (3.2% vs. 1.4%, respectively), with mortality increasing across these quartiles from lowest to highest (Jokela et al., 2008). And more recently Klein and colleagues (2012) reported that children with ADHD were more likely than children without ADHD to have died by the age 41 follow-up. But the sample sizes in that study were small and therefore warrant replication with larger samples. Yet in view of the numerous adverse effects of ADHD on health discussed in this chapter, one can reasonably foresee that people with ADHD are more likely to experience significantly life-shortening medical problems, such as accidental injuries, coronary heart disease or cancers, to a greater extent than typically developing people as they enter middle age or late life stages.

CONCLUSION

This chapter has reviewed the myriad health problems and risks associated with ADHD in children, teens, and adults. They are clearly substantial and serious, indicating unequivocally that ADHD is more than just a serious mental health problem—it is a serious *public health* problem. At the very least, such findings ought to give considerable pause to anyone who contends that ADHD is a phantom disorder, that it is simply a label used to provide a psychiatric diagnosis for oth-

erwise normally exuberant children who do not want to take responsibility for their own behavior, that it merely reflects parental or teacher intolerance for such childhood exuberance, or that it is an otherwise benign condition with little or no health consequences. Henceforth, such claims ought to be dismissed as the scientifically illiterate statements they represent rather than be considered to reflect a true scientific debate over the validity and worth of the diagnosis of ADHD. That validity and utility have been well established by more than two centuries of research and thousands of published studies on the distinguishing symptoms, associated impairments, and developmental risks that befall those children and adults unfortunate enough to receive a clinical diagnosis of this condition. Even more than the evidence presented in previous chapters, the evidence reviewed here overwhelmingly demonstrates that ADHD comprises a harmful dysfunction (Wakefield, 1992, 1997) and is therefore deserving of the status of a true mental disorder as much or more than any other child or adult psychiatric disorder currently known.

KEY CLINICAL POINTS

- ✓ ADHD in both children and adults is associated with poorer health, more general bodily concerns, a slightly greater risk for otitis media, twice the population risk for asthma, and a greater risk for coronary heart disease by adulthood than controls. The disorder does not appear to be associated with any greater risks for diabetes or hypertension, despite a greater risk for obesity, and is not associated with significant visual difficulties.
- ✓ Compared to typically developing children, children with ADHD on average have poorer dental health and, specifically, a greater risk for caries, missing teeth, filed surfaces, gingivitis, bruxism, bleeding gums, plaque buildup, and a five times greater likelihood of oral trauma, as well as poorer oral hygiene, greater dental office behavioral difficulties, and less effective communication styles toward dental professionals. Dental health in adults with ADHD remains to be studied in any detail.
- ✓ Teens and adults with ADHD are more likely to smoke tobacco, to smoke more often, and to be more stable or consistent smokers than are comparison individuals. While the predilection to smoke may be a form of self-medication given the positive impact of nicotine on ADHD symptom reduction, it may also be a consequence of poorer inhibition, novelty seeking, and risk taking.
- ✓ Teens and adults with ADHD appear to be more likely to use marijuana, but this risk may be a function of comorbid CD.
- ✓ Teens with ADHD may not be more likely to use alcohol than other teens unless they have comorbid CD or deviant peer relationships accompanied by reduced parental monitoring. But by adulthood, there is greater evidence of an association between ADHD and increased alcohol use and abuse, regardless of any relationship between ADHD with CD.
- ✓ Teens and adults with ADHD may be at greater risk of abusing other substances, but this risk is primarily, although not completely, a function of comorbid CD or antisocial personality disorder. The abuse of substances may feed forward to worsen the symptoms of ADHD and associated EF deficits, such as working memory.
- ✓ Treatment of ADHD in childhood with stimulant medications is not linked to any increased risk of substance use in adolescence or adulthood. Continued treatment with medication into adolescence may reduce the likelihood of substance use and abuse, although the findings for such a protective effect are mixed and rather weak.
- ✓ Adults with substance use disorders are three to seven times more likely to have ADHD, which makes it essential that clinicians who work with drug-abusing clients routinely screen them for the possibility of ADHD. The presence of ADHD in substance-abusing adults is associated with worse drug use and other forms of psychopathology, and may interfere with response to treatment of the substance abuse.
- ✓ The recent generation of children with ADHD is 1.5 times more likely to be overweight or obese, whereas adults growing up with ADHD are 1.5 to 2.0 times more likely to be overweight or obese. ADHD is also more common in children and adults who are being treated for obesity, again necessitating in such cases the screening and appropriate management of ADHD. It is primarily the HI symptom dimension of ADHD that increases these risks.
- ✓ Females with ADHD demonstrate an increased risk (three to six times) for eating disorder pathology generally and BED or frank bulimia by adolescence. Con-

versely, women in treatment for BED or bulimia are four times more likely to have adult ADHD. Persons with eating disorder pathology and ADHD are likely to have more severe eating problems and to be less responsive to efforts at self-change or interventions for weight control than are those who do not have ADHD. Again, these risks are a function more of the HI symptom dimension of ADHD than of its inattentive dimension, but they are also related to the degree of peer and parent–child relationship problems.

- ✓ Children with ADHD may be three to five times more likely to manifest enuresis or encopresis than are typically developing children. This risk appears to be greater in children who also have comorbid ODD. Yet these difficulties affect only a minority of children with ADHD.
- ✓ There is a two-way relationship between ADHD and seizure disorders or epilepsy, in which the presence of one condition increases the risk for the other by 2.5 times over the population risk for either condition. More children with ADHD manifest increased frontal–temporal theta band activity on EEG, which is thought to indicate reduced brain arousal or responsiveness to stimulation.
- ✓ Both children and adults with ADHD are more likely to have sleep difficulties, including greater time to fall asleep, frequent night waking, restlessness during sleep, and sleep-disordered breathing; more than half of these individuals are described as having daytime tiredness and more frequent episodes of daytime sleepiness than typically developing children or adults. The presence of anxiety or depression or ASDs with ADHD may further increase the risk for these sleeping difficulties. These sleeping problems may be more associated with the severity of the HI symptom dimension of ADHD than the inattentive dimension, but reduced sleep and daytime tiredness may exacerbate daytime inattention.
- ✓ Children, adolescents, and young adults with ADHD manifest a significantly increased risk for PIU or computer gaming usage or frank Internet/gaming addiction. Moreover, individuals with PIU or Internet/gaming addiction are more likely to have elevated ADHD symptoms. The risk for PIU/addiction is linked not only to severity of ADHD symptoms, especially impulsivity, but also depression, anxiety, and hostility/aggression. Yet it is possible that the association with depression (and possibly suicidality) and anxiety may be as much consequences of rather than predispositions to PIU/addiction.
- ✓ ADHD in children, and more recently in adults, has been repeatedly linked to an increased risk (two to five times) for accidental injuries of all types (trauma, burns, poisonings, etc.), more severe injuries, as well as repeated injuries. The comorbidity of ODD/aggression and ADHD in children further exacerbates these risks. Likewise, children admitted to hospitals due to accidental injuries are three times more likely to have ADHD (approximately 30%) than children admitted for other reasons. Factors contributing to these elevated risks are inattention, impulsivity and risk taking, motor incoordination, comorbidity with ODD/CD, anxiety, and depression, and parental characteristics such as reduced parental monitoring of the child's activities.
- ✓ The evidence base is relatively thin, but it suggests that children with ADHD may be three times more likely to be abused than typically developing children, with this risk greatly increased by the presence of comorbid ODD.
- ✓ ADHD in teens and adults is consistently associated with less safe driving habits, deficient driving performance, and greater inattention and impulsivity while driving. The disorder is also linked to more adverse driving outcomes, such as a greater risk for traffic citations (especially for speeding) and more such citations; license suspensions/revocations; and a greater risk for crashes, more crashes, more severe crashes; and being considered to be at fault in such crashes. Some of these adverse outcomes are also linked to and exacerbated by comorbidity with ODD/CD or antisocial personality disorder. ADHD medications may improve these driving performance problems. Adults with ADHD are also more likely to manifest aggression while driving, or road rage, and such hostility and emotional dysregulation is also a factor in their crash risks. Texting on cell phones while driving markedly worsens the driving performance of both teens with ADHD and typical teens.
- ✓ With regard to sexual behavior and adjustment, teens with ADHD engage in more risky sexual behavior in terms of starting sexual activity earlier; having more sex partners; and being less likely to use contraception and therefore more likely to be involved in a pregnancy or to contract a sexually transmitted disease. Risky sexual behavior is also related to ODD and CD, with the combination of both disorders associated with the

highest risks for early sexual activity and pregnancy involvement. In adults, ADHD in males may be associated with an increased risk for premature ejaculation.

- ✓ ADHD in teens and young adults may be linked to a mild increase in the likelihood of suicidal thinking or suicide attempts, but these risks are more a function of comorbidity with depression and, to a lesser extent, CD. The role of ADHD in suicidality appears to increase the likelihood of making an impulsive suicide attempt. These risks appear to be at their highest during high school, then decline throughout the 20s in longitudinal studies of ADHD and typical youth. Adolescent suicide attempters are also more likely to have ADHD, most likely owing to the role of impulsivity in distinguishing those who attempt suicide from those who are only depressed.
- ✓ In view of all of these factors, it is not surprising that ADHD in children and adults is associated with two to three times greater health care costs.
- ✓ A small but growing literature intimates that ADHD may be associated with a reduced life expectancy given that self-regulation/conscientiousness remains one of the most robust predictors of longevity, and that those with ADHD occupy the extreme lower end of the population distribution of these traits.

CHAPTER 12

Educational, Occupational, Dating and Marital, and Financial Impairments in Adults with ADHD

Russell A. Barkley

Both trade books (Adler, 2006; Barkley, 2010b; Hallowell & Ratey, 1994; Wender, 1995) and clinical textbooks (Goldstein & Ellison, 2002; Gordon & McClure, 1996; Triolo, 1999; Weiss, Hechtman, & Weiss, 2001) have noted the serious and pervasive adverse effects associated with attention-deficit/hyperactivity disorder (ADHD) in the domains of educational, occupational, social, and financial functioning. However, despite such trenchant clinical observations, the research literature on each of the domains of major life activities is relatively small. Here I briefly review what is known from research about each of these domains of impairment associated with adults with ADHD. Some of this material is adapted from that published in my earlier textbook on the topic of adults with ADHD (Barkley, Murphy, & Fischer, 2008).

EDUCATIONAL FUNCTIONING

Children with ADHD Growing Up

Chapter 6 on educational impairments indicates that the vast majority of clinic-referred children with ADHD are doing poorly at school, typically underperforming relative to their known levels of ability, as determined by intelligence and academic achievement tests. These classroom difficulties are believed to be the result of the inattentive, impulsive, and restless behavior associated with ADHD, the typically lower than average intelligence associated with the disorder (see Chapter 6; Rapport, Scanlan, & Denney, 1999), as well as the higher comorbidity of ADHD and learning disabilities (DuPaul, Gormley, & Laracy, 2012; Tannock & Brown, 2000). Given these deficits in academic skills and behavior, it is not surprising to find that as many as 56% of children with ADHD may require academic tutoring, approximately 30% may repeat a grade in school, and 30–40% may be placed in one or more special education programs. As many as 46% may be suspended from school and 10–35% may drop out entirely and fail to complete high school (Barkley, DuPaul, & McMurray, 1990; Barkley, Fischer, Edelbrock, & Smallish, 1990; Barkley, Fischer, Smallish, & Fletcher, 2006; Faraone et al., 1993; Szatmari, Offord, & Boyle, 1989; Weiss & Hechtman, 1993).

By adolescence, these chronic and cumulative experiences with school failure, learning disorders, school misbehavior, and sometimes lower intelligence begin to generate other adverse educational outcomes. For instance, the academic outcome of the hyperactive (ADHD) adolescents was considerably poorer in Barkley and Fischer's Milwaukee follow-up study at the

teen follow-up than that of the typically developing adolescents followed concurrently. At least three times as many hyperactive (ADHD) children had failed a grade (29.3 vs. 10.0%) or been suspended (46.3 vs. 15.2%) or expelled (10.6% vs. 1.5%) (Fischer, Barkley, Edelbrock, & Smallish, 1990). Others have also identified such high educational risks in longitudinal studies dating back as much as 40 years (Ackerman, Dykman, & Peters, 1977; Mendelson, Johnson, & Stewart, 1971; Stewart, Mendelson, & Johnson, 1973; Weiss, Minde, Werry, Douglas, & Nemeth, 1971; Wilson & Marcotte, 1996). In another sample of clinic-referred teenagers with ADHD, a similar risk for school retention and suspension was documented (Barkley, Anastopoulos, Guevremont, & Fletcher, 1991). Almost 10% of the hyperactive sample followed into adolescence had quit school at this follow-up point in the Milwaukee Study, compared to none of the normal sample (Barkley, Fischer, et al., 1990). Fischer and colleagues (1990) also found that the levels of academic achievement on standard tests were significantly below normal on tests of math, reading, and spelling, falling toward the lower end of the normal range (standard scores between 90 and 95).

Fischer and colleagues (1990) examined whether the presence of conduct disorder (CD) within the hyperactive group at follow-up accounted for these greater than normal rates of academic failure. The results indicated that although hyperactivity alone increased the risk of suspension (30.6% of pure hyperactives vs. 15.2% of controls) and dropping out of school (4.8% of pure hyperactives vs. 0% of controls), the additional diagnosis of CD greatly increased these risks (67.4% were suspended and 13% dropped out). Moreover, the presence of CD accounted almost entirely for the increased risk of expulsion within the hyperactive group, in that the pure hyperactive group did not differ from typically developing children in expulsion rate (1.6 vs. 1.5%), whereas 21.7% of the mixed hyperactive/CD group had been expelled from school. In contrast, the increased risk of grade retention in members of the hyperactive group was entirely accounted for by their hyperactivity, with no further risk occurring in the mixed hyperactive/CD group.

In general, it appears that academic performance difficulties in adolescence are associated with having had persistent ADHD since childhood, whereas school disciplinary actions such as suspensions and expulsions are more closely linked to comorbid conduct problems or CD than to ADHD alone (Barkley, Fischer, et al., 1990; Fischer et al., 1990; Wilson & Marcotte, 1996). Children with ADHD who have the lowest levels of adaptive functioning in childhood are also the most likely to have comorbid psychiatric disorders and academic impairments in adolescence (Barkley, Shelton, et al., 2002; Greene, Biederman, Faraone, Sienna, & Garcia-Jetton, 1997; Wilson & Marcotte, 1996). Here *adaptive functioning* refers to the development of self-sufficiency, as measured by instruments such as the Vineland Adaptive Behavior Scales.

These evident trends toward lower academic performance and more grade retentions, suspensions, and expulsions in the adolescent years increase, such that by adulthood, the percentage of those with ADHD dating to childhood have even greater difficulties in these areas than the percentages noted in adolescence and, of course, greater than those in control groups. Hyperactive children in follow-up studies into adulthood had less education, achieved lower academic grades, failed more of their courses, were more often retained in grade, failed to graduate high school, and did not attend college than were children in control groups (Klein et al., 2012; Lambert & Hartsough, 1998; Mannuzza, Gittelman-Klein, Bessler, Malloy, & LaPadula, 1993; Mannuza, Klein, Bessler, Malloy, & LaPadula, 1998; Weiss & Hechtman, 1993).

Children Diagnosed with ADHD Followed to Adulthood

The Milwaukee Study (Barkley, Fischer, Smallish, & Fletcher, 2006) found much the same results at the age 21 follow-up: More than three times as many hyperactive than control group members had been retained in grade at least once (42 vs. 13%) during their schooling or had been suspended from high school at least once (60 vs. 18%). The hyperactive group members had completed fewer years of education and had a lower grade point average (1.69 vs. 2.56 out of a possible 4.0) and class ranking in their last year of schooling (69th percentile vs. 49th percentile) than those in the control group. More of the hyperactive group than the control group had also received special educational services while in high school, and had been suspended or expelled from school or been truant relative to the control group. Of significant social and economic impact, however, was the finding that 32% of the hyperactive group had failed to complete high school compared to 0% of the control group. Substantially fewer hyperactive than control children had ever enrolled in college

(21 vs. 78%) or were currently attending at this follow-up point (15 vs. 66%). These findings were reaffirmed 6 years later at the age 27 follow-up (Barkley et al., 2008). In the Canadian follow-up study, approximately 20% attempted a college program, yet only 5% completed a university degree program, compared to over 41% of control children (Weiss & Hechtman, 1993). The longest running (30-year) follow-up study of hyperactive children into midlife likewise indicates that less education is an outcome of childhood ADHD, with 30% either not completing high school or getting a general equivalency diploma (GED), compared to just 4% of the control group (Klein et al., 2012). These findings demonstrate that the educational domain is major in terms of impaired functioning and reduced attainment for children growing up with ADHD.

As noted previously, children with ADHD followed into adulthood in the previous studies and clinic-referred adults diagnosed with ADHD do not have identical impairments. Studies of children with ADHD often indicate that estimates of their intellect are significantly lower than estimates for children in control groups, averaging about 7–10 IQ points difference (see earlier discussion; Barkley, 2006). This does not seem to be the case for clinic-referred adults with ADHD in prior studies. For them, intelligence estimates seem to fall within the normal range and are comparable to estimates for control groups of clinic-referred adults (Barkley, Murphy, & Kwasnik, 1996; Murphy & Barkley, 1996; Murphy, Barkley, & Bush, 2002). Although Biederman and colleagues (1993) found that their sample of adults diagnosed with ADHD had IQ scores significantly below scores of their control groups, the IQ scores for the adults with ADHD were 107–110, nearly identical to the results of our own studies of adults with ADHD. The adults with ADHD in the Biederman and colleagues study therefore seem to differ significantly from the control groups only by virtue of the fact that the control group had above-average IQs (110–113).

Academic Histories of Adults Diagnosed with ADHD

Even so, individuals diagnosed with ADHD in adulthood do seem to have a higher risk for adverse educational outcomes and lower academic functioning at some time during their schooling than do control adults, just as was found in children with ADHD followed over development (Able, Johnston, Adler, & Swindle, 2007; Young, Toone, & Tyson, 2003). My colleagues and I (Barkley et al., 2008) studied this domain extensively in a large sample of clinic-referred adults diagnosed with ADHD relative to two different control groups (clinical, community). The adults reported that they were significantly more likely to be currently impaired in any educational activities (89%) and to have been so impaired during childhood (91%), and they were more often rated by others as such in their current and childhood educational adjustment (63 and 66%, respectively) than were those in a community control group (1, 6, 3, and 2%, respectively; Barkley et al., 2008). These adults with ADHD were also rated by others (mostly parents) who knew them well as more likely than control adults to have been impaired as children in various school situations, such as classwork (64 vs. 2%), homework (66 vs. 3%), classroom behavior (37 vs. 0%), recess (27 vs. 0%), and interactions with other children (35 vs. 0%), among other settings, and in overall time management at school (65 vs. 2%) compared to the community group (Barkley et al., 2008). In most settings, adults with ADHD were at least two to three times more likely than the clinical control group to have been impaired, and vastly more so than the community control adults. These results show that adult ADHD has a substantial adverse impact on school activities in the childhood histories of these adults.

Between 16 and 40% of clinic-referred adults have repeated a grade, in keeping with the figures reported for children with ADHD discussed earlier in this chapter (Barkley et al., 2008; Biederman et al., 1993; Murphy & Barkley, 1996; Roy-Byrne et al., 1997). Up to 43% have also received some form of extra tutoring services in their academic histories to assist them with their schooling (Biederman et al., 1993). My colleagues and I found that 16–35% of young adult samples with ADHD had received special educational services in our prior studies (Barkley et al., 2008; Murphy et al., 2002; Roy-Byrne et al., 1997), a figure about half that found in hyperactive children followed to young adulthood but still higher than normal. A history of behavioral problems (41–44%) in school occurs more often in adults with ADHD than in control adults (1–3%), and they are likely to have been suspended from school four times more often and to have been truant from school three times more often than controls (Barkley et al., 2008; Murphy & Barkley, 1996). Yet adults with ADHD seen in clinics are far more likely to have graduated high school (78–92%) and attended college (68%)

than are clinic-referred children with ADHD followed to adulthood (discussed earlier), for whom the high school graduation rate is only about 64% (Barkley et al., 2008). However, fewer of them graduate from college (30%) compared to control groups (54–62%; Barkley et al., 2008).

A number of studies indicate that clinic-referred adults with ADHD may have less education than adults without ADHD seen at the same clinic or community control groups (Able et al., 2007; Barkley et al., 2008; Roy-Byrne et al., 1997; Sobanski et al., 2008; Young et al., 2003), a finding that is consistent with adult follow-up studies of ADHD children (Mannuzza et al., 1993). Yet this is not always the case because a few studies did not find such differences (Murphy & Barkley, 1996; Murphy et al., 2002). Torgersen, Gjervan, and Rasmussen (2006), using a Norwegian sample (n = 45), found that only 20% of their adults with ADHD had 12 or more years of education—a figure well below those of other studies of ADHD in adults. This Norwegian sample appears to have far greater severity of ADHD than is typical of North American samples.

In summary, while adults with ADHD diagnosed in adulthood may be less likely to experience adverse educational outcomes than children followed to adulthood, the former still do so at far higher rates than control groups. And while a higher proportion of them graduate from high school than children with ADHD followed to adulthood, the adult-diagnosed groups are less likely than control groups to graduate from college, and they have less education. Certainly a majority of these individuals diagnosed with ADHD as adults report current impairment in educational activities and as having been so as children compared to the reports of control groups. As in general population samples, generally males were also more likely than females to experience these adversities; these differences were further exacerbated by the presence of ADHD. But both sexes with adult-diagnosed ADHD are more impaired educationally than are controls of the same sex (Barkley et al., 2008).

Archival Records of Academic Performance

Our large study of adults with ADHD (Barkley et al., 2008) obtained high school transcripts of many of the participants. From those transcripts, we coded the percentage of grades that were D's, F's, or unsatisfactory (U's). For elementary school and high school, we also coded the average number of days per year they were reported as having been absent from school on the transcript. From high school transcript we recorded participants' class ranking in their senior year or last year of high school attended. For high school and college, we computed their grade point averages using a 0- to 4-point scale (grades of F to A) or, if reported in numerical scores (e.g., 90–100, 80–89, 70–79), we recoded them as 0 (50–59), 1 (60–69), and so on. If any verbal or quantitative test scores were available on the high school transcript, we recorded that information as well. We did likewise for the verbal and quantitative Scholastic Aptitude Test (SAT) scores that may have been recorded on college transcripts. All of this information is reported in Table 12.1 for each group. On their elementary school transcripts, the ADHD group had a greater percentage of poor or failing grades than either of the control groups, which did not differ from each other. The clinical and community control group participants did not differ in their average number of days absent in elementary school.

In high school, once again, the adults with ADHD had a significantly greater percentage of D's and F's on their transcripts and were ranked lower in class standing than were adults in either control group. Not surprisingly, then, we also documented a lower grade point average for the ADHD group than for the two control groups. Unlike their elementary school period, we did find that the ADHD group had significantly more days absent from high school than did adults in either of our control groups. Of note is that the clinical and community control groups did not differ in any of these respects.

Among those who attended college and consented to allow us to obtain their transcripts, we found results consistent with those noted earlier for high school. Once again, the percentage of unsatisfactory grades (D's and F's) was significantly higher for the ADHD group than for either control group. The adults with ADHD had also withdrawn from more college classes for which they had initially registered than had the clinical control adults, a finding subsequently noted by Advokat, Lane, and Luo (2011) in their study of college students with ADHD. Again, we found a significantly lower college grade point average in the adults with ADHD than was the case in either control group. This was also the case in other studies of college students with ADHD (Advokat et al., 2011; Heiligenstein, Guenther, Levy, Savino, & Fulwiler, 1999). The results for SAT scores did not differ across the groups, however. But Advokat and colleagues (2011) did find such ADHD students to

TABLE 12.1. Educational Functioning by Group for the UMASS Study

Measure	(1) ADHD Mean	(1) ADHD *SD*	(2) Clinical Mean	(2) Clinical *SD*	(3) Community Mean	(3) Community *SD*	*F*	*p*	Pairwise contrasts

SAT quantitative score	491.8	127.5	547.0	119.1	532.3	121.2	2.1	NS	

Note. Sample sizes for interview reports are ADHD = 145, clinical control = 94, and community control = 108. For elementary school, they were 70, 44, and 33, respectively. For high school percent D's and F's, they were 116, 80, and 86. For class ranking, they were 52, 37, and 53. For days absent, they were 44, 30, and 35. For verbal and quantitative test percentiles, they were 51, 31, and 41. For grade point average, they were 115, 78, and 86. For college, percent D's and F's. they were 75, 75, and 69. For percent withdrawals, they were 74, 71, and 69. For grade point average, they were 74, 73, and 68. For SAT scores, they were 42, 39, and 34.

SD, standard deviation; *F, F*-test results of the analysis of variance (or covariance); *p,* probability value for the *F*-test; NS, not significant; [S], significant main effect for sex (see text for details); [G×S], significant group × sex interaction (see text for details); [A], age used as a covariate in this analysis; percent D, F, and U grades, percentage of grades recorded on transcript that were D's, F's, or unsatisfactory; mean days absent/sem., average number of days absent per semester.

Statistical analyses: Groups were initially compared using two-way (groups × sex) analysis of variance (or covariance as necessary). Where this analysis was significant ($p < .05$) for the main effect for group, pairwise comparisons of the groups were conducted, the results of which are shown in the last column.

have lower ACT scores than control students. These educational problems in college students with ADHD may be linked to not only their inattentive symptoms but also decreased social and academic adjustment, lower decision-making self-efficacy, and poorer study skills, which are known to be linked to that inattention (Norvilitis, Sun, & Zhang, 2009).

The large study by Barkley and colleagues (2008) used official archival records to document objectively the adverse educational impact of ADHD in clinic-referred adults in comparison to both clinical and community control groups. Our extensive and detailed examination of school records corroborated the self-reported information of these adults and the reports obtained from others (see Table 12.1) with regard to the lower educational functioning of adults with ADHD. They did so across elementary, high school, and college educational histories. Despite having verbal and quantitative test scores that were comparable to those of the control groups in both high school and college, adults with ADHD received more unsatisfactory grades, had a lower overall grade point average, received a poorer class ranking, and, in high school, had more days absent from school than adults in our other two groups. That ADHD in adults is associated with educational impairment, and is more likely to be so than other outpatient clinical disorders, is readily apparent in the totality of these findings. Moreover, the most salient of these adverse educational outcomes (years of education, high school graduation, grade point average, etc.) both in children with ADHD followed to adulthood and adult-diagnosed cases, are mainly linked to severity of ADHD, and to a lesser extent to academic achievement skills and antisocial behavior, and not to other confounding factors, such as IQ (Barkley et al., 2008; Biederman et al., 2008). ADHD may be seen to exact a considerable toll in the educational sphere of major life activities that can be specifically attributed to it, and not to just outpatient psychiatric status, as represented in our clinical control group.

Academic Achievement Skills

Concerning actual tested academic achievement skills, children and adolescents with ADHD often manifest significant deficits on tests of academic achievement relative to control groups (Frazier, Youngstrom, Glutting, & Watkins, 2007). Early studies of adults diagnosed with ADHD indicate that they perform significantly more poorly on tests of math than those in control groups (Biederman et al., 1993). Only those adults with ADHD who were relatives of children with ADHD were found to score significantly lower on tests of reading in that study. As a consequence, more of the adults with ADHD qualified as reading disabled (6%) than did control adults (0%). Other studies have also found that clinic-referred adults with ADHD perform more poorly on reading achievement tests than do members of control groups from the same clinic (Roy-Byrne et al., 1997). Yet the mean scores on both achievement tests in these studies were still within the normal range for these adults with ADHD. And in a more recent study, the small differences in achievement did not survive statistical control for IQ (Laasonen, Lehtinen, Leppamaki, Tani, & Hokkanen, 2010). Instead, deficient academic achievement skills were most notable in adults with dyslexia, a condition that can coexist in a small but significant percentage of children and adults with ADHD (Barkley et al., 2008). The problem in some of these studies is the use of supernormal control groups and not subnormal functioning in the clinic-referred adults with ADHD. Studies of children with ADHD almost routinely indicated that they scored below normal in their academic achievement skills both in childhood (Barkley, 2006; Frazier et al., 2007; Rapport et al., 1999) and when followed into young adulthood (see Barkley et al., 2008).

Our large study of adult-diagnosed ADHD also found that participants were deficient in math, spelling, reading rate, and reading comprehension, even if their single-word reading was not different from that of our two control groups (Barkley et al., 2008). There is evidence from that study as well that in growing into adulthood, childhood ADHD has a more adverse impact on these skills than is seen in clinic-referred adults, but both groups of people with ADHD are more deficient in most domains of achievement than control groups. Impairment of reading comprehension, in contrast, seemed to occur more in the clinic-referred adults with ADHD than in the children growing up with ADHD, for some unknown reason. In general, large studies and meta-analyses of the literature on this issue seem to confirm that adults with ADHD (including college students), like children with the disorder, are more deficient than control groups on academic achievement tests (Frazier et al., 2007) even if the differences are not as substantial as they are in children and teens diagnosed with ADHD.

Learning Disabilities

The prevalence of actual learning disabilities (LD) in adults diagnosed with ADHD (0–22%) (Barkley et al., 2008; Biederman et al., 1993; Matochik, Rumsey, Zametkin, Hamburger, & Cohen, 1996; Torgersen et al., 2006) is well below that found in children with ADHD (19–50%) (Barkley et al., 2008; DuPaul et al., 2012; Lambert & Sandoval, 1980l Semrud-Clikeman et al., 1992). However, in our large study of adult-diagnosed individuals with ADHD, we found that 21% could be considered to have an LD in reading comprehension and 41% in listening comprehension (both defined as placing at or below the 14th percentile on achievement tests) compared to our community control group (10 and 15%, respectively; Barkley et al., 2008).

Differences between Adults with Child-Diagnosed ADHD and Adult-Diagnosed Cases

All this suggests the following: Clinically diagnosed adults with ADHD share some of the same types of academic difficulties in their histories as do children who were hyperactive or diagnosed with ADHD, then followed over development; however, their intellectual levels and high school graduation rates are higher, more are likely to have attended college, and their likelihood of having achievement difficulties or LD is considerably less in most respects than that seen in children with ADHD followed to adulthood. Yet adults diagnosed with ADHD in adulthood are still more impaired in most of these educational areas than adults in the control groups.

This higher level of intellectual and academic functioning in clinic-referred adults with ADHD relative to children with ADHD followed to adulthood makes sense given that they are self-referred to clinics in comparison to children with ADHD. This fact makes it much more likely that these adults have the sufficient educational level to be employed and to have health insurance. They may also be expected to have a sufficient level of intellect and self-awareness to perceive themselves as needing assistance with their psychiatric problems and difficulties in adaptive functioning. Children with ADHD who are brought to clinics by their parents are less likely to have these attributes by the time they reach adulthood. They are not as educated, they have considerable problems sustaining employment, they are more likely to have had a history of aggression and antisocial activities, and they are not as self-aware of their symptoms as adults with ADHD who are self-referred to clinics (Barkley et al., 2008). Only 3–5% of hyperactive children followed to adulthood in the Milwaukee Study endorsed sufficient symptoms to receive a clinical diagnosis of ADHD at age 21. That figure was 48% if their parents' reports were used and 66% if a developmental reference (98th percentile) was used instead of the DSM criteria (Barkley, Fischer, Smallish, & Fletcher, 2002), as noted in earlier chapters. This suggests that children with ADHD brought to clinics as children may have a more severe form of ADHD with earlier onset, or one that at least predisposes them to more severe impairments in school, than do adults self-referred to clinics and then diagnosed with ADHD.

OCCUPATIONAL FUNCTIONING

Children with ADHD as Adults

As I discussed in our earlier text on adult ADHD (Barkley et al., 2008), the results from past studies suggest that, as adolescents, individuals with ADHD function no differently in their jobs than do normal adolescents (Weiss & Hechtman, 1993). However, these findings need to be qualified by the fact that most jobs taken by adolescents are unskilled or only semiskilled, usually part-time, and typically of limited duration (summer months). As children with ADHD enter adulthood and take on full-time jobs that require skilled labor, independence of supervision, acceptance of responsibility, and periodic training in new knowledge or skills, their deficits in attention, impulse control, and regulation of activity level, as well as their poor organizational and self-control skills may begin to handicap them on the job. The findings from the few outcome studies that have examined job functioning suggest this may be the case. Two studies (in New York and Montreal) examined occupational status by adulthood and reported that their hyperactive groups ranked significantly lower than control groups (Mannuzza et al. [1993] and Weiss & Hechtman [1993], respectively). This remained the case at the 33-year follow-up of the New York study (Klein et al., 2012). Employer ratings captured in the Montreal study revealed significantly worse job performance in the hyperactive group than in the control group (Weiss & Hechtman, 1993). More of the hyperactive group had also reported having been fired or laid off than had members of the control group.

The Milwaukee follow-up study (Barkley et al., 2006) obtained employer ratings of work performance at the age 21 young adult assessment and found that hyperactive participants were rated as performing significantly worse at work than were controls.

Children who grow up with ADHD are likely to have lower socioeconomic status than their peers or control subjects in these studies (Klein et al., 2012; Weiss & Hechtman, 1993) and not only to move and change jobs more often but also to have more part-time jobs outside their full-time employment. They are also more likely to have had an adverse impact on their parents' own occupational involvement, absenteeism, lost work income, and need for disability assistance (Birnbaum et al., 2005; Kvist, Nielsen, & Simonsen, 2013; van Roijen et al., 2007; Swensen et al., 2003, 2004). Employers have been found to rate adults who as children grew up with ADHD as less adequate in fulfilling work demands, less likely to be working independently and to complete tasks, and less likely to be getting along well with supervisors. They also do more poorly at job interviews than do typically developing individuals (Weiss & Hechtman, 1993). And these adults report that they find certain tasks at work too difficult for them. Finally, children with ADHD followed to adulthood are more likely to have been fired from jobs, as well as laid off from work, relative to control participants. In general, adults who grow up with hyperactivity or ADHD appear to have a poorer work record and lower job status than typically developing adults (Weiss & Hechtman, 1993). These findings were corroborated in my own Milwaukee follow-up study with Mariellen Fischer at the age 21 follow-up (Barkley et al., 2006).

My colleagues and I studied these occupational outcomes again at the age 27 follow-up (Barkley et al., 2008). We found that significantly fewer members of the group whose ADHD had persisted to adulthood (H + ADHD group) were currently employed compared to both those whose ADHD had not persisted (H – ADHD) and the community control adults. Members of the H + ADHD group also reported that they were more likely to have problems with others at work, as well as difficulties with their behavior and workplace performance more generally compared to these other two groups. Table 12.2 shows the results of our dimensional measures of occupational functioning in this study. It is mainly the hyperactive group with current ADHD that is most impaired in these various indices of occupational success relative to the control groups. While both hyperactive groups had lower status jobs relative to our control group at this follow-up, the H + ADHD group rated themselves as having lower workplace performance quality than the other two groups. The groups did not differ in members' current annual salary or in the length of time they had held their current positions. But the two hyperactive groups reported working fewer hours per week than did the community control group. While we have yet to document differences in earnings in adults who were children with ADHD, our participants were still relatively young (mean age 27). In contrast, the 30-year follow-up of the New York samples did show a lower annual salary in their hyperactive group by midlife (mean age 41; Klein et al., 2012).

The H + ADHD group also had held more jobs since leaving high school. Given such a higher job turnover rate, we again adjusted for this difference across groups in the questions dealing with workplace adjustment by computing the percentage of jobs held in which these problems had been reported to occur. The H + ADHD group experienced a greater percentage of jobs in which members had trouble getting along with others, behavior problems, got fired or dismissed from the job, or had been disciplined formally by their supervisors than both the H – ADHD and control groups. Members of the currently employed ADHD group also reported quitting more jobs due to hostility with others than the community group, with the H – ADHD group placing between these two extremes but not differing significantly from either of the other groups. In summary, this follow-up study provides even more detailed findings on the adversities in adult occupational outcomes experienced by adults who as children were diagnosed with ADHD.

More recent follow-up studies of children with ADHD continue to document poorer occupational adjustment in these cases by adulthood. Using a large population-based sample followed from adolescence to age 37, Brook, Brook, Zhang, Seltzer, and Finch (in press) documented that teens diagnosed with ADHD as adults had 2.46 greater odds of having impaired work performance than those without ADHD (47 vs. 21%, respectively). Impaired work performance in that study was a composite variable of eight questions dealing with having been unemployed or laid off, truant from work, and receiving negative evaluations of work quality from a workplace supervisor. Age, annual income, and current marijuana use were also significant, though lesser, predictors of adult impaired work performance, in addition to adolescent ADHD.

TABLE 12.2. Occupational Functioning for Each Group on Dimensional Measures in the Milwaukee Study

	(1) H +ADHD		(2) H – ADHD		(3) Community				Pairwise

% jobs disciplined	28.1	34.0	8.1	22.2	3.1	15.6	17.77	<.001	1 > 2, 3

Note. SD, standard deviation; *F, F*-test results of the analysis of variance (or covariance); *p* = probability value for the *F*-test; NS, not significant; K, thousands of dollars; work quality rated 1–5 (1 = *excellent,* 5 = *poor*); [IQ], Wechsler Adult Intelligence Scale WAIS–III Vocabulary and Block Design scores were used as covariates on these measures. Where covariates were used, means are marginal means. Work quality was rated from 1 (*excellent*) to 5 (*poor*).

Statistical analyses: Groups were initially compared using one-way (groups) analysis of variance (or covariance as necessary). Where this analysis was significant ($p < .05$) for the main effect for group, pairwise comparisons of the groups were conducted, the results of which are shown in the last column.

Mordre, Groholt, Sandstad, and Myhre (2012) found that among children admitted to psychiatric hospitals in Norway and followed for 28 years, 19% were currently receiving a disability pension (comparable to Supplemental Security Income [SSI] in the United States) and that among those with current ADHD, 30% were on disability pension. This greater likelihood of disability proved not to be a consequence of comorbid internalizing or externalizing disorders but specific to ADHD. Another study, this time in the United States, found that, by adulthood, a childhood diagnosis of ADHD was associated with a reduction in employment by 10–14 percentage points, a 33% reduction in earnings, and a 15 percentage point greater likelihood of being on social assistance (Fletcher, 2014). While some of these results were also a function of reduced educational attainment and comorbid health and mental health conditions, ADHD remained a significant contributor to these outcomes.

Adult-Diagnosed Individuals with of ADHD

The previous findings pertain to children with hyperactivity or ADHD followed into adulthood, some of whom no longer have the disorder. In contrast, all clinic-referred adults diagnosed with ADHD, by definition, have the disorder. As noted earlier, for these and other reasons, the results of children with ADHD followed to adulthood may not necessarily be representative of clinic-referred adults diagnosed with the disorder. Though opinions abound on the topic in trade books on ADHD in adults, there was very little research on the occupational functioning of clinic-referred adults with ADHD until the late 1990s. In one such study of 172 adults with ADHD, we (Murphy & Barkley, 1996) reported that such adults were more likely to have been fired from employment (53 vs. 31%), to have impulsively quit a job (48 vs. 16%), and were more likely to report chronic employment difficulties (77 vs. 57%). The ADHD group also had changed

jobs significantly more often than those in the control group (6.9 vs. 4.6). Similar findings were later reported by De Quiros and Kinsbourne (2001). Their adults with ADHD reported more frequent job changes and poorer job performance than did control adults. More recently, in a large survey of 10 national samples using an adult ADHD symptom screener, de Graaf and colleagues (2008) found that 3.5% of the workers surveyed screened positive for likely ADHD, and those cases had a greater number of days of lost work performance than those without such high ADHD symptoms. Based on their level of intelligence, research shows that adults with ADHD are significantly underemployed in their occupational level of attainment (Biederman et al., 2008; Faraone & Biederman, 2005). They may also have higher rates of unemployment, particularly if they have comorbid psychiatric disorders, and be more impaired in terms of their occupational training (Sobanski et al., 2007, 2008).

A notably poor picture for employment comes from two Scandinavian countries. Torgersen and colleagues (2006) used a Norwegian sample in which just 16% of individuals with ADHD were employed at the time of referral—a figure well below that seen in studies using U.S. samples. The selection criteria used in that study suggest that members of this sample had severe ADHD and antisociality, so the symptoms likely do not correspond to the severity of ADHD seen in adult outpatient clinics. Yet the general pattern of employment difficulties is in keeping with the outcomes of follow-up studies of hyperactive children. A similar result was evident in another Norwegian study in which just 22% of adults diagnosed with ADHD were currently working, compared to 72% of the general population (Gjervan, Torgersen, Nordahl, & Rasmussen, 2012). In a study of a large Swedish sample of adults with ADHD (n = 414), Halmoy, Fasmer, Gillberg, and Haavik (2009) found that only 24% were currently employed (vs. 79% of controls). ADHD was found to predict being unemployed. Other predictors were anxiety, depression, and substance abuse. But being in treatment for ADHD was associated with a higher likelihood of being employed, as it was in the previously discussed Gjerven, Torgersen, and colleagues (2012) study, with stimulant treatment in childhood increasing the likelihood of being employed in adulthood by more than three times (odds ratio = 3.2; Halmoy et al., 2009). The inverse is also the case, in that ADHD is more prevalent among adults who are unemployed or disabled (Kessler, Adler, et al., 2006).

One study of workplace beliefs and attitudes revealed that degree of ADHD symptoms among employees was associated with more dysfunctional career beliefs, more decision-making confusion, more commitment anxiety, and more external conflict (Painter, Prevatt, & Welles, 2008). In another study college students working in teams have more difficulties performing necessary but uninteresting tasks (Coetzer & Trimble, 2010). College students have reported more difficulties and more severe difficulties in their workplace functioning in the jobs they may be doing while in college (Shifrin, Proctor, & Prevatt, 2010).

In 2008, we reported the results of our large study of adults diagnosed with ADHD in adulthood (Barkley et al., 2008). We interviewed participants about their occupational history, adversities, and current functioning, and we also obtained ratings from employers, with permission, for a subset of adults in our three groups (ADHD, clinical control, and community control). Employers were kept blind to the diagnostic status of the participants and were told only that we were conducting a survey of job satisfaction and performance, and requested their cooperation in completing a short questionnaire, for which they received $20. The interviewer also completed a global estimate of the social and occupational functioning adapted from the DSM-IV to provide a clinician summary rating of the current occupational, social, and academic functioning of the participant.

We reported that, contrary to some studies cited earlier, the groups did not differ in the proportion of members currently employed: ADHD = 73%, clinical = 71%, and community = 77%. But significantly more members of both the ADHD and clinical groups claimed that they had problems getting along with others at work (30, 18, and 7%, respectively) and had difficulties with their behavior or work performance on the job (53, 50, and 5%, respectively). The results for the dimensional measures obtained in this study are shown in Table 12.3; those measures are similar to the ones obtained in the Milwaukee age 27 follow-up shown in Table 12.2. The groups did not differ in the length of time members' had held their current work positions, averaging between 4 and 5 years, nor did they differ in the average number of hours per week they reported working (38–43 hours). Interestingly, adults in the clinical control group had significantly higher status employment, as determined on the Hollingshead Job Index, than did participants in either the ADHD or community group, who did not differ from each other.

Note. Sample sizes: For SOFAS, ADHD = 145, clinical control = 94, and community control = 108. Job index: 137, 87, 103, respectively. Time on job: 104, 66, 83. No. of jobs since high school: 139, 91, 97. Longest time held job: 142, 90, 105. Hours worked: 105, 66, 81. Salary: 105, 65, 79. Self-rated work quality: 105, 66, 84. % jobs trouble with others: 141, 90, 104. % jobs behavior problems and % jobs quit for boredom: 138, 90, 96. % jobs fired: 139, 89, 97. % jobs quit for hostility, % Jobs disciplined: 139, 90, 97. Employer ratings: 39, 25, 50.

SD, standard deviation; *F, F*-test results of the analysis of variance (or covariance); *p,* probability value for the *F*-test; NS = not significant; [S], significant main effect for sex (see text for details); [G]×S, significant group × sex interaction (see text for details); [A], age used as a covariate in this analysis; K, thousands of dollars; work quality rated 1–5 (1 = *excellent,* 5 = *poor*); impair scores are rated 0–3 (0 = *never or rarely,* 3 = *very often*); hyperactive–imp., hyperactive–impulsive symptom score; Respons., responsibilities; overall work performance rated 1–5 (1 = *excellent,* 5 = *poor*).

Statistical analyses: Groups were initially compared using two-way (groups × sex) analysis of variance (or covariance as necessary). Where this analysis was significant ($p < .05$) for the main effect for group, pairwise comparisons of the groups were conducted, the results of which are shown in the last column.

This was also true with regard to current annual salary. But on numerous other measures, the adults with ADHD showed greater occupational impairment and more adverse outcomes related to their employment than did community control adults and, to a lesser extent, than those in the clinical control group.

The adults with ADHD were rated by the clinician as functioning at a lower level than those in the clinical and community groups. While the clinical group members were also rated as more impaired, they were less so than the ADHD group. Both the ADHD and clinical groups had held more jobs since leaving high school than had the community group, even after we controlled for the age differences between these groups. And the longest time they had ever held a specific job was significantly lower for members of these groups than for the community group. The ADHD and clinical group members rated themselves as demonstrating significantly lower work quality than did participants in the community group, but they did not differ from each other in this regard. Participants reported the number of jobs on which they had experienced various difficulties, and we converted these to a percentage of the total jobs they had held since leaving high school. The adults with ADHD reported having trouble with others, behavior problems at work, being fired or dismissed from a job, quitting a job out of boredom, and being disciplined by their supervisor on the job in a higher percentage of the jobs they had held than did participants in both the clinical and the community control groups. The adults in the ADHD group also reported quitting more jobs due to their own hostility in the workplace than did adults in the community group. Based on this self-reported information, our results clearly show that adults with ADHD have greater problems with occupational functioning than those seen in the same clinic who are not diagnosed with ADHD, or those from our general community control group. Just as ADHD was found earlier to exact a significant toll on educational functioning, so also does it adversely impact the occupational functioning of adults diagnosed in adulthood.

The results of the employer ratings are also shown in Table 12.3. Although employers were blind to the diagnoses of our participants, they rated the adults with ADHD as having significantly greater problems with inattention in the workplace than was the case for either control group. Even though the clinical control adults had higher symptom ratings in this domain than those in the community group, they still fell well below the adults with ADHD. Interestingly, employers rated both the ADHD and clinical control adults as having more symptoms of hyperactive and impulsive behavior than adults in the community group. Compared to community control adults, the adults with ADHD were rated as being more impaired by their symptoms in performing assigned work, pursuing educational activities at work, being punctual, using good time management, and managing their daily responsibilities. When compared to the clinical control group, the ADHD group was again rated as more impaired in performing assigned work, time management, and daily responsibilities. As a consequence, the adults with ADHD were rated as having a poorer overall work performance level than were adults in either of the control groups. Such findings are important, in that they corroborate the reports of the adults themselves that indicate ADHD has a detrimental effect on occupational functioning, and that this effect is greater than that seen in clinically referred adults who are not diagnosed with ADHD.

The foregoing results for employer ratings must be qualified by the exceptionally small samples within each group for whom permission was granted to obtain employer ratings, and those ratings were returned to the project staff. Specifically, we had employer ratings for just 39 ADHD group members (27%), 25 clinical control members (26%), and 50 of the community control members (46%). However, additional analyses indicated that those on whom we had employer ratings in each group could be viewed as being representative of their entire group because the subsets did not differ from the entire groups on key demographic and ADHD severity measures, as well as clinician social and occupational functioning ratings.

The totality of previous results shows consistentcy between the literature on children with ADHD followed to adulthood and the smaller literature on clinic-referred adults with ADHD in finding numerous adverse events and greater impairment in the occupational functioning of adults with ADHD. These problems typically exceed the levels of impairment noted in adults having other, non-ADHD outpatient disorders, as well as community control adults, once more attesting to the fact that ADHD in adults is a more impairing disorder than most seen in outpatient settings. Children growing up with persistent ADHD, as discussed earlier in our age 27 follow-up (Barkley et al., 2008), may experience even more workplace adjustment problems than do clinic-referred adults with ADHD. While both groups have comparable rates of difficulties getting along with others and behavior problems at work,

children whose ADHD continued to adulthood experience far more firings and disciplinary actions at work as a percentage of jobs held than do clinic-referred adults with this same disorder. All of this suggests that childhood ADHD may predispose individuals toward lower occupational status regardless of the persistence of ADHD to age 27, most likely due to its adverse effects (noted earlier) on educational success and eventual years attained. But ADHD that persists to adulthood appears to have a far more adverse impact on current job functioning than does simply having ADHD as a child.

In our large study of ADHD cases diagnosed in adulthood, we (Barkley et al., 2008) were able to examine predictors of several of these outcomes (employer ratings of workplace performance and the percentage of jobs from which individuals had been dismissed or fired). We found that lower workplace performance ratings were significantly predicted by severity of self-reported ADHD symptoms and by employer ratings of severity of ADHD in the workplace. The percentage of jobs from which participants had been fired was also predicted by severity of self-reported current ADHD, severity of childhood CD, and higher antisocial activity. In a separate study, we also found that emotional impulsiveness was also a contributor to the likelihood of being fired from a job in this study (Barkley, 2010a; Barkley & Murphy, 2010). Others have subsequently found that emotional dysregulation in the workplace largely mediated the link between ADHD and occupational impairment (Gjervan, Hjerndal, & Nordahl, 2012).

The same analyses were done for the children in the Milwaukee Study samples followed to age 27 (discussed earlier). However, we did not have employer-rated workplace performance at this follow-up, so instead we substituted self-rated work performance quality, which was also significantly impaired in the H + ADHD group (see earlier discussion). Work performance was again predicted by the number of current ADHD symptoms (self-reported). But nonverbal IQ was important here as well, to our surprise. The percentage of jobs from which participants had been fired was predicted by years of education and by the number of self-rated current oppositional defiant disorder (ODD) symptoms. Better educated and less emotionally dysregulated (oppositional) participants were less likely to be dismissed from their jobs. Both predictors make perfect sense. While ADHD symptoms, criminal activities, and childhood CD symptoms had been associated with job dismissals in the UMASS Study adults, that did not occur here.

Other research and later reviews of this literature find that ADHD in adults is associated with a variety of adversities in workplace functioning and occupational health (Kupper et al., 2012), as well as work-related economic costs (Secnik, Swensen, & Lage, 2005). Adults with ADHD who are drawn from general population samples manifest higher levels of unemployment (Kupper et al., 2012) even if this is not always evident in clinic-referred samples, such as those used in my own studies (discussed earlier). They also have reduced workplace productivity; more behavioral and emotional difficulties in the workplace; and a greater risk for accidents, trauma and workplace injuries, and traffic accidents (Chapters 11 and 29). As a consequence, adult ADHD has substantial economic impact through greater absenteeism and lost productivity, among other problems it contributes to workplace functioning (Kupper et al., 2012; Secnik et al., 2005).

DATING, MARRIAGE, AND COHABITATION

Studies of adults with ADHD routinely document impairment in globally rated measures of psychosocial impairment (Barkley et al., 2008; Rucklidge, Brown, Crawford, & Kaplan, 2007; Sobanski et al., 2007, 2008; Young et al., 2003), and a small body of research has demonstrated a pattern of risky sexual behavior in teens and young adults with ADHD (see Chapter 11). All this might imply that adults with ADHD would have more difficulties in their dating and marital/cohabiting relationships. However, very few studies have focused on relationships that adults with ADHD have with others.

Children with ADHD as Adults

Most longitudinal studies of children with ADHD followed to young adulthood have not typically studied or reported problems in dating and marriage or rates of marriage, separation, or divorce (Weiss & Hechtman, 1993), most likely owing to the relatively young age of the children at adult follow-up (typically 20–30 years of age). In the Weiss and Hechtman (1993) study, just 29% of their participants were married at the young adult follow-up (mean age = 25 years). My follow-up study with Mariellen Fischer, discussed earlier, also did not find any group differences in the percentages of our groups that were currently married or separated/divorced (Barkley et al., 2008). The majority of our

groups were still single at the age 27 follow-up (55–67%). But that some marital difficulties are in the offing for the hyperactive group with persistent ADHD (H + ADHD) was evident in the self-reported quality of current marital or cohabiting relationships among those living with an intimate partner or who were formally married. Ratings of marital dissatisfaction and a greater likelihood of extramarital affairs were more apparent in this group than in the H – ADHD (nonpersistent) and community groups (Barkley et al., 2008). We found no differences in the percentages of our groups that were currently dating someone, if they were currently unmarried. Nor did we find any differences in the average number of people they had dated in the past 5 years (two people), in the average length of that dating relationship (3 years), or in the longest time they had dated someone continuously (average = 3.5 years). But ADHD groups had a higher percentage reporting fair-to poor-quality dating relationships, with a percentage four to five times that in the community group. Supporting the idea that the lack of differences in divorce rates in these follow-up studies may have to do with the relatively young age at follow-up of the samples, the 30-year follow-up study in New York recently reported higher divorce rates in their hyperactive children than in their control group by midlife (31 vs. 12%; Klein et al., 2012).

Adult-Diagnosed ADHD

That ADHD in clinic-referred adults might eventually be associated with higher percentages of separation and divorce has been suggested not only in the follow-up studies but also in a few earlier studies of adults with ADHD. Using an older sample of adults, Biederman and associates (1993) were among the first to report a higher incidence of separation and divorce among adults with ADHD, whether clinic-referred and diagnosed (28%) or as non-referred adult relatives of children with ADHD who subsequently met criteria for the disorder in a research study (36%). Murphy and Barkley (1996), also using an older sample than that in the Milwaukee Study, replicated these marital risks in a large study of clinic-referred adults in comparison to a clinical control group of adults without ADHD seen at the same clinic. They also found a marginally significant reduction in self-reported marital satisfaction on the Locke–Wallace Marital Adjustment Test (Locke & Wallace, 1959; $p < .08$) and lower but nonsignificant spouse reports on this same instrument. However, in another study, we did not find a higher divorce rate in clinic-referred adults with ADHD (Murphy et al., 2002), so the pattern here is rather mixed. But the weight of the evidence suggests that there is some relationship between ADHD and adults' risk for divorce.

This relationship between ADHD and separation/divorce or even never having been married may increase with age, as suggested in the previously discussed studies of children with ADHD followed to adulthood. Indicative of such a relationship is the recent finding that older adults diagnosed with ADHD (ages 60–94) are more likely to be divorced or never married, to have fewer family members in their social network, and to experience emotional loneliness (Michielsen et al., in press). Level of ADHD symptoms in that study was positively correlated with degree of emotional support given, emotional and social loneliness, greater recreational social participation, and lower income.

In a Canadian study with small samples of adults with ADHD ($n = 33$) and control adults ($n = 26$), Minde and colleagues (2003) found that marital and family functioning were more impaired in the ADHD group than in the control group, regardless of the sex of the parent with ADHD. As in the study by Murphy and Barkley (1996), self-reported marital adjustment was lower in adults with ADHD than in control adults, with 58% falling in the maladjusted range of their measure (vs. 25% for the control group). Yet their spouse reports on this same measure did not differ from spouse reports of the control group members. These authors, however, did not find higher rates of separation or divorce in the ADHD group, despite its comparable divorce/separation rate (27%) to that found in the Biederman and colleagues (1993) study (discussed earlier). This may have been a result of the small samples and low statistical power in that Canadian study.

The greater marital dissatisfaction and functioning in adults with ADHD are not surprising given that adults with ADHD rate themselves as being more impatient, easily frustrated and angered; as having frequent temper outbursts and more unstable personal relationships; and as breaking off those relationships over trivial matters and have difficulty maintaining friendships (Barkley & Murphy, 2010; De Quiros & Kinsbourne, 2001; Murphy & Barkley, 1996). Such dissatisfaction also arises from the emotional dysregulation associated with the disorder (Barkley & Murphy, 2010). Relationship and marital problems would also be expected given all of the difficulties with impulsiveness, attention, self-regulation, and executive functioning evident in adults

with ADHD (see earlier chapters). The greater likelihood and diversity of financial difficulties demonstrated below in the ADHD groups also would be expected to weigh heavily on marital or cohabiting relations.

A small Canadian study by Eakin and colleagues (2004) found evidence of poorer self-rated marital adjustment and family dysfunction in adults with ADHD (n = 33) than in control adults (n = 26). But the partners of these adults did not rate their marriages as more poorly adjusted or dysfunctional. Once more, the problem in such small studies is low statistical power to detect group differences. In our large study of adults with ADHD compared to clinical and community control groups (discussed earlier), we collected some measures of marital status and satisfaction (Barkley et al., 2008). Our results showed that the two clinic-referred groups (ADHD, clinical control) were less likely ever to have been married than members of the community control group. The ADHD group specifically was significantly less likely to be currently married (vs. being currently single) than the community group, but it did not differ significantly from the clinical group. Among those who were currently married, the ADHD group also had a higher percentage of members who rated the quality of their marriage as poor than the community group. The clinical group, once again, did not differ from either of these other groups. There was no difference in the incidence of divorce among our groups. In that sense, our results disagree with the earlier reports of higher divorce rates by Biederman and colleagues (1993) and our own earlier study (Murphy & Barkley, 1996), but they agree with the report of Minde and colleagues (2003) and another of our large studies (Murphy et al., 2002). The disparity in findings across these studies is not readily explained at this time and leaves open to doubt whether ADHD in adults is associated with a greater likelihood of divorce. Less in doubt is the consistently greater proportion of ADHD groups reporting poorer quality of their marital relationships.

When we examined sex differences in marital status in our studies, a few findings were noteworthy. Comparisons of males and females with ADHD within each group showed no differences for ever being married or being currently married, but females were more likely to have been divorced (21 vs. 7%, p = .013). As for the duration of marriage, the average length of time participants had been in their current marriages did not differ across groups when we controlled for age. (Marginal means were ADHD = 14.2, clinical = 12.9, community = 14.7 years.) And there were no sex differences in the percentage of participants who rated the quality of their marriage as poor.

We administered the Locke–Wallace Marital Adjustment Test (Locke & Wallace, 1959) to our participants and to a smaller sample of current spouses of our participants. We found that both the ADHD and clinical control groups reported significantly lower marital satisfaction than did the community control group (Barkley et al., 2008). In fact, the average score for both the ADHD and clinical groups fell within the range believed to reflect marital dysfunction (less than 100). The same results were observed for spousal reports on this same measure. Our results agree with our earlier report (Murphy & Barkley, 1996) and those of Minde and colleagues (2003) and Eakin and colleagues (2004) concerning greater marital dissatisfaction in the adults with ADHD compared to adults from a community sample. But unlike those studies, we also found greater dissatisfaction in the reports of their spouses. Nevertheless, our large study shows that such marital dissatisfaction, whether in self- or spousal reports, is not specific to just the ADHD group but also can be found in clinic-referred adults who are not diagnosed with ADHD. This is hardly surprising given that adults in the clinical group were also experiencing significant psychiatric disorders and psychological maladjustment, as well as higher than normal levels of ADHD symptoms, even if not formally diagnosed with ADHD, that would be expected to have some impact on marital relationships.

More detailed ratings of marital problems were collected in a pilot study involving 80 couples in which one partner had ADHD (Robin & Payson, 2002). The partners with ADHD had significantly more marital issues, felt more unloved, and reported a more negative impact of ADHD on the marriage than did the partner in the dyad without ADHD. Interestingly, the male partners without ADHD reported significantly greater marital problems on these three scores than did the female partners who did not have ADHD. This may imply perhaps that female partners who do not have ADHD are either more tolerant of their male partner's ADHD in a marriage or are less willing to express it than are males reporting about their female partner with ADHD. In research on a related topic, two studies with college students, one in the United States and the other in China, found that increased levels of ADHD symptoms were associated with increased fear of intimacy in intimate relationships, lower expectations for intimacy in the relationships, and lower relationship

self-confidence but no greater levels of sexual anxiety (Marsh, Norvilitis, Ingersoll, & Li, in press).

A recent study that observed the patterns of communication in intimate romantic couples directly corroborates results of these earlier studies based on rating scales. That study compared couples in which one partner had ADHD to a control group of couples without ADHD (Canu, Tabor, Michael, Bazzini, & Elmore, in press). Results indicated that couples in which one partner had ADHD combined type reported less relationship satisfaction and showed more negativity and less positivity in their behavior during a conflict resolution task compared to couples in which the partner had either the inattentive type of ADHD or no ADHD.

Such conflicted communication patterns seem to be consistent with another recent finding from two studies on the risk of violence in intimate partner relationships in adults with ADHD. Wymbs and colleagues (2012) studied adult males with a history of ADHD and found them to be more verbally aggressive and violent with their romantic partners than males without such a history. The presence of conduct problems in the males with early ADHD also was found to contribute further to the risk for such behavior. More recently, a study in England employed a representative sampling involving 7,369 households from which ratings of adult ADHD symptoms and reports of violence were collected (González, Kallis, & Coid, 2013). After adjusting for demographic factors and known clinical predictors of violence (antisocial personality, substance misuse, anxiety disorders), results indicated that adult ADHD was moderately associated with violence (odds ratio = 1.75) and that principally the hyperactive–impulsive dimension of the disorder, and not inattention, was linked to violence. Such violence was primarily with intimate partners. Mild to moderate levels of ADHD were linked to such intimate partner violence, whereas severe ADHD levels were linked to violence primarily through comorbidity.

To summarize, longitudinal studies of ADHD in children followed into young adulthood have not consistently documented differences in marriage or divorce probabilities, but the one study that went on the longest (33 years), extending into midlife, did so. Even so, the few studies examining ratings of marital or cohabitation satisfaction have suggested emerging problems in those relationships by young adulthood. Studies of clinic-referred adults or those ascertained by other means (parents of ADHD children) present a more mixed picture, with half finding higher divorce rates and others not doing so. But all studies have found that clinic-referred adults with ADHD, like children growing up with persistent ADHD to age 27, rate the quality of their marital or intimate relationships as less satisfactory. Ratings of marital communication, as well as direct observations of communication patterns, suggest lower positivity and greater negativity in conflict resolution tasks. And populationwide studies suggest a link between moderate levels of ADHD symptoms and likelihood of intimate partner violence. Adults with ADHD may be more likely to have children with ADHD, and child ADHD has been shown to increase the likelihood of parental marital problems and divorce even after researchers account for genetic relationships between parents and children (Schermerhorn et al., 2012). Perhaps this explains the mixed results in studies of adults with ADHD concerning rates of divorce; it is primarily couples with one partner who has ADHD *and* a child with ADHD that are likely to have the highest risk of marital problems and divorce. It is a hypothesis worthy of future research.

The problems noted earlier in intimate (dating, cohabiting, and marriage) relationships mean that clinicians working with adults with ADHD will have to identify regional resources to help their clients address these social difficulties. Intervention in relationships will be required for many adults with ADHD and their partners, beyond just the clinical management of ADHD symptoms via traditional treatments. Clinicians may also find it useful to share the trade book by Pera (2008) with adult clients with ADHD who have difficulties in their intimate relationships (see also Chapter 34).

MONEY MANAGEMENT

Until 2006, there seemed to be no research on the specific money management problems that may be associated with ADHD in clinic-referred adults other than off-handed references to a few problems. De Quiros and Kinsbourne (2001) reported that two items from their Adult Problem Questionnaire that pertained to money matters were rated as occurring more often in their ADHD group than in their control group. These concerned frequent shopping sprees and having trouble sticking to a budget. But given the poor impulse control and self-regulation associated with the disorder, it is reasonable to anticipate problems with handling money in adults with ADHD.

Children with ADHD as Adults

Subsequently, one study of children with ADHD (hyperactivity) followed to adulthood reported results for financial management at the age 21 follow-up. In the Milwaukee Study, Mariellen Fischer and I found that significantly more members of the community control group than members of the hyperactive (ADHD) group had ever had a credit card; otherwise, the groups did not differ in the proportion ever having had a car loan, other bank loans, or currently owing money to others (Barkley et al., 2006). Significantly fewer members of the ADHD group had a savings account, and more of the ADHD group reported having trouble saving money to pay their monthly bills. The groups' current annual salary amounts did not differ. Although the amount of average savings for the ADHD group was lower than that of the community control group, this difference was not significant. The groups did not differ in terms of debt amount of members who had owned credit cards, taken out current car loans, or had other outstanding bank loans. But members of the ADHD group owed significantly more money to other private individuals than did members of the community control group. Given that the participants in this study had an average age of approximately 21 years, there was not enough time since leaving school for differences in financial status and management issues to have become apparent. Even so, this study intimates that there might be some impact of ADHD on financial management later in adulthood if these current trends were to continue.

To explore that possibility, we again collected data on financial management from these same participants 6 years later at the age 27 follow-up (discussed in an earlier textbook; Barkley et al., 2008). The results for the categorical measures can be observed in Table 12.4. In all but one of the 13 money issues, a significantly larger percentage of the group with persistent ADHD to age 27 (H + ADHD) had problems than did the community control group. The exception was for writing checks with insufficient funds, in which no group differences were found. In seven of these problem areas, the H + ADHD group also had a higher risk than the nonpersistent ADHD (H – ADHD) group, including trouble managing their money, buying on impulse, missing rent and credit card payments, exceeding credit card limits, not having a savings account, and having a poor credit rating (self-reported). In some areas, the two hyperactive groups had more participants with problems than the community group but did not differ from each other, suggesting that having been a child with hyperactivity and ADHD carried some risk for financial problems even if the ADHD had not persisted to this follow-up. These areas included difficulty saving money, having utilities turned off for nonpayment, having a vehicle repossessed, declaring bankruptcy, and not saving for retirement. This was also evident in other problem areas in which the H – ADHD group fell below the H + ADHD group's level of risk yet remained at higher risk than the community controls, such as in managing money, buying on impulse, missing rent payments, and having a poor credit rating. In summary, both hyperactive groups had higher percentages of many of these financial problems than did the control group, which suggests that growing up with ADHD from childhood is a risk factor for financial difficulties even if that ADHD does not fully persist to age 27. But when ADHD does persist, it increases the risks of financial difficulties even more. Those problem areas in which the H + ADHD group differed from both the H – ADHD and community groups are visually depicted in Figure 12.1.

On the dimensional measures of finances, we found that members of both hyperactive groups were earning less money per month than members of the community control group, yet the hyperactive groups did not differ from each other in terms of income. The three groups did not differ statistically in the amount they had saved. A better index here of propensity to save is probably the ratio between money currently saved and total annual income, which in part controls for the greater income received by the control group, whose members therefore have the potential to save more. This measure clearly showed that members of the two hyperactive groups were saving proportionately about three times less as a function their annual income than were the control participants (3 vs. 4 vs. 11%, respectively).

The frequency with which various money problems had occurred in these groups did not differ across most other measures, except for exceeding the credit limit on credit cards, which the H + ADHD group did more often than the other two groups. The H + ADHD group members also reported having significantly poorer credit ratings than the other groups. Yet the H – ADHD group also reported a poorer rating than the community control group, which indicates that poor credit can be associated with children with ADHD growing up, even if their ADHD does not persist fully

TABLE 12.4. Money Management Problems by Group for the Milwaukee Study

Measure	(1) H + ADHD		(2) H – ADHD		(3) Community		χ^2	*p*	Pairwise contrasts
	N	%	*N*	%	*N*	%			
Trouble managing money	39	71	33	41	15	20	33.89	<.001	1 > 2 > 3
Difficulty saving money	35	65	43	54	14	19	32.11	<.001	1, 2 > 3
Problems buying on impulse	42	78	36	45	18	24	36.61	<.001	1 > 2 > 3
Ever missed paying rent	17	31	13	16	4	5	15.70	<.001	1 > 2 > 3
Had utilities turned off for nonpayment of bills	23	43	26	33	8	11	18.03	<.001	1, 2 > 3
Missed credit card payment	28	58	26	37	29	39	6.22	.045	1 > 2, 3
Exceeded credit limits on cards	28	64	27	39	33	45	6.98	.031	1 > 2, 3
Wrote check with insufficient funds to cover the amount	37	70	50	63	38	51	5.21	NS	
Had a vehicle repossessed	6	15	8	13	1	1	7.96	.019	1, 2 > 3
Declared bankruptcy	5	9	15	19	3	4	8.90	.012	1, 2 > 3
Do not have a savings account	33	61	31	39	20	27	15.61	<.001	1 > 2, 3
Not saving for retirement	42	76	53	66	34	45	14.16	.001	1, 2 > 3
Have a poor credit rating	29	54	26	32	6	8	32.42	<.001	1 > 2 > 3

Note. Sample sizes for the comparisons on interview information were H + ADHD = 55 , H – ADHD = 80, and community = 75 for all categories except car repossession, where N's = 40, 61, 69, respectively; exceeding credit card limits, where *N*'s = 44, 70, and 73, respectively; and missing a credit card payment, where *N*'s = 48, 71, and 74, respectively. *N,* sample size endorsing this item; %, percent of group endorsing this item; χ^2, results of the omnibus chi-square test; *p* = probability value for the chi-square test; pairwise contrasts, results of the chi-square tests involving pairwise comparisons of the three groups. H + ADHD, hyperactive group that currently has a diagnosis of ADHD at follow-up; H – ADHD, hyperactive group that does not have a diagnosis of ADHD at follow-up. A poor credit rating was categorized as a self-report of a credit rating of 4 or 5 (*poor* or *very poor*).

Statistical analyses: Pearson chi-square.

to age 27. We created a sum of the number of different money problems experienced by the participants. Here again the group with persistent ADHD (H + ADHD) had significantly more such problems than the other two groups, but the H – ADHD group also had more problems than the control group. Such findings suggest that as clinic-referred children with ADHD develop into adulthood, they have significantly more financial problems than do community control children, but the greatest money problems are found in children whose ADHD persists to age 27.

The Milwaukee Study also delved in detail into the extent to which participants engaged in various gambling activities and the size of their wagers. We did so because we believed that the impulse control problems experienced by the hyperactive groups might make them more susceptible to the ubiquitous opportunities for gambling now extant in the United States. We found little evidence for this hypothesis. The groups did not differ in the percentage that had ever bet money (73–80%), and specifically bet at state lotteries (73–78%), racetracks (25–37%), sports (47–56%), card games (48–67%), and slot machines (71–78%). There was also no difference in how often they played the state lottery; the average was less than four times per year across the groups and $3–5 per bet. There also were no differences in the frequency with which the groups had engaged in betting at the racetrack, on sports, and at slot machines, or differences in how much they spent each time, lost in a day, or the largest amount ever lost for those activities. The groups also did not differ in the number of different types of betting activities in which members had ever engaged. So we concluded that ADHD in children is not associ-

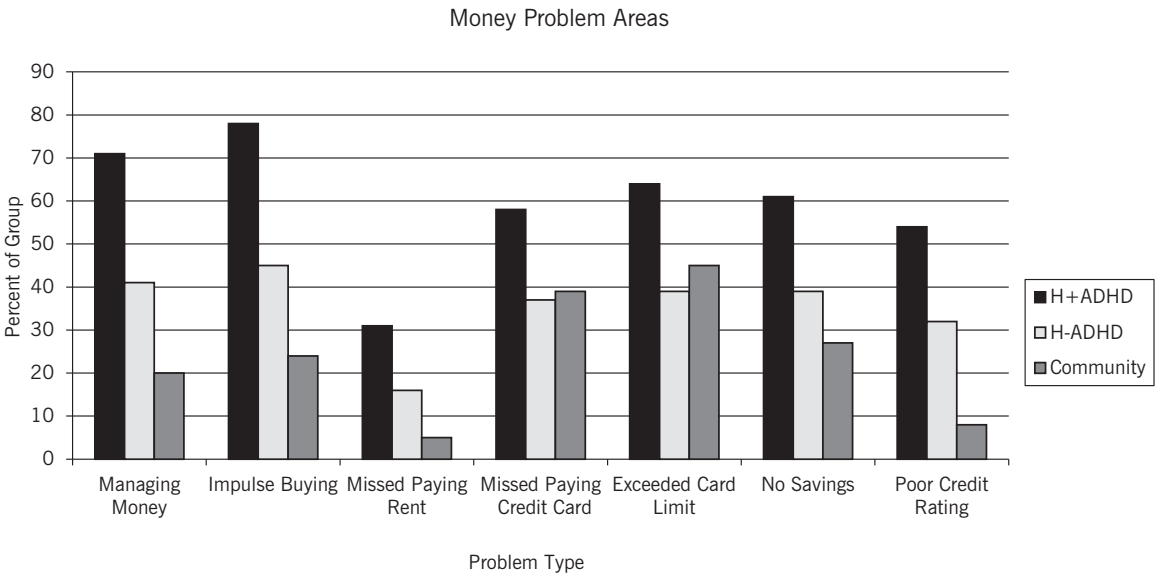

FIGURE 12.1. Percent of each group having various money management problems in the Milwaukee Study. These are the measures on which the H + ADHD group differed significantly from the H – ADHD and the community control groups. H + ADHD, hyperactive group that currently has a diagnosis of ADHD at follow-up; H – ADHD, hyperactive group that does not have a diagnosis of ADHD at follow-up. ated with elevated levels of gambling by young adulthood except perhaps for card playing as they grow up. We should not be surprised by this finding for several reasons. First, in the New York follow-up study (Mannuzza et al., 1993, 1998), the hyperactive group was no more likely than the control group to be diagnosed with pathological or addictive gambling-related disorders. Second, other research indicates that excessive gambling is related principally to antisocial personality disorder (ASPD) and not to ADHD (Raylu & Oei, 2002). Our subsequent analyses of our young adults who did and did not have ASPD largely confirmed this conclusion. Our young adults with ADHD were not more prone to gambling than the general population but those who likely had ASPD were more likely to bet on sporting events, play slot machines more often, and bet and lose significantly more money at most of these activities (Barkley et al., 2008). One recent study (Dai, Harrow, Song, Rucklidge, & Grace, in press) did find an association between ADHD and problem gambling, as well as performance on a simulated gambling task in small samples of adults with ADHD and controls. The findings were partially mediated by degree of impulsivity in the adults. But the study neither examined nor controlled for the overlap of adult ADHD with CD or ASPD; thus, it is not clear whether ASPD accounted for this association, which was not evident in prior studies. Future research is needed to sort out factors that may contribute to problem gambling in adults with ADHD.

More recent research has confirmed this association between ADHD in childhood and financial problems in adulthood. A large population-based study revealed that the presence of ADHD at ages 14–16 years was associated with 3.33 times the likelihood of high financial stress (worries about finances) by age 37 years (Brook et al., in press). Nearly 30% of those with ADHD were classified as having such a degree of financial distress, compared to just 11% of individuals without ADHD. Apart from ADHD, current smoking was also a significant, though far less substantial, predictor of high financial stress in adults.

Adults Diagnosed with ADHD

The only other study to look at financial problems in adults with ADHD to date was our UMASS Study, in which we compared adults clinically diagnosed with ADHD to clinical and community control groups (Barkley et al., 2008). The following discussion is taken largely from that textbook. We used the same financial interview with these participants as we did in the previously discussed Milwaukee age 27 follow-up, permitting a direct comparison of the two studies. The results concerning the percentage of each group experiencing 12 different money management problems appear in Table 12.5. More adults with ADHD reported problems in eight of the 12 areas of money management than did adults in the community control group. The ADHD group had a higher proportion of its members reporting problems with managing money, saving money, buying on impulse, nonpayment of utilities resulting in their termination, missing loan payments, exceeding credit card limits, having a poor credit rating, and not saving for retirement. Relative to the community control group, the adults with ADHD appeared to have pervasive problems with the management of their finances. The findings are consistent with the far less comprehensive report of De Quiros and Kinsbourne (2001) noted earlier, indicating a greater likelihood of shopping sprees and poor adherence to a budget in their adults with ADHD.

There were also problems that affected even a larger percentage of the ADHD group than the clinical control group. Those comparisons are depicted in Figure 12.2 and give a better picture of the risks associated specifically with ADHD and not just outpatient referral status. The ADHD group members were more likely to have trouble saving money, to buy on impulse, to avoid paying their utilities, and not to save for retirement. While the clinical control group also had difficulties in five of these areas compared to the community control group, they were less likely than the ADHD group to have such difficulties, particularly in saving money and buying on impulse. Those four areas of money management in which the ADHD group differed from both the clinical and community control groups involve rather specific financial problems having to do with deferred gratification (saving and putting money away for retirement), impulse buying, and probably organization and

meeting deadlines (nonpayment of utilities resulting in their termination).

We also had participants answer five financial questions having to do with the frequency with which they may have experienced a money problem. In all five measures, adults with ADHD reported these difficulties more often than did adults in our community control group. Money difficulties were also more common in the ADHD than in the clinical control group in at least four of these six areas, including missed rent, utility, and loan payments and having more total money problems. Missed loan payments was the most common problem reported across groups, though it was significantly more common in ADHD group members than in the two control groups. We also computed a money problem diversity score by summing the number of different problem areas in which a participant reported a problem across the 12 areas reported in Table 12.5. This index revealed that adults with ADHD have a significantly greater number of financial problems than either adults without full ADHD referred to clinics or community adults.

In comparison to the persistent ADHD group in our Milwaukee follow-up study discussed earlier, the percentages here for the clinic-referred adults with ADHD in the UMASS Study are nearly identical, with one exception: the larger percentage of the former group that had not yet begun saving for retirement—a difference that likely arises from the younger age of the sample used in the Milwaukee Study than that used in the UMASS Study. Overall, this is a striking replication of findings across two different methods of ascertaining ADHD in adults. It suggests that the disorder is strongly associated with financial management problems. What the Milwaukee Study adds to this conclusion is that risk for financial problems is also higher in individuals who had ADHD in childhood but were diagnosable as such at age 27 years.

One should not be surprised at these difficulties with money management given the problems with in-

hibition, executive functioning, and self-regulation associated with ADHD, as discussed in earlier chapters. These seem to be the only studies of adults with ADHD or children who grew up with ADHD that actually examine the impact of ADHD on specific problem areas related to financial management. From these studies we can conclude that the disorder does seem to have an adverse impact on many aspects of financial management, such as saving money, buying on impulse, and repaying debts. With advancing age, there will likely arise greater opportunities for problems with finances to become even more apparent in adults with ADHD at midlife.

Predicting Financial Problems

In the prior studies, my colleagues and I examined some possible predictors of these financial problems (Barkley et al., 2008). The financial outcome (criterion) we selected for prediction was the number of different money problems experienced by participants, described earlier as the money problem diversity score. Our analyses of the adults in the UMASS Study (clinic-referred adults) indicated that the severity of ADHD symptoms made a significant contribution to this money problem index, but so did the number of childhood CD symptoms retrospectively recalled, though of a much smaller magnitude than the degree of variance explained by ADHD severity. Education, IQ, criminal diversity, and the self-ratings of depression, anxiety, and hostility made no significant contribution to this index. Thus, ADHD largely accounts for the degree of financial difficulties of these participants, explaining nearly 21% of variance in the diversity of such problems.

We conducted the same type of analysis in the Milwaukee Study, which indicated that five predictors were significant and accounted for nearly 24% of the variance. These were severity of childhood hyperactivity (ADHD), pervasiveness of childhood ADHD and behavior problems, the number of CD symptoms at adolescent follow-up, and the number of ADHD symptoms (self-reported) and years of education at the prior age 21 follow-up. This study shows that not only adulthood (age 21) but also childhood ADHD symptoms and their pervasiveness predict current money problems. Beyond that, the severity of teen CD symptoms made a smaller additional contribution. In other words, persistence of ADHD to age 21 is a further predictor of financial problems; in addition, initial childhood ADHD severity and the development of CD symptoms by age 15 may further accentuate these financial adversities. Years of education was not an unexpected predictor given its link to occupational status and hence to income. These two studies are consistent in showing that ADHD and, to a lesser extent, CD are related to extent of current financial problems in adulthood. In subsequent papers, we reported that emotional impulsiveness is also associated with some of the financial problems (impulse buying, exceeding credit card limits, etc.) in both the Milwaukee follow-up study (Barkley & Fischer, 2010) and the study of adults diagnosed with ADHD (Barkley & Murphy, 2010).

In conclusion, it makes sense that adult ADHD would be associated not only with financial problems, in view of the symptoms and poor self-regulation associated with the disorder that would hamper sound judgments about managing money and credit, but also educational and occupational problems (discussed earlier) that would place more constraints on income of people with ADHD relative to those without the disorder. These findings also imply that clinicians who work with adults with ADHD need to be aware of resources in their region that may be able to assist these adults with managing their finances and associated legal problems, beyond just the traditional mental health treatments used to manage the disorder. Resources that may prove useful include the trade book for adults with ADHD on managing finances (Klein & Sarkis, 2009) and my own book for adults with ADHD (Barkley, 2010a).

ECONOMIC IMPACT OF ADHD-RELATED IMPAIRMENTS

Only a few studies have examined the economic costs associated with some of the previously discussed impairments, but their findings are both sobering and rather staggering in terms of the likely adverse economic impact associated with ADHD. The previous chapter covered the substantial health care-related costs of ADHD for both the patient and his or her immediate family. Recall the $1.8 billion in annual costs for ADHD-related treatments and $12.1 billion in other health care costs, not to mention $14.1 billion in health care costs for immediate family members (Birnbaum et al., 2005). But these other domains of impairments in major life activities discussed here for adults with ADHD also have their economic costs. For instance, in the aforementioned study, Birnbaum and colleagues also calculated that the cost of work loss associated with ADHD

was $3.7 billion annually. In a later study, Kessler, Lane, Stang, and van Brunt (2009) found that adult ADHD is linked to 4–5% poorer work performance and estimated the cost in the workplace to be $4,336 annually per worker with ADHD. This did not include the cost of workplace accidents that are believed to be more common in adults with ADHD. Fletcher (2014) recently estimated that by adulthood, childhood ADHD is associated with a 15% increase in the likelihood of receiving social (financial) assistance, a 10–14% reduction in the likelihood of being employed, and a 33% lower annual income. Furthermore, the cost in lost wages (hence, associated taxes paid and value to society) for those who do not complete high school compared to those who do is $630,000 over the course of one's working life (Chapman, Laird, Ifill, & KewalRamani, 2011). Considering that teens and young adults with ADHD are two to three times less likely to complete high school than the general population greatly adds to the societal economic costs of this disorder. Consider also the cost of criminal activities by teens and young adults with ADHD, which has been estimated to be $25,000 per youth and perhaps as high as $65,000 (Jones, Foster, and the Conduct Problems Prevention Research Group, 2009) at an estimated annual cost of $2–4 billion. Add to all of this the excessive costs of auto crashes associated with ADHD, estimated to be $2,600 per crash, with three times more crashes per patient with ADHD, and the uncalculated costs of greater bodily injury from such crashes (Barkley & Cox, 2007), and one can see the remarkable economic toll of ADHD that extends into adulthood. It should be evident that the total economic burden of ADHD far exceeds the intervention costs to treat this disorder in adults.

KEY CLINICAL POINTS

- ✓ The small literature on the educational histories of adults with ADHD has suggested numerous adverse effects of the disorder in the domain of major life activities, consistent with the follow-up studies of children with ADHD, but often suggesting somewhat less impairment in clinic-referred adults.
- ✓ Compared to children with hyperactivity or ADHD followed over development, the intellectual levels of adults with ADHD are higher, their high school graduation rates are higher, more are likely to have attended college, and their likelihood of having achievement difficulties is considerably less in most respects than that seen in children with ADHD followed to adulthood.
- ✓ Nevertheless, adults with ADHD rate themselves as being more impaired in educational settings than do adults in control groups. This is corroborated by the ratings provided by others, which indicate that ADHD is associated with impaired functioning in all of the specific educational situations we examined, including classwork, homework, class behavior, and behavior at recess and in the lunchroom, as well as overall time management.
- ✓ Although as many adults with ADHD graduate high school as those in control groups, fewer graduate from college, resulting in the ADHD group having less years of education.
- ✓ More of the adults with ADHD reported having been retained in grade, receiving special education, and being diagnosed with LD or behavior disorders while in compulsory schooling than did adults in either of the two control groups.
- ✓ Studies that obtained official school transcripts revealed a similar pattern. The ADHD group has a significantly greater percentage of poor (D) or failing grades (F) both on their elementary school and high school transcripts. They also had a lower grade point average and more days absent from school during high school than did the adults in control groups.
- ✓ Similarly, among college attendees, those with ADHD had more unsatisfactory grades, withdraw from more classes, and may have lower college entrance testing scores than did college students in control groups.
- ✓ Evidence of lower academic ability was also found on tests of educational achievement. The adults with ADHD had poorer scores in their arithmetic, spelling, and reading and listening comprehension skills than did adults in control groups.
- ✓ In contrast, follow-up studies indicate that having ADHD as a child is a major risk factor for most types of educational problems, whether or not the ADHD persists to age 27. Both hyperactive (child ADHD) groups were less educated, less likely to graduate high school, less likely to attend college, and more likely to have received various forms of educational assistance in school than the control groups. Compared to clinic-referred adults, it is clear that children growing up with ADHD are even more adversely affected in their edu-

cational careers, as implied by the earlier research literature.

- ✓ Concerning specific LD, clinic-referred adults with ADHD were more likely to have spelling and comprehension disorders (reading and listening) than community control groups, whereas only their listening comprehension disorders distinguished them from clinical control groups. Noteworthy is that the most common area of deficiency or specific LD had to do with reading and listening comprehension—abilities established previously to be deficiencies in children with ADHD related to their working memory deficits. Childhood ADHD, regardless of its persistence to adulthood, is more likely to be associated with specific LD than is adult ADHD.
- ✓ In their occupational functioning, clinic-referred adults with ADHD are rated by clinicians as functioning at a lower level overall than adults in control groups. They have experienced a number of problems in a higher percentage of their previous jobs than adults in control groups: getting along with others, demonstrating behavior problems, being fired, quitting out of boredom, and being disciplined by supervisors.
- ✓ Growing up as a child with ADHD is associated with lower job status and fewer current working hours per week regardless of whether the ADHD persists into adulthood. Even so, those with persistent ADHD experience even more difficulties in current workplace functioning than do either nonpersistent or control groups. Noteworthy is that children with ADHD that persists to adulthood have a far greater percentage of jobs in which they are fired or experience disciplinary actions than do clinic-referred adults with the disorder.
- ✓ Employer ratings corroborate these self-reports. Adults with ADHD are rated as having significantly more symptoms of inattention in the workplace, and as being more impaired in performing assigned work, pursuing educational activities, being punctual, using good time management, and managing daily responsibilities. These problems have also been found in earlier studies of children with ADHD followed to adulthood. Both types of studies provide direct evidence via not only self-reports but also blinded employer rating that ADHD has an adverse impact on workplace functioning.
- ✓ The results presented here clearly demonstrated that ADHD in adults is associated with a number of adverse outcomes and more impaired functioning in their educational and occupational histories than is the case for adults without ADHD or those diagnosed with other clinical disorders. Being diagnosed as ADHD in childhood has an even more adverse effect on one's educational career, eventual job status, and workplace adjustment problems (firings and disciplinary actions) than when ADHD is diagnosed in self-referred adults.
- ✓ Treating children with ADHD medications was found in several studies to result in a greater likelihood of being employed by adulthood, suggesting that longer term treatment of children and teens with medication may have downstream benefits on employability.
- ✓ Clinicians are likely to be asked to involve themselves in the educational impairments of those adults with ADHD still pursuing further education at the time of clinical evaluation. They may be asked to make recommendations concerning the need for and types of accommodations these adults are likely to require in those settings. In so doing, clinicians need to familiarize themselves with the standards of evidence required under the Americans with Disabilities Act for obtaining such accommodations (see Chapter 33).
- ✓ Clinicians may also be asked to evaluate workplace impairments and the types of accommodations that may be needed to deal with these impairments. When clinicians are untrained or uncomfortable in doing so, they should refer their patients to other professionals who specialize in vocational assessment, accommodations, and rehabilitation for the expertise that may be required to address the workplace difficulties of adults with ADHD. Here, again, familiarity with the appropriate aspects of the Americans with Disabilities Act will be required to obtain such accommodations (see Chapter 33).
- ✓ The pervasive adverse impact of ADHD in the workplace also indicates that long-acting ADHD medications will likely help adults with ADHD, much as they have done for the educational functioning of children with ADHD, and they may be even more useful given the longer hours adults spend in their jobs than they likely spent in school settings as children. In fact, long-acting medications may even need to be supplemented further with immediate-release medications to provide the additional hours of coverage these adults are likely to require beyond what was necessary to cover a child's school day. Less likely to be feasible

or adopted in employment settings are the behavioral interventions that have proven so useful in educational settings with children with ADHD; medication is therefore a more convenient and effective intervention component for adults with the disorder. Workplace accommodations may offer some additional benefits beyond medication for adults with ADHD, but no research is available to demonstrate their efficacy.

- ✓ Both children with ADHD as adults and clinically diagnosed adults with ADHD have more negative communication styles and display less positivity during conflict resolution discussions. They also report less satisfaction in their intimate, cohabiting, or marital relationships than do those without ADHD. The partners of these adults are also more likely to report that the relationship is less satisfying, particularly if the unaffected partner is male. Some recent evidence suggests that ADHD in adults may be associated with an increased risk of verbal aggression and violence in intimate domestic relationships apart from any risks posed by comorbid ASPD and mood or anxiety disorders.
- ✓ Evidence is mixed as to whether adult ADHD is associated with a higher frequency of divorce, but this may be partly due to the age of the sample. In contrast, children with ADHD followed to midlife do experience higher divorce rates that were not evident at earlier follow-ups.
- ✓ Clinicians need to be prepared to identify regional resources that assist adults with ADHD and their partners in addressing these intimate relationship problems apart from applying traditional ADHD interventions.
- ✓ Detailed research now documents that both children growing up with ADHD followed to ages 27–36 years and adults with ADHD diagnosed in adulthood experience a diversity of financial management problems, impulsive buying, excessive use of credit, and lower credit ratings and higher financial stress than comparison cases. These financial problems are largely due to the severity of ADHD itself, with symptoms of CD by adolescence making a smaller contribution to these adult financial problems.
- ✓ Excessive or pathological gambling may not to be a problem for adults with ADHD or children grown up with the disorder, although research on the issue is scant and results are mixed. That risk seems mostly to be the result of any comorbidity with ASPD or CD but possibly may be linked to impulsivity.
- ✓ Again, clinicians need to be cognizant of regional resources that can be brought to bear to assist adults with ADHD who have financial (and related legal) difficulties, beyond just applying traditional ADHD interventions for symptom reduction and management.
- ✓ The economic costs of ADHD calculated to date for lost workplace productivity, annual income, social assistance, educational failure, crime, and driving risks, not to mention the health care costs linked to the disorder apart from costs of treatment, are substantial. They far outweigh the costs that would be associated with intervention to treat this disorder effectively.

CHAPTER 13

Comorbid Psychiatric Disorders and Psychological Maladjustment in Adults with ADHD

Russell A. Barkley

As discussed in earlier chapters, children and adolescents diagnosed with attention-deficit/hyperactivity disorder (ADHD), especially if they are clinic-referred, have a high likelihood of having a second or even third psychiatric disorder besides ADHD. So do adults given a clinical diagnosis of ADHD (Marks, Newcorn, & Halperin, 2001). This chapter is an updated version of my earlier review of this topic in our book on ADHD in adults (Barkley, Murphy, & Fischer, 2008). Although the pattern of comorbidity in adults with ADHD is generally consistent with that seen in children followed to adulthood, there are some important differences that will be noted here. In general, 84% of children with ADHD that persists to adulthood have at least one other disorder; 61% have two disorders, and 45% have three comorbid conditions (Barkley et al., 2008). For clinic-referred adults with ADHD, these figures are 80, 66, and 20%, respectively. Adults with ADHD were also more likely to have at least three or more disorders (39%) compared to the clinical (20%) and community (4%) control groups (Barkley et al., 2008). Sobanski and colleagues (2008) likewise found that 76–87% of adults with ADHD (depending on subtype) had a lifetime occurrence of another psychiatric disorder. Similarly high rates of comorbidity were found by McGough and associates (2005) among parents of children with ADHD. They assessed psychiatric comorbidity in the parents of children with ADHD who were participating in a study of the genetics of the disorder. McGough and colleagues evaluated 435 parents who completed rating scales and structured diagnostic interviews. Parents who also had ADHD were more likely to have experienced psychopathology over their lifetime; 87% (vs. 64% of parents without ADHD) had at least one other disorder, and 56% (vs. 27% of parents without ADHD) had at least two other disorders. Specifically, ADHD was associated with higher rates of disruptive behavior disorders, substance use, and mood and anxiety disorders. Males were more likely to have exhibited disruptive behavior disorders, while female sex and oppositional defiant disorder (ODD) increased the risk of anxiety and depression.

EXTERNALIZING DISORDERS

ODD and Conduct Disorder

As in childhood ADHD, children with ADHD followed to adulthood have a considerable risk for comorbid ODD and conduct disorder (CD). For instance, in

the Milwaukee Study, Barkley and colleagues (2008) found that by age 27, approximately 47% of children whose ADHD persisted to that age had ODD compared to 16% of those with nonpersistent ADHD and 4% of control children followed to adulthood.

This is also true for clinic-referred adults with ADHD compared to both clinical control groups without a diagnosis of ADHD and normally developing, non-referred adults. For example, Miller, Nigg, and Faraone (2007) found that 27–31% of adults with ADHD had one externalizing disorder, and 27–41% had two or more compared to 28 and 14%, respectively, of control adults. Approximately 24–50% of adults with ADHD had current ODD, and 7–36% either had CD currently or at some time over the course of their earlier development (Barkley et al., 2008; Barkley, Murphy, & Kwasnik, 1996; Biederman et al., 1993; Cumyn, French, & Hechtman, 2009; Harpold et al., 2007; Murphy & Barkley, 1996; Murphy, Barkley, & Bush, 2002, Spencer, 2004; Wilens et al., 2009). Although these figures are below those reported in studies of children with ADHD, the rates for adults with ADHD may still be double or triple the rates reported for control adults (Barkley, Fischer, Edelbrock, & Smallish, 1990; Fischer, Barkley, Smallish, & Fletcher, 2002; Weiss & Hechtman, 1993).

Epidemiological studies also indicate an association between ADHD and these other disruptive disorders (Kessler et al., 2006; Secnik, Swensen, & Lage, 2005) as did the study of nonreferred adult relatives with children with ADHD reported by McGough and colleagues (2005). Among parents of children with ADHD who also meet criteria for ADHD, disruptive behavior disorders also occur significantly more often (Minde et al., 2003). For instance, Biederman and colleagues (1993) found that 53% of these parents have had ODD and 33% have had CD sometime in their lives, figures that are closer to those seen in follow-up studies of children with hyperactivity or ADHD.

Adults with ADHD who had ODD sometime in their childhood were at significantly greater risk of having bipolar disorder, multiple anxiety disorders, and substance use disorders than adults with ADHD without such a history of childhood ODD (Harpold et al., 2007). In a community sample, they were also at greater risk for more severe psychiatric symptoms, except for those involving dysthymia, generalized anxiety disorder, social phobia, and somatization, than were adults with ADHD alone or ODD alone. However, in a clinical sample, the comorbid group had more severe symptoms of antisocial personality, borderline personality, CD, mania, and schizophrenia (Gadow et al., 2007), with both disorders acting synergistically on the latter disorders when comorbid. The comorbid group was also likely to be younger, less likely to be employed, and less likely to be married. Likewise, adults with ADHD and comorbid ODD also manifest a distinct set of personality traits compared to those with ADHD alone; they are more likely to show histrionic, narcissistic, aggressive–sadistic and negativistic personality traits (May & Bos, 2000). All of this suggests that comorbid ADHD and ODD in adults, like its childhood counterpart, comprises a far more severe impairment constellation than is seen in either disorder alone.

Personality Disorders

Antisocial personality disorder (ASPD) is often an associated adult outcome in a significant minority of those children or adolescents who have both ADHD and CD. For instance, in the Milwaukee follow-up study (Barkley et al., 2008), 39% of children in whom ADHD persisted to adulthood had ASPD compared to 16% with nonpersistent ADHD and 4% of control children. It should therefore not be surprising to find that 7–44% of clinic-referred adults diagnosed with ADHD also qualify for a diagnosis of this personality disorder, typically between 25 and 30% (Biederman et al., 1993; Shekim, Asarnow, Hess, Zaucha, & Wheeler, 1990; Torgersen, Gjervab, & Rasmussen, 2006). Even among those who do not qualify for this diagnosis, many receive higher than normal ratings on personality traits associated with this personality disorder (Tzelepis, Schubiner, & Warbasse, 1995). A study of a large general population sample likewise found an association between ADHD in adults and ASPD (Kessler et al., 2006). Not surprisingly, then, a recent review of the literature involving 18 prospective studies documented a link between ADHD (with or without CD) and greater risk for later ASPD, a link also documented in 13 cross-sectional or retrospective studies (Storebø & Simonsen, in press). When the two disorders are comorbid, there is a greater incidence of violence and repetition of violence that may also be further exacerbated by comorbidity of ASPD and substance use disorders (González, Kallis, & Coid, 2013).

Although the issue has not been as extensively studied as ASPD, other personality disorders (PDs) are

also more common in children with ADHD that persists to adulthood (66%) in comparison to those with nonpersistent ADHD (28%) or control children (12%) (Barkley et al., 2008). For instance, in that study, a sizable minority of children with persistent ADHD had passive–aggressive (33%) or borderline PD (30%) compared to the nonpersistent group (19 and 13%) and the control group (3 and 0%).

There has been much less research on the occurrence of PDs other than ASPD in clinic-referred adults with ADHD. Miller and colleagues (2007) did find that ADHD in adults is a significant predictor of risk for having either a Cluster B or Cluster C PD. Whereas just 1–9% of adults with ADHD had a Cluster A disorder (compared to 3% of controls), 22–47% had a Cluster B disorder (vs. 9% of controls), and 16–23% had a Cluster C disorder (vs. 4% of controls). Consistent with these findings, Cumyn and colleagues (2009) found high rates of PDs (51%) compared to a clinical control group of adults (38%), as did Williams and colleagues (2010), who found that 45% of adults with ADHD had a PD (9% Cluster A, 17% Cluster B, and 28% Cluster C).

With regard to the comorbidity of adult ADHD and borderline PD, some results suggest that it is the overlap of ADHD and borderline PD that creates the impulsivity associated with this PD, along with a higher risk for substance use disorders and ASPD (Ferrer et al., 2010). In contrast, those adults who have borderline PD without ADHD seem to be at a greater risk for mood and anxiety disorders (Ferrer et al., 2010).

Substance Use Disorders

As noted in Chapters 5 and 11, substance dependence and abuse are known to occur to a more frequent degree among children with hyperactivity or ADHD followed to adolescence or adulthood, especially among those who had ODD in childhood and developed CD by adolescence or ASPD by adulthood (Barkley, 2006; Barkley et al., 2008; Harpold et al., 2007; Tercyak, Peshkin, Walker, & Stein, 2002). For instance, the Milwaukee Study (Barkley et al., 2008) revealed that children with ADHD that persisted to adulthood were significantly more likely to have a current substance use disorder (SUD) but not necessarily a past SUD (25% currently, 54% past) than children whose ADHD did not persist (10% currently, 53% past) or the control group (13% currently, 40% past).

Studies have found lifetime rates of alcohol dependence or abuse disorders ranging between 13 and 53% in adults diagnosed with ADHD, whereas 8–59% may manifest some other form of substance dependence or abuse disorder (Barkley et al., 1996, 2008; Biederman, 2004; Biederman et al., 1993, 1995; Duran, Fistikci, Keyvan, Bilici, & Caliskan, 2013; Minde et al., 2003; Murphy & Barkley, 1996; Murphy et al., 2002; Roy-Byrne et al., 1997; Shekim et al., 1990; Sobanski et al., 2008; Wilens, 2004; Wilens et al., 2009). Two large epidemiological studies (Kessler et al., 2006; Secnik et al., 2005) likewise found a link between alcohol use disorders and ADHD.

Tzelepsis and colleagues (1995) reported that of their 114 adults with ADHD, 36% had experienced alcohol dependence or abuse, 21% for cannabis, 11% for cocaine or other stimulants, and 5% for polydrug dependence. Moreover, at the point of their initial evaluation, 13% met criteria for alcohol dependence or abuse within the past month. Likewise, Torgersen and colleagues (2006) found that 45% of their sample of 45 adults with ADHD in Norway had lifetime alcohol abuse (33% currently), 51% for cannabis (36% currently), 49% for amphetamines (33% currently), and 16% for opiates (4% currently). Parents of children with ADHD who themselves have ADHD have also been found to have elevated risks for SUDS, primarily involving alcohol (McGough et al., 2005; Minde et al., 2003). Even so, the risk of SUDS in adults with ADHD, as in children with ADHD, may be mediated mainly by earlier or comorbid ODD, CD, or ASPD (Barkley et al., 2008; McGough et al., 2005; Wilens, 2004). The interaction of ADHD with ASPD and SUDS, as noted earlier, comprises a set of major predictors for violence and repetition of violence (González et al., 2013).

In summary, there is a clear clustering of risks for disruptive, antisocial, and drug use disorders with ADHD in adults, as was evident in Chapter 5 for children and adolescents with ADHD, especially as those youth enter young adulthood. While the elevated risks exist in the minority of cases, and is especially evident in those who had conduct problems as children or among their family members, the proportion is not inconsiderable. It poses a substantial economic cost to society, averaging $40,000 per youth with ADHD and CD by adolescence (Jones, Foster, & Conduct Problems Prevention Research Group, 2009) and by adulthood the cost for antisocial activities alone ranges between $2 and $4 billion U.S. dollars (Fletcher & Wolfe, 2009).

INTERNALIZING DISORDERS

In general, it appears that 32–41% of adults with ADHD may have one internalizing disorder, and 25–29% may have at least two or more (Miller et al., 2007). Below I discuss the risk for specific internalizing disorders.

Anxiety Disorders

As noted in Chapter 5, perhaps 25% of children with ADHD have an anxiety disorder (see Tannock, 2000). This was also the case in some adulthood follow-up studies of children whose ADHD had persisted to adulthood. The group with persistent ADHD had a greater risk for generalized anxiety disorder than did the nonpersistent ADHD group (16 vs. 1%) or controls (3%). Overall, the persistent ADHD group had twice the rate of risk for any anxiety disorders (46%) than that for children whose ADHD had not persisted (23%) or the community control group (9%) (Barkley et al., 2008). Posttraumatic stress disorder (PTSD) was also more common in the persistent than in the nonpersistent ADHD group (18 vs. 6%) or the control group (1%) in that same follow-up study. These results, however, do not agree with prior follow-up studies of children with ADHD into adulthood, where no such elevated risk of anxiety disorders or PTSD was evident (Mannuzza, Gittelman-Klein, Bessler, Malloy, & LaPadula, 1993; Mannuzza, Klein, Bessler, Malloy, & LaPadula, 1998; Rasmussen & Gilberg, 2001; Weiss & Hechtman, 1993). Why this should be so is not immediately obvious. But some research on adults with PTSD does imply that ADHD may be a risk factor for developing PTSD in male veterans (Adler, Kunz, Chua, Rotrosen, & Resnick, 2004).

Many studies of clinic-referred adults diagnosed with ADHD find an overrepresentation of anxiety disorders. The corresponding figure among adults is 16–43% for generalized anxiety disorder and 52% for a history of overanxious disorder (Barkley et al., 1996, 2008; Biederman et al., 1993; Duran et al., 2013; Minde et al., 2003; Shekim et al., 1990) with 37–43% having had any anxiety disorder compared to 11–26% of controls (Michielsen et al., 2013; Sobanski et al., 2008; Wilens et al., 2009). Torgersen and colleagues (2006) found that 13% of their adults with ADHD had lifetime panic disorder, and 18% had lifetime social phobia. Moreover, some recent research suggests that the risk for comorbid anxiety symptoms increases with age in adults with ADHD (Michielsen et al., 2013) and may be a function, in part, of comorbidity with depression (Fischer et al., 2007) and a childhood history of ODD (Harpold et al., 2007).

But not all studies of ADHD in adults have found it to be associated with anxiety disorders. Several of our own prior studies (Murphy & Barkley, 1996; Murphy et al., 2002) did not find that anxiety is overrepresented in those clinical samples of adults with ADHD compared to either community or clinical control groups (Barkley et al., 2008). Neither did Roy-Byrne and colleagues (1997) in comparison to a clinical control group. And although Cumyn and colleagues (2009) found a significantly higher rate of anxiety disorders in their adults with ADHD versus clinical control adults, they nevertheless reported relatively low rates in both groups (6–11% of adults with ADHD and 1–4% of controls).

Despite conflicting results for clinic-referred adults, the weight of the evidence leans toward such an association of risk. Moreover, the link between ADHD and anxiety disorders has been reported in two large epidemiological studies of adults (Kessler et al., 2006; Secnik et al., 2005). The prevalence of anxiety disorders among adults with ADHD who are relatives of clinically diagnosed children with ADHD is 20%, again suggesting some comorbidity with ADHD (Biederman et al., 1993). Parents of children with ADHD who themselves have ADHD likewise have significantly more anxiety disorders than do those parents in a control group (McGough et al., 2005; Minde et al., 2003). And college students with ADHD reported higher ratings of anxiety symptoms than do control students (Prevatt, Dehili, Taylor, & Marshall, in press). In conclusion, although there is some inconsistency concerning the comorbidity of ADHD in adults with anxiety disorders, the weight of the evidence favors some association, as it does in childhood ADHD (Angold, Costello, & Erkanli, 1999).

Research primarily with children with both ADHD and anxiety, as discussed in the Chapter 5, suggests that the comorbid conditions may result in reduced impulsivity and possibly more impaired working memory, and may manifest different symptoms of anxiety than anxiety disorders or phobias seen alone (see also Schatz & Rostain, 2006). No research could be located on these issues in adults with ADHD.

Mood Disorders

Major depression does seem to have some inherent affinity with ADHD in children, especially those hav-

ing CD (Angold et al., 1999; Spencer et al., 2000). Yet some follow-up studies have not been able to document an increased risk for depression or dysthymia among hyperactive children followed to adulthood (Klein et al., 2012; Mannuzza et al., 1998; Weiss & Hechtman, 1993). My own Milwaukee follow-up study of a large sample of hyperactive children found a prevalence of 28% for major depression by young adulthood (age 21)—a finding quite consistent with the studies on clinic-referred adults diagnosed with ADHD. But this excess comorbidity for depression or dysthymia did not persist to the age 27 follow-up (Barkley et al., 2008). However, at that follow-up, children whose ADHD had persisted to that age were more likely to have at least one mood disorder (13%) or depressive personality disorder (15%) than those whose ADHD had not persisted (3 and 5%) or the community control group (4 and 0%).

In contrast, the relationship seems to be stronger or more evident in clinic-referred adults diagnosed with ADHD. Approximately 13–45% of adults meeting ADHD diagnostic criteria also have concurrent major depressive disorder (Barkley et al., 1996, 2008; Biederman et al., 1993; Cumyn et al., 2009; Duran et al., 2013; Fischer et al., 2007; Michielsen et al., 2013; Roy-Byrne et al., 1997; Tzelepis et al., 1995), and 36–71% may experience it over their lifetime (Barkley et al., 2008; Sobanski et al., 2008; Spencer et al., 2000). And the risk for depressive symptoms appears to increase with age in adults with ADHD (Michielsen et al., 2013). However, in studies that used a clinical control group, this rate of depression did not differ even if the rate was higher than that in a community sample (Barkley et al., 2008; Murphy & Barkley, 1996; Roy-Byrne et al., 1997). One study of Norwegian adults with ADHD reported a lifetime prevalence of 53% and current prevalence of 9% for major depression (Torgersen et al., 2006).

Dysthymia, a milder form of depression, has been reported to occur in 19–37% of clinic-referred adults diagnosed with ADHD (Barkley et al., 2008; Murphy et al., 2002; Roy-Byrne et al., 1997; Shekim et al., 1990; Tzelepis et al., 1995). This rate is greater than that seen in a clinical control group, at least for current depression (27 vs. 16%, respectively) if not for lifetime occurrence (Barkley et al., 2008). Rucklidge and Kaplan (1997), in one of the few studies of women with ADHD, found that they reported more symptoms of depression, anxiety, stress, and low self-esteem, and a more external locus of control than did women in the control group. But psychiatric diagnoses were not reported in this study, which makes it difficult to compare this to earlier research using such diagnoses. In a study of parents of children with ADHD who also have ADHD, Minde and colleagues (2003) did not find a greater prevalence of major depression relative to a control group of parents (15 vs. 8%). The study, however, used small samples, limiting its representation of parents with ADHD and its statistical power to detect group differences. It also did not find elevated rates of ASPD, which, as discussed earlier, might be a potential moderator between ADHD and depression. In contrast, in the much larger study of a group of parents with ADHD who also had children with ADHD, McGough and colleagues (2005) did find more mood disorders than in their comparison group.

In general, the weight of the evidence suggests a low but significant relationship between ADHD in adults and risk for depression, or at the very least dysthymia. The fact that relatives of children with ADHD who themselves have ADHD also have elevated rates of depression does suggest some familial/genetic association between the disorders, as does the literature on comorbidity between the disorders in epidemiological samples of children (Angold et al., 1999) and adults (Kessler et al., 2006).

Some recent research has examined possible mediators of the connection between ADHD symptoms and those of depression. For example, Meinzer, Petit, Leventhal, and Hill (2012) found that the degree of hedonic responsiveness is a direct mediator between severity of ADHD inattentive (but not hyperactive–impulsive [HI]) symptoms and those of depression. "Hedonic responsivity" refers to the degree of reactivity to pleasurable or rewarding stimuli and is a heritable difference among individuals. The failure to respond to rewarding stimuli has previously been linked to the degree of anhedonic symptoms in depression and, in this study, to the degree of inattention in ADHD adults. Seasonality may be another risk factor, in that adults with ADHD have significantly higher rates of seasonal affective disorder (Rybak, McNeely, Mackenzie, Jain, & Levitan, 2007), which, according to one study, occurs in as many as 27% of adults with ADHD and in significantly more women than men (Amons, Kooij, Haffmans, Hoffman, & Hoencamp, 2013). A third mediator between adult ADHD and depression may be the degree of deficits in executive functioning (EF), particularly as assessed by ratings of EF in daily life rather than neuropsycho-

logical EF tests (Knouse, Barkley , & Murphy, 2012). Poor time management, poor self-organization, and poor problem solving in particular showed the most robust relationships between adult ADHD and depression. These various mediators, along with the degree of stress and occupational, educational, social, financial, and other impairments adults with ADHD are likely to experience, may act to increase the risk for depression, along with the increased family/genetic loading for depression among those clinically diagnosed with ADHD (Faraone & Biederman, 1997).

Noteworthy to recall, as discussed in Chapter 11, is that depression and ADHD may be a potent combination for increasing the risk of suicide attempts in not only children but also adults.

The relationship between ADHD in adults and *bipolar disorder* (BPD) is less well established. Follow-up studies of children with ADHD into adulthood typically do not report elevated rates of this disorder by adult outcome (Barkley et al., 2008; Barkley, Fischer, Smallish, & Fletcher, 2002; Mannuzza et al., 1993, 1998; Weiss & Hechtman, 1993). This was also the case in the large epidemiological study by Kessler and colleagues (2006) and in the Norwegian sample studied by Torgersen and colleagues (2006), in which the prevalence was 7% for lifetime disorder and 2% currently. These figures are comparable to what is often found in follow-up studies of children with hyperactivity and ADHD into adulthood (Barkley et al., 2008; Fischer et al., 2002) and are close to the base rate for the general population. Conflicting with these results are those studies by Biederman (2004), who reported an elevated risk for this disorder in clinic-referred adults (11–14%). Secnik and colleagues (2005) also reported a small but elevated risk for comorbidity of ADHD and BPD (4.5 vs. 0.6%). Even if adults with ADHD do not qualify for a diagnosis of BPD, they may show elevated levels of symptoms of bipolar spectrum disorder (51%; Halmoy et al., 2010). The relationship of ADHD to BPD in adults is therefore open to some doubt; most studies do not find this association. Clearly the issue is in need of more research before we can be confident of any directionality of this pattern of comorbidity between ADHD and BPD.

However, the reverse direction is far less in doubt. There is a very high occurrence of ADHD in samples diagnosed with BPD that is related to age of onset; it can run as high as 38–98% of child and adolescent BPD cases and 9–35% of adult cases (Klassen, Katzman, & Chokka, 2010). The coexistence of these two disorders in adulthood is associated with a more severe course of disorder, more severe mood symptoms, and lower psychosocial functioning (Klassen et al., 2010). Childhood or current ADHD may also be associated with an earlier onset of first affective episode, more frequent occurrence of such episodes, and more interpersonal violence than is seen in adults with BPD without ADHD (Ryden al., 2009).

Obsessive–Compulsive Disorders

Obsessive–compulsive disorder (OCD) has not been shown to be overrepresented in children with ADHD followed to adulthood (Barkley et al., 2008; Mannuzza et al., 1993, 1998; Weiss & Hechtman, 1993). One study initially reported the occurrence of OCD in 14% of clinically diagnosed adults with ADHD (Shekim et al., 1990). In a later study in Turkey, Duran and colleagues (2013) also found a higher than expected prevalence of OCD in adult outpatients with ADHD (17%). However, Tzelepis and colleagues (1995) were unable to replicate this finding and reported that only 4% of their adults met diagnostic criteria for OCD. Roy-Byrne and colleagues (1997) likewise reported a 4.3–6.5% prevalence rate, which was not significantly different from that of their clinical control group. In a large sample of clinic-referred adults, we found no higher incidence of OCD relative to a community group, but did find it to a small degree in a clinical control group (Barkley et al., 2008). Spencer (1997) found that OCD was more common (12%) only among those adults with a comorbid tic disorder, whereas the figure for adults with ADHD without tics was approximately 2%. Thus, OCD does not appear to be significantly associated with ADHD in clinic-referred adults unless tic disorders or Tourette syndrome are also present.

To summarize, past research suggests a higher than expected association between ADHD in adults and comorbid ODD, CD, ASPD, SUDs, and probably depressive disorders (major depression and dysthymia). The link between ADHD and SUDs is likely mediated by the association of ADHD with CD or ASPD. So may be the link between ADHD and major depression. The relationship between adult ADHD and adult anxiety disorders is inconsistent in past research. The link between ADHD and BPD is even less well established, especially for adults with ADHD. There seems to be no elevated risk for OCD among adults with ADHD.

PSYCHOLOGICAL MALADJUSTMENT

The previously discussed research has approached the subject of comorbidity with ADHD from the psychiatric, categorical view of disorders. Another approach is the psychological, dimensional view that examines differences between groups on more continuously scaled measures of these same domains of psychological maladjustment. At least five prior studies have taken this approach to evaluating their clinic-referred adults with ADHD using variations of the Symptom Checklist–90—Revised (SCL-90-R; Derogatis, 1986). The study by Shekim and colleagues (1990) also reported results for this instrument, but not in comparison to any clinical or community control group. They did find that patients with ADHD and panic disorder have significantly higher scores on many of the scales of this instrument than did those without panic disorder. My colleagues and I conducted four of these five studies (Barkley et al., 1996, 2008; Murphy et al., 1996, 2002) and found that clinic-referred adults with ADHD had significantly greater elevations on most if not all scales of the SCL-90-R relative to either clinical control or community control groups. The exception is the study in which Roy-Byrne and colleagues (1997) compared individuals with probable ADHD and those with possible ADHD and no ADHD, all of whom had been seen at a psychiatric clinic. No differences were found among these groups on any of the SCL-90-R scales. Likewise, we have found children whose ADHD persisted to adulthood to be significantly more maladjusted on all of these scales than either children whose ADHD did not persist or a control group (Barkley et al., 2008). Thus, the previous study by Roy-Byrne and colleagues is truly the exception to the rule: Adults with ADHD do manifest significantly more psychological maladjustment on most dimensions of such maladjustment than do either community control adults or clinic-referred adults without ADHD seen at the same clinic.

Using a different set of instruments, Ramirez and colleagues (1997) found that adults with high levels of ADHD symptom express more anger, and in more dysfunctional ways, and are more labile in anxious/depressed moods than those with lower symptoms levels. Higher elevations on all scales of psychopathology were also evident on the Young Adult Behavior Checklist (Achenbach, 2001; for both self- and other-report forms) in our study of clinic-referred adults with ADHD (Barkley et al., 2008). In these findings, displayed in Table 13.1, one can also see that adults referred to the same clinic who did not meet DSM-IV criteria for ADHD, although they had significantly elevated symptoms of the disorder, were significantly more maladjusted than control adults on all scales. Similar to the findings of Ramirez and colleagues, noted earlier, the scales on which members of the ADHD group displayed even more maladjustment than the clinical control group included Anxiety–Depression, Attention Problems, Intrusive, Aggressive, and Delinquent on the self-report version and just the Aggressive scale on the other-report form.

Taken together, these results indicate that adults with ADHD are more psychologically maladjusted than adults without diagnosable ADHD seen at the same clinic or community adults. They are most likely to differ from adults with other psychiatric disorders on scales evaluating externalizing psychopathology, such as Aggression, Antisocial Behavior, and Disruptive or Intrusive Behavior, and to a lesser extent on Anxiety–Depression. Given the variety of comorbid disorders associated with ADHD in adults documented earlier, this pattern is not unexpected.

INTELLECTUAL DISABILITY

There is very little research on comorbidity of intellectual disability (ID) and ADHD. Perhaps this is because most researchers who study ADHD in adults select samples with at least low-average or higher IQ. As indicated in Chapter 4, children with ADHD typically average 7-10 points less in their intelligence quotients (IQs) than do control groups of typically developing children (Frazier, Demareen, & Youngstrom, 2004). Although the correlations between ADHD severity and IQ in these studies and those of general population samples are rather small ($r < .30$), most are significant, implying some relationship between these two variables that share 5–9% of their variance (see Barkley, 1997, for a discussion; also Simonoff, Pickles, Wood, Gringras, & Chadwick, 2007). The detrimental relationship of ADHD to IQ can emerge as early as the preschool years (Friedman-Weieneth, Harvey, Youngwirth, & Goldstein, 2007; Loe et al., 2008). All this seems to imply that children with the disorder would have a higher percentage of cases qualifying as ID than would control cases, since the ADHD distribution of IQ would be shifted about one-half a standard devia-

TABLE 13.1. Young Adult Self-Report and Other-Report Form Scales for the Adult Behavior Checklist by Group (*T*-Scores) in the UMASS Study

	(1) ADHD		(2) Clinical		(3) Community				Pairwise

Aggressive[A, G×S]	62.4	7.6	58.7	6.3	50.6	1.7	48.7	<.001	1 > 2 > 3
Delinquent[A]	59.5	7.6	57.9	7.8	51.5	3.5	14.1	<.001	1, 2 > 3

Note. Sample sizes for the self-report scales are ADHD = 120, clinical control = 75, and community control = 83. For the other-report scales, they are ADHD = 76, clinical control = 38, and community control = 45.

SD, standard deviation; *F, F*-test results of the analysis of variance (or covariance); *p,* probability value for the *F*-test; NS, not significant, [S], significant main effect for sex (see text for details), [G×S], significant group × sex interaction (see text for details); [A], age used as a covariate in this analysis.

Statistical analyses: Groups were initially compared using two-way (groups × sex) analysis of variance (or covariance as necessary). Where this analysis was significant ($p < .05$) for the main effect for group, pairwise comparisons of the groups were conducted, the results of which are shown in the last column.

tion to the left of that for typical children. Children with ADHD followed to adulthood likewise are typically found to have slightly but significantly lower IQ scores than controls (Barkley et al., 2008) and could therefore be expected to have a higher than usual percentage of individuals with ID, though few researchers have actually computed the figure from their results.

Study results are mixed on whether ADHD in clinic-referred adults is associated with lower IQ, however. Intelligence estimates for such adults fell in the normal range and were comparable to those of control groups of clinic-referred adults in several of my own prior studies (Barkley et al., 1996, 2008; Murphy & Barkley, 1996; Murphy et al., 2002). In contrast, Biederman and colleagues (1993) found that their adults diagnosed with ADHD had IQ scores significantly below those of their control groups. Yet the IQ scores for the adults with ADHD were 107–110, nearly identical to the results of our own studies of adults with ADHD. The adults with ADHD in the Biederman and colleagues study therefore seem to differ significantly from the control groups only by virtue of the fact that the control group had above-average IQs (110–113).

Among adults with borderline to mild ID, one study indicated that IQ was negatively affected by ADHD severity to a low but significant degree (Xenitidis, Paliokosta, Rose, Maltezos, & Bramham, 2010). Similarly, two separate meta-analyses examining IQ in adults

with ADHD indicated mild reductions in IQ associated with the disorder (effect size of about 0.25) (Bridgett & Walker, 2006; Hervey, Epstein, & Curry, 2004), with one review concluding that the differences were not of much clinical significance and likely arose due to comorbidity rather than to ADHD itself (Bridgett & Walker, 2006). In the other review, Hervey and colleagues (2004) implied that such mild deficits may be linked to the few subtests of IQ batteries that evaluate working memory, as well as perceptual–motor speed, both of which are often moderately or more impaired in adults having the disorder. Excepting these subtests, adult ADHD may not be associated with lower intelligence, as indexed by other subtests. In general, then, it seems reasonable to conclude that at least clinic-referred adults with ADHD are of average IQ, probably do not differ from typical adults to an appreciable extent, and therefore likely do not have a higher percentage of ID than the adult population. This is not the case for children growing into adulthood with ADHD, in whom deficits in IQ are greater and so the likelihood of a higher percentage placing in the ID range of IQ would be expected.

What of the inverse relationship of ADHD among individuals with ID? Studies of children and teens routinely reveal that those with ID are 2.5–4.0 times more likely to have ADHD than controls without ID, or about 14–40%, and that ADHD is the most common comorbidity found in cases of ID (Baker, Neece, Fenning, Crnic, & Blacher, 2010; Neece, Baker, Crnic, & Blacher, 2013). Studies of adults with ID suggest that approximately 20% may qualify for a diagnosis of ADHD based on high levels of symptoms on an ADHD screening scale (La Malfa, Lassi, Bertelli, Pallanti, & Albertini, 2008); this is likewise about four or five times greater than the prevalence in general population samples. Among individuals with comorbid ID, ADHD symptoms are often more severe and appear to cohere with each other in ways not seen in individuals with ADHD only, they are less likely to remit with age (Xenitidis et al., 2010), and they may be linked to higher rates of aggressive behavior (Cooper et al., 2008). Objective measures of attention and inhibition likewise show adults with comorbid ADHD + ID to have more severe deficits, even after researchers control for general IQ, than do adults with ADHD only (Rose, Bramham, Young, Paliokosta, & Xenitidis, 2009).

Thus, the comorbidity of ADHD and ID is largely a one-way risk. Whereas having adult ADHD does not appear to increase the risk for ID, though a very minor detrimental effect on IQ may be evident in large samples, having ID results in a substantially elevated risk of having ADHD. The coexistence of both disorders is a harbinger for more severe and persistent ADHD and increased aggression.

KEY CLINICAL POINTS

- ✓ In general, there appears to be convincing evidence that ADHD increases the liability for certain other psychiatric disorders. More than 80% of members of ADHD groups had at least one other disorder, more than 50% had two other disorders, and more than 33% had at least three other disorders—all of which occurred more frequently than in control groups.
- ✓ There is a markedly elevated risk for ODD, and to a lesser extent for CD, in clinic-referred adults with ADHD and in adults who as children had ADHD.
- ✓ Adults with ADHD show a greater risk for alcohol use disorders than do clinic-referred or control adults and also a greater risk for cannabis use disorders compared to community controls. Results suggest that alcohol use disorders and risk for any drug use disorder may be specifically linked to ADHD, though the level and type of drug use disorders probably have more to do with comorbid ODD, CD, and ASPD, as well as local access to specific drugs, than to ADHD per se.
- ✓ The internalizing disorders of major depressive disorder, dysthymia, and anxiety disorders are more likely to occur in individuals with ADHD referred to clinics than in a community control group. But major depressive disorder and anxiety disorders are also significantly elevated in clinical controls without ADHD seen at the same ADHD clinic and therefore may not be linked as specifically to ADHD as to general outpatient psychopathology. Even so, epidemiological studies in both children (Angold et al., 1999) and adults (Kessler et al., 2006) find some association between ADHD and depression, which makes it unlikely that findings of a limited association are purely due to referral bias.
- ✓ It seems to be dysthymia or depressive personality disorder that is most convincingly elevated in individuals with ADHD beyond that risk seen in clinical control groups.
- ✓ BPD and OCD symptoms are not significantly elevated in the ADHD groups and are therefore not generally comorbid with ADHD.

- ✓ In a dimensional examination of comorbidity using the SCL-90-R, adults with ADHD (whether clinic-referred adults or children who have grown up) showed elevations on all scales of psychological maladjustment relative to community controls and on most of the scales relative to clinical control groups. There is clearly greater maladjustment of all types associated with ADHD than in clinical or community comparison groups. Such findings imply that ADHD is a more severe psychological disorder than many outpatient disorders seen in the same clinics.
- ✓ IQ may be somewhat lower, if at all, in adults with ADHD, and this difference may be due in part to subtests of IQ batteries that evaluate working memory and perceptual–motor speed, both of which are typically deficient in individuals with ADHD. It is therefore unclear whether ADHD is associated with mild intellectual delay, independent of these subtests.
- ✓ Clinicians need to be aware and to assess specifically for the high comorbidity of ADHD and other psychiatric disorders, particularly dysthymia, depression, ODD, CD, alcohol use disorders, and drug use disorders more generally.
- ✓ Such comorbid disorders and psychological problems are highly likely to require separate treatment approaches than those likely to be aimed at the management of ADHD symptoms and their related impairments.
- ✓ ADHD in adults, particularly when seen in clinic-referred adults, is therefore likely to require polypharmacy more than is the case for childhood ADHD given the higher risk for comorbid mood and anxiety disorders than is seen in children. While ADHD drugs, such as stimulants and nonstimulant norepinephrine reuptake inhibitors, are clearly indicated for such cases, they are unlikely to address the risk for mood disorders evident here, and likely require separate medical (i.e., antidepressant, mood stabilizing) and psychological (i.e., cognitive-behavioral) treatments in their own right.
- ✓ The elevated risk for anxiety disorders in both clinic-referred adults with ADHD and children with ADHD that persists to adulthood also suggests (1) that the nonstimulant, atomoxetine, may be of some benefit for these comorbid cases given that it does not exacerbate anxiety and may reduce it to some extent, and (2) that cognitive-behavioral interventions having utility in management of anxiety disorders generally may be of some benefit for this comorbid population.
- ✓ Drug detoxification and rehabilitation programs will also be required for that subset of individuals with comorbid ADHD and drug use disorders, many of whom are also likely to have ASPD or a history of CD. Early and aggressive treatment of the ADHD seen in these comorbid cases at initial entry into detox or rehabilitation programs offers the best chance of assisting these individuals with their rehabilitation efforts. Ignoring it is highly likely to result in recurrent treatment failures due to the significant self-regulation and executive deficits identified with this disorder.

Etiologies of ADHD

Russell A. Barkley

Since the previous edition of this volume, great strides have been made in understanding the etiologies of ADHD; indeed, this may be the area that has advanced most in research in the interim, more than any other topic on ADHD. Certainly it is among the most important topics because an understanding of etiologies may lead to improvement in treatments of the disorder and possibly someday even its prevention in some cases. Despite some inconsistencies across studies, laboratories, samples, and measures that will always be part of scientific research into mental disorders, important conclusions can be drawn about the causes of ADHD from the extant and voluminous research. There is no doubt now among investigators that ADHD is a "neurodevelopmental" disorder and has even been classified as such in the most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013; also see Chapter 2). Although, clearly, there are multiple etiologies that contribute to attention-deficit/hyperactivity disorder (ADHD), evidence points to primarily genetic and neurological factors and their interactions with the environment, particularly biologically influential features of it (e.g., toxins and infections), as the greatest contributors to the occurrence of the disorder.

Our knowledge of the final common neurological pathways through which these factors produce their effects on cognition and behavior has advanced remarkably in the past decade. Converging lines of evidence come from multiple studies using functional and structural neuroimaging research, such as positron emission tomography (PET), magnetic resonance imaging (MRI), and functional MRI (fMRI), along with more recent means of analyzing their results to obtain incredibly detailed portraits of neuronal networks and brain microstructure. So numerous are these studies that meta-analyses of their findings have become routinely published reviews in this literature every few years. While abnormalities at the neurochemical or cellular level that may underlie this disorder have still proven difficult to document, even this area of research suggests that more is involved in this disorder than just disturbances in one or two neurotransmitter activities, such as dopamine or norepinephrine, and that developmental processes involved in cell migration, termination, and support may also be implicated. Remarkably, studies have begun to combine the findings from molecular genetics with those from neuroimaging and neurophysiology to allow us to better understand the impact of variations in gene structure (polymorphisms and copy number variants, both common and rare) on the development, structure, and functioning of various brain networks that are implicated in the disorder. Yet further evidence also indicates that some cases of

ADHD may be acquired as a consequence of exposure to various biohazards, especially during fetal brain development and, to a lesser but still significant extent, postnatal development. Still others may arise from interactions between genetically at-risk children and environmental toxins and adversities. In a few cases, ADHD might arise from new genetic mutations that occur in the sperm or fertilized egg in becoming a fetus; thus, a new genetic case of ADHD may arise that was not inherited from parents.

Just as importantly, there is no credible evidence to indicate that the social environment alone can lead to a child developing ADHD. No convincing evidence or even a scientific hypothesis concerning the social causation of ADHD has been advanced during the past decade, and those from earlier decades, such as poor parenting, have not proven to be consistent with the known scientific findings on the disorder. Nor do such simplistic ideas have any explanatory or predictive value in understanding the disorder or driving further scientific research to test it (falsifiability). What was stated in the previous edition and has now become even more abundantly clear, given what is now known, there cannot be such explanations. That is, because numerous studies of twins and families have made it abundantly clear that the majority of variation in behavioral traits that comprise ADHD is the result of genetic and related factors. What little variation remains is best explained by the child's exposure to unique events that affect him or her and not the siblings. These environmental events are likely to be biological hazards such as prematurity, prenatal toxins, prenatal infections, and postnatal events (lead poisoning, traumatic brain injuries, etc.) that disrupt further brain development and even interact with genetic susceptibilities (candidate gene polymorphisms) to the disorder. Some unique psychosocial adversities may likewise interact with genetic susceptibilities toward disorder. Yet we are now able to conclude unequivocally that ADHD cannot and does not arise from purely main effects of social factors, such as childrearing, family conflict, marital difficulties, insecure infant attachment, television or video games, the pace of modern life, or interactions with peers, among other popular notions from earlier epochs. This is not to say that such social factors may not have some influence on current and future functioning in cases of ADHD, or that they may not interact with neurological and genetic susceptibilities to the disorder. Social environments are clearly influential and supported in research based on their impact on risks for subsequent impairments in major life activities; risks for comorbid disorders; and access to diagnostic, treatment, and educational resources, all of which impact current and eventual adult outcomes of the disorder. But the prevailing evidence makes clear that these social factors alone do not create ADHD de novo in an otherwise normal or typical child. Continuing claims to the contrary by lay critics bespeak a stunning ignorance of the prolific literature on the neurological and genetic contributions to the disorder and even the growing evidence of gene × bioenvironment interactions.

So abundant is the literature now on the etiologies of ADHD that only broad highlights can be presented here given the space limitations. But the advances have been most impressive even if the detailed results of individual studies cannot be thoroughly presented here.

GENETIC FACTORS

It is now clear that ADHD is among the most genetically influenced of all psychiatric disorders, rivaled perhaps by bipolar disorder and autistic spectrum disorders, but exceeding the genetic contribution to anxiety and depression, among most other disorders. For the most part, ADHD is not the result of abnormal chromosomal structures, as in Down syndrome; chromosomal fragility (as in fragile X) or transmutations; or extra chromosomal material, as in XXY syndrome. However, children with rare genetic abnormalities may have an increased risk for developing ADHD, such as those with veliocardiofacial syndrome, although they may have a different profile of ADHD symptoms and risk for comorbid psychiatric disorders than do children with idiopathic ADHD (Antshel et al., 2007). Children with fragile X syndrome also may have even higher rates of ADHD inattention symptoms than do control children (93 vs. 38%) (Farzin et al., 2006; Tranfaglia, 2011). Likewise, 24% of children with Turner syndrome have ADHD in comparison to 1.3% in the control children (Russell et al., 2006). While children with such chromosomal abnormalities may have more problems with attention, and even higher than typical rates of ADHD, such genetic abnormalities are very uncommon in children with ADHD. By far, most research evidence suggests that ADHD is highly hereditary in nature, making heredity one of the most substantiated etiologies for ADHD.

Family Aggregation Studies

Multiple lines of research support such a conclusion. For more than 40 years, researchers have noted the significantly higher prevalence of psychopathology generally, and ADHD specifically, in the parents and other relatives of children with ADHD (Cantwell, 1972; Morrison & Stewart, 1971). In particular, higher rates of ADHD, conduct problems, substance abuse, and depression have been repeatedly observed in studies of these families dating back several decades (Barkley, DuPaul, & McMurray, 1990; Biederman et al., 1992). Research indicates that parents of children with ADHD are two to eight times more likely to have the disorder than parents of control children. Between 10 to 35% of the immediate family members of children with ADHD are also likely to have the disorder; the risk to siblings of children with ADHD is approximately 32% (Biederman et al., 1992; Biederman, Keenan, & Faraone, 1990; Faraone et al., 1992; Levy & Hay, 2001; Welner, Welner, Stewart, Palkes, & Wish, 1977). Not only do children of parents with ADHD have a higher risk for ADHD, but both the type and severity of the children's ADHD and other externalizing disorders are significantly correlated with the severity of their parents symptoms and disorders (Bornovalova, Hicks, Iacono, & McGue, 2010; Macek, Gosar, & Tomori, 2012), especially those of the father (Macek et al., 2012), and this tendency is genetically transmitted from parent to child (Bornolova et al., 2010). Higher than expected rates of family aggregation of the disorder have been found in African American families similar to rates reported in families of European American children (Samuel et al., 1999). And these higher rates are equally evident in the families of both girls and boys with ADHD (Faraone et al., 2000; Faraone & Doyle, 2001). Even more striking, research shows that if a parent has ADHD, the risk to the offspring is 57% (Biederman et al., 1995). Further evidence for the familial clustering of ADHD in families of affected children came from a study in which Smalley and associates (2000) identified families having at least two affected children with ADHD (n = 132). They then assessed the 256 parents in these families for various psychiatric disorders and found that 55% of the families had at least one parent with a lifetime diagnosis of ADHD. Thus, ADHD clusters far more than expected, as demonstrated by the higher rate of the disorder among biological relatives of children or adults with the disorder than is the base rate for the typical population, strongly implying a hereditary basis to this condition.

Interestingly, research by Faraone and Biederman (1997) at Massachusetts General Hospital suggests that depression among family members of children with ADHD may be a nonspecific expression of the same genetic contribution that is related to ADHD. This is based on their findings that family members of children with ADHD are at increased risk for major depression, whereas individuals who have major depression have first-degree relatives at increased risk for ADHD.

Some research suggests that ADHD with conduct disorder (CD) may be a distinct familial subtype of ADHD (Faraone, Biederman, Mennin, Russell, & Tsuang, 1998). Using sib-pairs in which both siblings had ADHD, Smalley and colleagues (2000) supported this view; they found that CD significantly clustered among the families of only those sib-pairs with CD. Nadder, Ritter, Silberg, Maes, and Eaves (2002) likewise supported this view by finding that while ADHD and oppositional defiant disorder (ODD)/CD have a shared genetic contribution, there are additional unique genetic contributions to ODD/CD. These conclusions are buttressed by support from twin (Thapar, Harrington, & McGuffin, 2001; Wood, Rijsdijk, Asherson, & Kuntsi, 2009) and molecular genetic (Hamshere et al., 2013) studies. This may also be the case for children with ADHD and bipolar disorder; evidence implies that this comprises a distinct familial subtype (Faraone, Biederman, & Wozniak, 2012). These family studies also indicate that ADHD is independent genetically from anxiety disorders (Biederman, Faraone, Keenan, Steingard, & Tsuang, 1991) and learning disabilities (Del'Homme, Kim, Loo, Yang, & Smalley, 2007; Doyle, Faraone, DuPre, & Biederman, 2001).

Some research has also suggested that girls who manifest ADHD may require a greater genetic loading (higher prevalence of family members) than do males with ADHD in order to express the disorder (Smalley et al., 2000; Faraone & Doyle, 2001). Further research using twins supports this view that females appear to have a higher threshold for expression of the disorder than do males with ADHD (Rhee, Waldman, Hay, & Levy, 1999).

Adoption Research

Adoption studies provide natural experiments concerning the likely hereditary transmission of disorders given that adoptive parents do not share genes with their adopted offspring. More than 40 years ago, both Cantwell (1972) and Morrison and Stewart (1973)

reported higher rates of hyperactivity in the biological parents of hyperactive children than in adoptive parents with such children. Both studies suggest that hyperactive children are more likely to resemble their biological parents than their adoptive parents in their levels of hyperactivity, thus supporting a likely hereditary basis to the disorder. Yet both studies were retrospective, and both failed to study the biological parents of the adopted hyperactive children as a comparison group (Pauls, 1991). Later, Cadoret and Stewart (1991) studied 283 male adoptees and found that if one of the biological parents had been judged delinquent or had an adult criminal conviction, the adopted-away sons had a higher likelihood of having ADHD. This is not surprising given that antisocial behavior is quite high among people with ADHD (see earlier chapters) and that a sizable percentage of adults with antisocial behavior have ADHD. In a later study, van den Oord, Boomsma, and Verhulst (1994), using biologically related and unrelated pairs of international adoptees, identified a strong genetic component (47% of the variance) for the Attention Problems dimension of the Child Behavior Checklist, a rating scale commonly used in research in child psychopathology. This particular scale has a strong association with, but is certainly not equivalent to, a diagnosis of ADHD (Biederman, Milberger, Faraone, Guite, & Warburton, 1994) and is often used in research to select subjects with the disorder. Other researchers compared the rates of ADHD in the first-degree adoptive relatives of 25 adopted children with ADHD, nonadopted children with ADHD and their families, and nonadopted control children without ADHD (Sprich, Biederman, Crawford, Mundy, & Faraone, 2000). They found that just 6% of the relatives of the adopted children with ADHD had ADHD—a figure very close to the prevalence of ADHD in adults in the population, suggesting that the children's ADHD did not arise from family environmental transmission. However, 18% of the relatives of the nonadopted children with ADHD were diagnosed with ADHD, compared to 3% for the control group. Thus, like the family association studies discussed earlier, results of adoption studies point to a strong possibility of a significant hereditary contribution to hyperactivity and ADHD.

Twin Studies

Studies of twins provide yet another avenue of evidence for a genetic contribution to ADHD. The evidence for the remarkably high heritability of ADHD traits is even more substantial in scope now than was the case in the prior edition of this volume, and it is now overwhelming. Relative to other psychological traits, the genetic contribution to individual differences (human variation) in ADHD symptoms is striking in magnitude and accounts for the majority of variance. As long as 40 years ago, studies demonstrated a greater agreement (concordance) for symptoms of hyperactivity and inattention between monozygotic (MZ) compared to dizygotic twins (DZ) (Goodman & Stevenson, 1989; O'Connor, Foch, Sherry, & Plomin, 1980; Willerman, 1973). Numerous large-scale twin studies were subsequently conducted. They were reviewed in a meta-analysis of 79 twin and adoption studies. Nikolas and Burt (2010) found that the majority of variance in the traits of ADHD are a result of genetic factors (averaging 71–73% for ADHD inattention and hyperactive-impulsive symptoms, respectively; ranging from 55 to 98%). Other reviews involving many studies find a heritability exceeding .8 (Boomsma, Cacioppo, Muthen, Asparouhov, & Clark, 2007; Grant et al., 2007). The genetic contribution may increase, the more extreme the scores along this trait happen to be, although this latter point is debatable. Thus, twin studies indicate that heritability explains the majority of variation in ADHD symptoms and can be even higher than 70–80% when clinical diagnostic criteria serve as the basis for determining ADHD (Rhee et al., 1999). Different genetic pathways may affect the two ADHD symptom dimensions differently (Kuntsi et al., 2014). Dominant genetic effects are larger for the inattention symptoms, whereas additive genetic effects make a greater contribution to the hyperactive–impulsive symptoms (Nikolas & Burt, 2010). This research adds substantially more evidence to that already found in family and adoption studies supporting a strong genetic basis to ADHD and its behavioral symptoms.

But twin studies can also tell us as much about certain general environmental contributions as they do about genetic factors affecting the expression of a trait, as was noted nearly 20 years ago (Faraone, 1996; Pike & Plomin, 1996; Plomin, 1995). Across the twin studies conducted to date, the results have been reasonably consistent in demonstrating that the shared environment contributes negligible, if any, individual variation in the traits underlying ADHD, and accounts for a range of 0–13% of the variance among individuals and is not statistically significant (see meta-analysis by Nikolas & Burt, 2010; also see Burt, Larsson, Lich-

tenstein, & Klump, 2012). Similar findings were noted earlier for other forms of child psychopathology (Pike & Plomin, 1996). Such shared environmental factors may include social class and family educational/occupational status, the general home environment, parental and child-rearing characteristics that are common or shared across children in the family, and other such nongenetic factors that were common to the twins under investigation in these studies. In their totality, such shared environmental factors on average seem to account for just 0–5% of individual differences in the behavioral trait(s) related to ADHD and are effectively zero (Burt et al., 2012). It is for this reason that I give little attention here to a discussion of purely social factors involved in the causation of ADHD. The numerous twin studies have not been able to verify that such common environmental factors contribute much of significance to individual differences in symptoms of ADHD.

The twin studies cited earlier also indicate the extent to which individual differences in ADHD symptoms are the result of nonshared (unique) environmental factors. Such factors affect the proband child but not the siblings. They include not only those factors typically thought to involve the social environment but also all biological factors that are nongenetic in origin and have the potential differentially to affect the child but not others in the family. Besides biological hazards or neurologically injurious events that may befall only one member of a twin pair, the nonshared environment also includes differences in the manner in which parents may have treated each child. Parents do not perfectly interact with all their children in an identical fashion, and such unique parent–child interactions conceivably might contribute more to individual differences among siblings than do factors related to the home and childrearing that are common to all children in the family. Yet, as noted earlier, one also has to consider biological hazards, for which there is ample evidence of involvement in ADHD (see below). Twin studies to date have suggested that approximately 9–20% of the variance in hyperactive–impulsive and inattentive behavior or ADHD symptoms can be attributed to such nonshared environmental (nongenetic) factors (see the meta-analysis by Nikolas and Burt, 2010). Research suggests that the nonshared environmental factors also contribute disproportionately more to individual differences in other forms of child psychopathology than do factors in the shared environment (Pike & Plomin, 1996). Thus, if researchers are interested in identifying environmental contributors to ADHD, then these twin studies suggest that such research should focus on biological, interactional, and social experiences that are specific and unique to the individual with ADHD and not part of the common environment to which other siblings have been exposed.

Molecular Genetic Research

The remarkably high heritability of ADHD would certainly encourage investigators to search for the specific gene variants that convey the risk for the disorder and account for the variation in symptoms in the population. This has certainly been the case since publication of the previous edition of this book. Quantitative genetic analyses of large samples of families show that a single gene does not account for the expression of the disorder (Faraone et al., 1992). Instead, like all complex traits, ADHD is polygenic. Several forms of gene variants have been investigated: microsatellite polymorphism (MSP), variable number of tandem repeat (VNTR) polymorphisms, single-nucleotide polymorphisms (SNPs), and copy number variants (CNVs). Faraone (personal communication, October 15, 2013) makes the point that distinguishing SNPs from CNVs is important to understanding this field of ADHD research. He describes SNPs as single base pair changes in the DNA sequence. CNVs are much larger deletions and duplications that remove or add segments of genes. They are typically rare, occurring in less than 5% of the population (and often much rarer); they usually change the function of a gene and therefore have etiological significance. While SNPs usually have no functional significance, studies that find them may indicate that functional gene variants contributing to ADHD will be nearby on the chromosome.

Research initially focused on dopamine regulating genes (*DAT1, DRD4, DRD5, DBH,* etc.) given the positive response of ADHD cases to dopamine agonists and reuptake inhibitors, as well as the large role of dopamine in the striatum and frontal cortex—two regions implicated in ADHD. But more recent research has used genomewide scans to identify multiple genetic sites in the genome that appear to be linked to variation in ADHD traits. While some of the potential gene variants identified are related to dopamine and norepinephrine function in the brain, other genes are related to brain growth, migration of cells, endpoint terminations, and cell support, among other important factors in brain development. So prolific has been the field of

molecular genetics of ADHD in the past decade that numerous reviews (Faraone & Mick, 2010; Franke et al., 2011) and meta-analyses now exist (Gizer, Ficks, & Waldman, 2009). Across multiple studies, at least eight gene variants have been identified as reliably linked to ADHD. These include such genes as the serotonin transporter gene (*5HTT*), the dopamine transporter gene (*DAT1*), the D4 dopamine receptor gene (*DRD4*), the D5 dopamine receptor gene (*DRD5*), the serotonin 1B receptor gene (*HTR1B*), and a gene coding for a synaptic vesicle regulating protein known as *SNAP25*. The contribution of each gene to trait variation is fairly small, such that having just one of these variants might elevate risk for the disorder by less than 50%. Results to date for the various linkage studies suggest that gene variants that have large effects on risk for the disorder probably do not exist (see Zhou et al., 2008). The results of studies to date suggest that the following genes may hold promise as contributors to variation in ADHD traits, but that they likely act in concert with each other to explain perhaps 20–30% of the variation in the disorder (Smoller et al., 2013; Yang et al., 2013): *SNAP25, DRD4, SLC6A3, HTR1B, SLC6A4, DBH, NR4A2, PER2, SLC6A1, DRD3, SLC9A9, HES1, ADRA2C, ADRB2, ADRA1B, DRD1, HTR1E, DDC, ST'X1A, ADRA1A, NFIL3, ADRA2A, ADRB1, SLC18A2, TPH1, BDNF, FADS1, FADS2, ADRBK1, ARRB1, DRD2, HTR3B, TPH2, SYT1, HTR2A, SLC6A2, ARRB2, PER1, PNMT, CHRNA4, COMT, ADRBK2, CSNK1E, MAOA, MAOB,* and *HTR2C* (Brookes et al., 2006). Genomewide association (GWA) scans require thousands of patients and family members to identify genes of significance, and this threshold, even when studies are combined, has not yet been adequately reached. But early results hold promise that sufficiently large samples will soon reveal the nature of the genes contributing to the disorder. For instance, some GWA studies identified additional candidates that warrant follow-up, including one that is under a genomewide significant linkage peak in a meta-analysis, *CDH13* (Lasky-Su et al., 2008). This gene is expressed in nicotinic receptors and neurite outgrowth (Canino & Alegria, 2008). As of this writing, an international consortium has assembled 15,000 children with ADHD and control children for an analysis of nonsynonymous (functional) variants, most of which are relatively rare in the population. Sequencing is just getting under way as of 2014 but is expected to identify some rare causal variants, similar to what is already going on in autism research (J. Nigg, & Barkley, 2014).

Rather than look for single genes, researchers are now looking for sets of genes that contribute to various functional networks or pathways known to exist in the brain. For instance, Poelmans, Pauls, Buitelaar, and Franke (2011) identified a coherent network related to nicotinic receptors (already one of the biochemical theories of ADHD) and to neural growth (relevant to newer theories of neurodevelopmental delay). Additionally, Stergiakouli and colleagues (2012) identified metabolic systems related to central nervous system (CNS) development and choleresterol metabolism (essential for neural development) as likely promising in ADHD research. Such efforts provoke new ideas about pathophysiology of ADHD. It is likely that more gene-pathway-based approaches will be fruitful in the future.

The most recent studies in this field suggest that rare CNVs may also contribute to risk for the disorder, and that ADHD cases are likely to involve more such rare CNVs than are found in general population samples (Elia et al., 2009, 2012; Lionel et al., 2011, Williams et al., 2010, 2012; Yang et al., 2013). This evidence of an increased burden of rare CNVs in ADHD implies that one genetic cause of ADHD is the accumulation of rare, large, deleterious deletions and duplications across the genome. For example, one initial study of this method found evidence of a rare CNV at a locus related to ADHD on chromosome 15 at q13.3 in a little under 1% of the population that doubles the risk of ADHD (Williams et al., 2012). Another study using a similar approach concluded that the *PARK2* gene (a gene associated with Alzheimer's disease) has a rare variant occurring in less than 1% of the population that is overrepresented in ADHD (Jarick et al., 2014). More studies of this type are likely to emerge.

Gene by Environment Interactions

As Nigg and I recently summarized (Nigg & Barkley, 2014), in the past decade, studies of gene by environment (G × E) effects have become the norm in psychiatric research. Most of these studies examine one or two selected genetic markers (candidates) in relation to selected measures of the environment. The hazards in such studies are many. In particular, (1) the environmental measure may itself be influenced by variation in unmeasured genes, and (2) if variables are not properly scaled, artifactual or "false-positive" effects are easily found. Nonetheless, initial efforts in this area have been interesting. A recent meta-analysis (Nigg, Nikolas, & Burt, 2010) indicated reliable and consistent in-

teractions of psychosocial distress measures and genotype, particularly for dopamine transporter (*DAT1*) and serotonin transporter, in predicting ADHD. However, these effects remain reliant on a few small studies and could still be overturned. Yet more work on G × E interaction in ADHD is likely to be of considerable interest in coming years.

Furthermore, recent years have seen exciting developments in "epigenetics," that is, the recognition that experience can alter the genome—and therefore the phenotype—sometimes dramatically. This occurs through methylation (modification of chromatin, the material in which DNA is "housed") to alter gene expression; that is, the expression of much of human variation may depend not only on DNA structure but also the regulatory markings that control whether and how a gene is expressed.

These two insights (the importance of G × E and the importance of epigenetic effects) have sparked a renaissance in studies of environmental contributions to ADHD (as well as several other psychiatric conditions) via interactions with genetic susceptibility to disorder.

Environmental Risks and Triggers

When G × E and epigenetic mechanisms are recognized, many possible environmental contributors to the etiology of ADHD emerge as potentially important. A fruitful way to think about the etiology of ADHD is to consider structural DNA (the part that, as far as we know, cannot be changed except by mutations) as conveying liability or susceptibility to ADHD. Experiences then activate the condition, either by causing direct changes in the brain or physiology, or via epigenetic markings that change gene expression. This model suggests that a given environmental risk will not affect all children: Some are "immune" to the effect, but others will be susceptible and develop ADHD in the presence of this risk.

NEUROLOGICAL FACTORS

A variety of etiologies have been proposed for ADHD. Brain damage was initially proposed as a chief cause of ADHD symptoms (see Chapter 1), resulting from known brain infections, trauma, or other injuries or complications occurring during pregnancy or at the time of delivery. Several studies show that brain damage, particularly hypoxic–anoxic types of insults, are associated with greater attention deficits and hyperactivity (Cruikshank, Eliason, & Merrifield, 1988; O'Dougherty, Nuechterlein, & Drew, 1984). ADHD symptoms also occur more in children with seizure disorders (Hesdorffer, Ludvigsson, Olafsson, Gudmundsson, Kjartansson, & Hauser, 2004; Holdsworth & Whitmore, 1974) and with focal stroke to the putamen (Max et al., 2002). However, most children with ADHD have no history of significant brain injuries, and such injuries are unlikely to account for the majority of children with this condition (Rutter, 1977, 1983).

Throughout the century, investigators have repeatedly noted the similarities between symptoms of ADHD and those produced by *lesions or injuries to the frontal lobes more generally and the prefrontal cortex specifically* (Benton, 1991; Levin, 1938; Mattes, 1980; see Chapter 1). Both children and adults suffering injuries to the prefrontal region have long been known to demonstrate deficits in sustained attention, inhibition, regulation of emotion and motivation, and the capacity to organize behavior across time (Fuster, 1997; Grattan & Eslinger, 1991; Stuss & Benson, 1986) that represent an ADHD-like syndrome sometimes called a "dysexecutive syndrome" or "frontal lobe disorder." The similarity of symptoms to those of ADHD do not seem coincidental given the abundant, reasonably definitive evidence that ADHD, at least in part, arises from structural and functional abnormalities in the frontal lobes and its interconnections with the anterior cingulate, basal ganglia, cerebellum, and anterior aspect of the corpus callosum (splenium), to be discussed more below. The difficulties in the networks implicating the anterior cingulate and basal ganglia would therefore imply some difficulties with emotion regulation given the linkage of these structures to the amygdala specifically and therefore the limbic system more generally.

NEUROPSYCHOLOGICAL EVIDENCE

Much of the neuropsychological evidence pertaining to ADHD has been reviewed in other chapters (Chapters 4, 10, and 15) and is not reiterated here in any detail. Such evidence does provide support, albeit very indirectly, for the neurological basis of ADHD given that such tests are linked to a greater or lesser extent with variation in functioning in certain brain regions. Suffice to say that a large number of studies have used neuropsychological tests of frontal lobe functions, perhaps as many as 500 at last count (see Chapter 15).

Results have often found deficits on tests believed to assess executive functions (EFs), such as response inhibition, response variability, working memory (both verbal and nonverbal, but especially nonverbal), both verbal and particularly nonverbal fluency (generating of novel options), timing-related behavior (especially time reproduction), temporal discounting and, to a lesser extent, planning and problem solving. And so by inference, these results would implicate the structures contributing to these EFs (frontal lobes, basal ganglia, and cerebellum, etc.). As discussed in Chapters 4 and 10, and later in Chapter 16, problematic in these studies is that although they identify significant differences between groups of patients with and without ADHD in their mean scores, at least half or more of these patients were not found to be impaired on the tests, implying that many patients with ADHD do not show a dysexecutive syndrome and may not have problems with functioning in the brain structures underlying these neuropsychological functions. In contrast, rating scales of EF routinely find that the vast majority of children and adults with ADHD place in the impaired range (93rd percentile or greater) on all dimensions of EF in daily life. Such results seem to support the view that ADHD is an EF deficit disorder (EFDD), a type of frontal lobe dysexecutive syndrome. They implicate problems in the functioning of prefrontal regions and their networks to other structures (basal ganglia, cerebellum, anterior cingulate, etc.). Moreover, research shows that not only do siblings of children with ADHD who themselves have ADHD show similar EF deficits but also those siblings of children with ADHD who do not actually manifest ADHD appear to have milder yet significant impairments in these same EFs (Seidman, Biederman, Faraone, Weber, & Ouellette, 1997). Such findings imply a possible genetically linked risk family phenotype for EF deficits in families of children with ADHD, even if symptoms of ADHD are not fully manifest in those family members. Evidence does suggest that the EFs apparent in ADHD arise from the same and substantial shared genetic liability as ADHD symptoms themselves (Coolidge, Thede, & Young, 2000).

NEUROLOGICAL EVIDENCE

Far more direct research evidence implicating brain structures and functions in causing ADHD is now available from various studies of the neurological integrity of patients with ADHD. These findings definitively support the view of ADHD as a neurodevelopmental disorder, as it is now classified in DSM-5 (Chapter 2).

Structural Brain Abnormalities in ADHD

Very early studies of the gross structure of the brain as portrayed by coaxial tomographic (CT) scan did not show differences between children with ADHD and typically developing children (B. A. Shaywitz, Shaywitz, Byrne, Cohen, & Rothman, 1983), but greater brain atrophy was found in adults with ADHD who had a history of substance abuse (Nasrallah et al., 1986). The substance abuse, however, seems more likely to account for these results than does the ADHD. CT methods are now considered relatively crude indices of brain structure and have largely been replaced by the approach to measurement I discuss next.

Nearly 20 years ago, researchers began using MRI to explore structural abnormalities in ADHD, and they were not disappointed. Research from that era routinely indicated differences in the structure (mainly size) of selected brain regions in those with ADHD relative to control groups (Tannock, 1998). These and later studies continued to find significantly smaller anterior right frontal regions, smaller size of the caudate nucleus, possibly reversed asymmetry in the size of the head of the striatum (caudate), and smaller globus pallidus regions in children with ADHD compared to control subjects (Aylward et al., 1996; Castellanos et al., 2002; Filipek et al., 1997). The putamen, however, has not been found to be smaller in children with ADHD (Aylward et al., 1996; Castellanos et al., 1996). Besides reduced size, there is some evidence of reduced neurometabolite activity in the right frontal region (Yeo et al., 2003), and the degree of this activity is associated with the degree of attention problems on a continuous-performance test. The size of the basal ganglia and right frontal lobe has also been shown in other studies to correlate with the degree of impairment in inhibition and attention in children with ADHD (Casey et al., 1997; Semrud-Clikeman et al., 2000). Filipek and colleagues (1997) did find smaller posterior volumes of white matter in both hemispheres in the regions of the parietal and occipital lobes, which might be consistent with the earlier studies showing smaller volumes of the corpus callosum in this same area. Castellanos and colleagues (1996) suggested that such differences in corpus callosum volume, particularly in the posterior regions, may be more related to the learning disabilities often found in a large

minority of children with ADHD than to ADHD itself. Numerous subsequent studies (Castellanos et al., 1996, 2001, 2002; Durston et al., 2004) also indicated smaller cerebellar volume in those with ADHD, especially in a central region known as the vermis. This evidence is consistent with the view that the cerebellum plays a major role in EF and the motor-presetting aspects of sensory perception that derive from planning and other executive actions (Akshoomoff, & Courchesne, 1992; Diamond, 2000; Houk & Wise, 1995), and that these functions may be deficient in children with ADHD.

So abundant now is the evidence from structural neuroimaging that multiple meta-analyses of these studies have been published since 2007. In their initial meta-analysis, Valera, Faraone, Murray, and Seidman (2007) found the largest differences between subjects with ADHD and controls in the cerebellum (especially the posterior inferior region of the vermis), followed by the splenium, right and total cerebral volume, and the right caudate. Bilateral prefrontal gray-matter and right globus pallidus volumes were modestly associated with ADHD, but the results were not statistically significant after researchers corrected for multiple comparisons. Subsequent meta-analyses that included new research since 2007 likewise found similar results. For instance, the article by Ellison-Wright, Ellison-Wright, and Bullmore (2008) reported a decrease in area in the right putamen/globus pallidus region linked to ADHD. This region is known to have sizable projections to prefrontal cortex. A meta-analysis by Nakao, Radua, Rubia, and Mataix-Cols (2011) included 14 separate studies across which findings revealed decreased global gray-matter volumes. There were smaller gray-matter volumes, associated with ADHD, in the caudate nucleus but larger gray-matter volumes in the left posterior cingulate cortex/precuneus. A subsequent meta-analysis by Frodl and Skokauskas (2012) that included 11 studies focusing on brain volume replicated the earlier results regarding reduced volumes in the right globus pallidus and putamen, and bilaterally in the caudate.

One of the more fascinating and revealing studies of neurological involvement in ADHD, initially published in 2006 by Shaw and colleagues, was a multisite, longitudinal study of large samples of children with ADHD and controls who were periodically rescanned over approximately a 10-year period (Shaw et al., 2006, 2007). This first serial developmental neuroimaging study of ADHD was able to compute the degree of delay in brain maturation across various brain areas associated with the disorder. The authors defined "cortical maturation" as that age at which peak cortical thickness was achieved. The median age at which half of the cortical points achieved their peak thickness was strikingly dissimilar between children with ADHD and controls (10.5 vs. 7.5 years, respectively). The prefrontal cortex showed the greatest magnitude of delay in development, as had been suggested in many of the earlier MRI studies noted earlier. Such findings are also highly consistent with the view that ADHD is a disorder of EF given that the prefrontal cortex is the executive brain (see Chapter 16). In a later report from this project, Shaw and colleagues (2011) noted a different relationship between hyperactivity–impulsivity symptoms and a slower rate or delay in the normal process of cortical thinning that is typical in later stages of brain development. The findings were discussed as underscoring a dimensional view of ADHD as the extreme end of the distribution of a normal trait(s) within the population given that thinning is linked to the number of ADHD symptoms, even in the control children. In short, ADHD is linked to a delay in brain maturation.

More recently, development of yet another form of imaging provides a means to analyze brain structure in ADHD, focusing on white-matter tracts that connect cortical and subcortical structures. This is known as diffusion tensor imaging (DTI), which is capable of detecting cumulative axonal membrane circumference, axonal density, and the thickness of the myelin sheath in brain white matter. Various approaches to analyzing fMRI findings in this way have been developed, but all are believed to index the axonal integrity and organization of the white-matter structures (van Ewijk, Heslenfeld, Zwiers, Buitelaar, & Oosterlaan, 2012). Enough studies (at least 15 to date) using this methodology have now been done to warrant meta-analysis of all of their findings. The results of just such a review revealed that white-matter integrity was significantly decreased in participants with ADHD, whether they were children, teens, or adults. The differences between participants with ADHD and control groups are as or more striking than those noted in the MRI studies concerning various gray-matter structures. The findings indicate that white-matter regions and tracts are also implicated in ADHD, such as in the inferior and superior longitudinal fasciculus, anterior corona radiata, corticospinal tract, cingulum, corpus callosum, internal capsule, caudate nucleus, cerebellum, uncinate fasciculus, forceps minor, areas within the basal ganglia, and there are widespread differences in the frontal, temporal, parietal, and occipital lobes. Some have con-

cluded that these results indicate that the myelination of these areas is delayed in children with ADHD (van Ewijk et al., 2012) and may remain maldeveloped in adults. Observing the results of these imaging methods leaves one in awe of not just the advances in modern imaging technology but also the widespread adverse maldevelopment with which ADHD is associated in brain development.

Functional Brain Abnormalities in ADHD

It is true that early studies using *psychophysiological measures* of nervous system (central and autonomic) electrical activity, variously measured (electroencephalograms, galvanic skin responses, heart rate deceleration, etc.), were inconsistent in demonstrating group differences between ADHD and control children. But when differences from normal were found in those studies, they consistently were in the direction of *diminished arousal or reactive arousal* in those with ADHD (see Ferguson & Pappas, 1979; Hastings & Barkley, 1978). More consistent evidence of these arousal disturbances comes from later research (Beauchaine, Katkin, Strassberg, & Snarr, 2001; Borger & van der Meere, 2000).

Far more consistent are the results of *evoked response potential* (ERP) and *quantitative electroencephalographic* (QEEG) measures often taken in conjunction with performance of vigilance tests (El-Sayed, Larsson, Persson, & Rydelius, 2002; Loo & Barkley, 2005; Loo & Makieg, 2012). Although results have varied substantially across these studies, the most consistent pattern for QEEG research is increased slow wave, or theta, activity, particularly in the frontal lobe, and decreased beta activity (Loo & Makieg, 2012). Children with ADHD have been found to have smaller amplitudes in the late positive components of their ERPs. These late components are believed to be a function of the prefrontal regions of the brain, are related to poorer performances on vigilance tests, and are corrected by stimulant medication (Johnstone, Barry, & Anderson, 2001; Pliszka, Liotti, & Woldorff, 2000). The EEG improvements from stimulant medication have been shown to be partly a function of the *DAT1* gene allele, particularly in its 10-repeat form (Loo et al., 2003) that may be overrepresented in ADHD (see earlier section on genetics). Thus, although the evidence is far from conclusive, EEG and ERPs related to sustained attention and inhibition suggest an underresponsiveness of children with ADHD to stimulation that is partially or wholly corrected by stimulant medication and that implicates involvement of the prefrontal cortical regions and related networks.

Numerous studies have now used various methods of functional neuroimaging. One such approach is assessing *cerebral blood flow* using single-photon emission computed tomography (SPECT) in children with ADHD and typically developing children (see Hendren, DeBacker, & Pandina, 2000, for an early review). Studies have consistently shown decreased blood flow to the prefrontal regions (particularly in the right frontal area) and pathways connecting these regions to the limbic system via the striatum, specifically its anterior region known as the caudate, and with the cerebellum. Degree of blood flow in the right frontal region has been correlated with behavioral severity of the disorder and reduced EEG activity, while that in more posterior regions and the cerebellum seems related to degree of motor impairment (Gustafsson, Thernlund, Ryding, Rosen, & Cederblad, 2000). Using this method, accompanied by injections of radiopharmaceutical iodine–123-labeled altropane that selectively binds to the dopamine transporter in the striatum, Dougherty and colleagues (1999) reported that the dopamine transporter was elevated by about 70% in adults with ADHD. More recently, a meta-analysis of nine studies using SPECT and other imaging methods targeting this transporter density indicated that these differences associated with ADHD were significant (Fusar-Poli, Rubia, Rossi, Sartori, & Balottin, 2012) but not of the magnitude initially estimated in the Dougherty and colleagues study. Those differences were closer to a 14% elevated density being linked to ADHD. Blood flow, and therefore brain activity, in these regions appears to be affected by methylphenidate, a stimulant often used to treat ADHD (Langleben et al., 2002).

Another approach to studying brain function that employs *PET* to assess cerebral glucose metabolism has indicated diminished metabolism in adults, particularly in the frontal region (Schweitzer et al., 2000; Zametkin et al., 1990). Using a radioactive tracer that indicates dopamine activity, Ernst and colleagues (1999) were able to show abnormal dopamine activity in the right midbrain region of children with ADHD; severity of symptoms was correlated with the degree of this abnormality. Ernst and colleagues (2003) later studied adults with ADHD during a decision-making task and found them to be less likely to activate the hippocampal and insular regions, and more likely to use the right anterior cingulate than did healthy controls. These demonstrations of an association between the metabolic activity

of certain brain regions and symptoms of ADHD and associated EF deficits are critical to proving a causal connection between findings that pertain to brain activation and the behavior comprising ADHD.

Important in the previously discussed research on brain structure is to show not only group differences in brain structure and development but also that such differences were correlated with functional difficulties in these regions, and that those difficulties are linked to the severity of ADHD symptoms. This makes a more convincing case that the findings on brain structure are actually related to problematic functioning in the brain that gives rise to the ADHD symptoms. Early research using *fMRI* indicated that children with ADHD had more abnormal patterns of activation during attention and inhibition tasks than did typically developing children, particularly in the right prefrontal region, basal ganglia (striatum, globus pallidus, and putamen), and the cerebellum (Rubia et al., 1999; Yeo et al., 2003). Again, the demonstrated linkage of brain structure and function with psychological measures of ADHD symptoms and executive deficits is exceptionally important in such research, permitting causal inferences about the role of these brain abnormalities in the cognitive and behavioral deficits comprising ADHD. In a later study, Durston and colleagues (2004) suggested that the reduced size of the brain (about 3–5%), particularly in the right frontal area, found in ADHD may be evident as well in siblings of children with ADHD who themselves do not have ADHD, which perhaps is consistent with the increased familial risk for the disorder and a spectrum of the phenotype for ADHD within these families. But the reduced volume of the cerebellum was also found to be specific only to the child with ADHD and not the unaffected siblings, implying that this region may be directly related to the pathophysiology of the disorder itself. Later, a meta-analysis of 16 fMRI studies (Dickstein, Bannon, Castellanos, & Milham, 2006) noted results highly consistent with those from the previously discussed structural MRI studies. The authors observed that ADHD involved widespread frontal hypoactivity. Also noteworthy was reduced activity in the basal ganglia and parietal cortices.

A more recent approach to studying brain functioning in ADHD involves *proton magnetic resonance spectroscopy* (MRS). This technique measures neurochemicals associated with neurotransmission in the brain. Perlov and colleagues (2009) published a meta-analysis of 16 studies using MRS to evaluate the anterior cingulate cortex, prefrontal cortex, basal ganglia (mostly striatum) and the frontal–striatal/thalamic–frontal circuits. The most consistent result was that choline compounds, such as the ratio of *N*-acetyl-aspartate and glutamate/glutamine to creatine, were significantly abnormal in the disorder.

Yet another approach to evaluating brain functioning uses more complex methods of analyzing fMRI results to investigate *functional interregional interconnectivity*. Several researchers who have done so found reduced functional connectivity in networks in the frontostriatal, frontoparietal, and frontocerebellar zones (Cubillo & Rubia, 2010; Tian et al., 2006; Zang et al., 2007). There was also evidence implicating the sensorimotor cortex and cerebellum (Tian et al., 2006; Zang et al., 2007). These functional abnormalities have been shown to improve with administration of the ADHD drug, methylphenidate (An et al., 2013).

All of these more recent results, published since the publication of the previous edition of this volume, have proven to be quite consistent with earlier reviews of this literature that reached similar conclusions—that abnormalities in the development and functioning of the frontal–striatal–cerebellar regions underlie ADHD (Arnsten, Steere, & Hunt, 1996; Benton, 1991; Fassbender & Schweitzer, 2006). These regions are shown in Figure 14.1.

Neural Networks Implicated in ADHD

Since publication of the previous edition of this volume, various authors have proposed models of ADHD based on these neurological findings, and others concerning neurochemical pathways and ADHD medication effects, that suggest at least three or four networks are involved in the disorder (Castellanos, Sonuga-Barke, Milham, & Tannock, 2006; Makris et al., 2009; Nigg & Casey, 2005; Sagvolden, Johansen, Aase, & Russell, 2005). For instance, Makris, Biederman, Monuteaux, and Seidman (2009) hypothesize that four networks are involved, and that they vary in their involvement across individuals with ADHD, perhaps accounting for some of the heterogeneity in the symptoms of the disorder across patients. Like the other theorists noted earlier, Makris and colleagues propose that there exists a motor activity–regulation network involving the dorsolateral prefrontal cortex, caudate, dorsal anterior cingulate cortex, cerebellum, and the supplementary motor area that give rise to the hyperactive symptoms of the disorder. The second network, which includes the cerebellar hemisphere, dorsal anterior cingulate cortex, dorsolateral prefrontal cortex, thalamus, and the inferior parietal lobule, and their inter-connections, under-

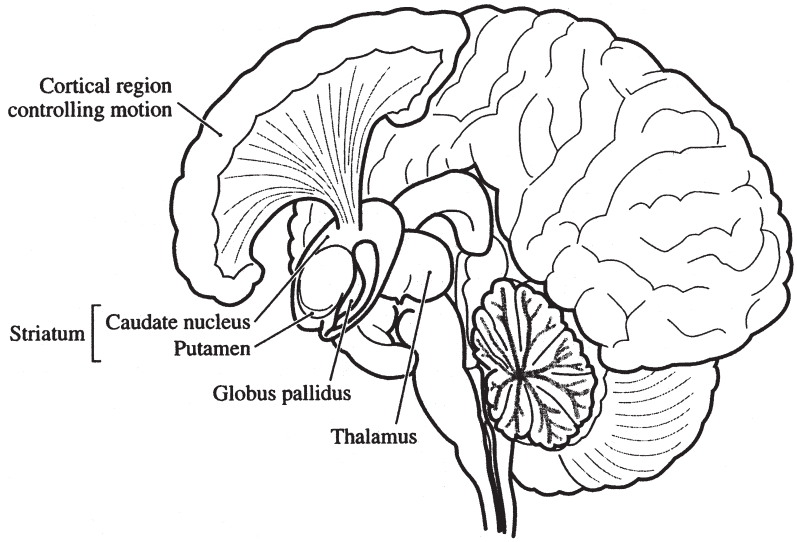

FIGURE 14.1. Diagram of the human brain showing the right hemisphere, and particularly the location of the striatum, globus pallidus, and thalamus. Most of the left hemisphere has been cut away, up to the prefrontal lobes, to reveal the striatum and other midbrain structures. Adapted with permission from an illustration by Carol Donner from page 53 of the article by M. B. H. Youdin and P. Riederer (1997). Understanding Parkinson's disease. *Scientific American*, *276* (January), pp. 52–59. Copyright by *Scientific American*, 415 Madison Avenue, New York, NY 10017-1111.

lies the attention or cold EF (so named for its role in holding information in working memory that guides behavior toward goals) deficits evident in ADHD (e.g., in working memory, planning, and problem solving). Yet a third network, which includes the cerebellar vermis, perigenual anterior cingulate cortex, orbitofrontal cortex, and nucleus accumbens, mediates impulse control, thus explaining the poor inhibition associated with ADHD. The fourth network would explain the deficits in emotional self-regulation evident in the disorder (see Chapter 3; Banaschewski et al., 2012; Barkley, 2010; Biederman et al., 2012b; Kuntsi et al., 2014; Surman et al., 2011) because it involves not only the cerebellar vermis, but also the perigenual anterior cingulate cortex, frontal–orbital cortex, and amygdyla, which can be thought of as the gateway into the emotional brain or limbic system. This is sometimes referred to as the "hot" executive network because of its involvement in emotion, particularly the top-down regulation of affective and motivational states in the service of goal-directed behavior, as well as the bottom-up impact of emotional/motivational states on higher executive functioning (Castellanos et al., 2006; Nigg & Casey, 2005).

Impact of ADHD Medication Treatment on Brain Development

Critics have argued that these differences in brain structure and functioning arise because many of the children in the earliest studies had a history of treatment with stimulant medication, which caused these abnormalities. But many, more recent studies that used treatment-naive patients found identical results, thus refuting the claims of such critics (Frodl & Skokauskas, 2012; Nakao et al., 2011; Paloyelis, Mehta, Kuntsi, & Asherson, 2007). But in point of fact, 29 studies to date have noted that the brain development of children treated with stimulant medications is closer to that of controls who do not have ADHD than to children with ADHD never treated with stimulants (Ivanov, Murrough, Bansal, Hao, & Peterson, 2014; Paloyelis et al., 2007; Sobel et al., 2010). These findings have been observed now in meta-analyses of this body of studies, which makes this a very robust result (Frodl & Skokauskas, 2012; Spencer et al., 2013). Such a result suggests that treating ADHD with medication may result in a greater normalization of brain development,

known as a "neuroprotective effect" (a better term is a "growth-enhancing effect"), than if the medications had never been used. This makes some sense given that clinically effective doses of stimulants increase brain activity in the very regions that have been found to be underactive in the various functional neuroimaging studies discussed earlier (i.e., caudate, prefrontal cortex, cingulate and cerebellum) (Shafritz, Marchione, Gore, Shaywitz, & Shaywitz, 2004; Vaidya et al., 1998). So such a continuous increase in functioning sustained over months or years of development from daily medication use could result in a near-normalization of functioning. In a related study, researchers have found that this effect is also evident on neuropsychological tests of EF in which stimulant-treated children with ADHD have results closer to those of the typically developing control group than to untreated children with the disorder (Semrud-Clikeman, Pliszka, & Liotti, 2008). Although these past studies have been limited to the category of stimulant medications, it is not unreasonable to assume that similar results might arise in response to nonstimulant medications, such as atomoxetine, that overlap in the brain regions they affect by as much as 70% or so with those regions affected by stimulant treatment (Shulz et al., 2012). Granted, these findings cannot be considered definitive evidence of neuroprotection or growth or functional acceleration in the brain development of children with ADHD because children were not randomized to treated and untreated groups, then serially scanned over years of time. But such studies are impossible to do because of ethical, not to mention financial, constraints, so we are left with the evidence that can be obtained from these existing studies that compare treated and untreated cases of ADHD. Undoubtedly, this is one of the most extraordinary findings from neuroimaging studies of the past 15 years, even if it is presently unheralded in the media and runs counter to the prevailing view of those who hold that ADHD medications may be detrimental to brain development and functioning over the course of development.

Neurotransmitter Deficiencies

For many years, possible neurotransmitter dysfunctions or imbalances have been proposed (Arnsten, 2009; Tripp & Wickens, 2008), resting chiefly on the responses of children with ADHD to ADHD medications known to act through dopamine and noradrenergic reuptake inhibitors and agonists (Pliszka, McCracken, & Maas, 1996). Substantial evidence now indicates that three types of medications are effective for managing ADHD symptoms. The first type includes the stimulants, methylphenidate and amphetamine. Both methylpheniate (Volkow et al., 2012) and amphetamine (Riccardi et al., 2008) have been shown through neuroimaging research to increase dopamine (DA) availability (Swanson, Baler, & Volkow, 2011; Volkow et al., 2012), especially in striatum, likely via blockade of the DA transporter (Spencer et al., 2006) that may ultimately increase the rate of DA release. Amphetamine may also increase DA release. Both agents also increase DA and norepinephrine (NE) availability in the hippocampus and prefrontal cortex. Another effective agent for ADHD management is atomoxetine, which is known to block the NE transporter (Takano, Gulyas, Varrone, Maguire, & Halldin, 2009) and is therefore a reuptake inhibitor. More recently, evidence indicates that the ADHD medication guanfacine extended release (XR), originally an antihypertensive medication, acts as an alpha$_2$ receptor agonist serving to more finely tune neural signal transmission (Arnsten, 2009; see Chapters 27 and 35 for more on ADHD medications).

Given the long-standing findings that normal children show a positive, albeit lesser response to stimulants (Rapoport et al., 1978), however, evidence of drug response by itself cannot be used to support a neurochemical abnormality in ADHD. Even so, given that the magnitude of the response to medication is far greater in ADHD than in control cases, some inferences can still be made about the role of neurochemistry and cellular mechanisms in ADHD. Specifically, it is not unreasonable to investigate the involvement of these two neurotransmitters and the DA and NE transporters in the etiology of ADHD.

Early direct evidence from studies of cerebrospinal fluid in children with ADHD and typically developing children, collected before such studies would have failed to pass review by institutional review boards, indicated decreased brain DA in children with ADHD (Halperin et al., 1997; Raskin, Shaywitz, Shaywitz, Anderson, & Cohen, 1984). Evidence from other studies conducted nearly 30 years ago using blood and urinary metabolites of brain neurotransmitters indicates conflicting results (S. E. Shaywitz, Shaywitz, Cohen, & Young, 1983; S. E. Shaywitz et al., 1986; Zametkin & Rapoport, 1986). What limited evidence there was in those early studies seemed to point to a selective deficiency in the availability of both DA and NE, but this evidence was hardly conclusive. But more recent research using

peripheral indicators of catecholamine systems does imply some dysregulation in these neurotransmitters in ADHD (Halperin et al., 1997). Scassellati, Bonvicini, Faraone, and Gennarelli (2012) reviewed 71 studies of such indices and concluded that four of them were reliably implicated in ADHD: increased NE, decreased MHPG (3-methoxy-4-hydroxyphenylethylene glycol), decreased phenlyethylamine, and decreased MAO (monoamine oxidase); the latter was interpreted in this review as possibly impairing the degradation of NE and therefore lowered MHPG levels in individuals with ADHD, which might be a compensatory mechanism for the reduced noradrenergic activity in synapses of patients with the disorder.

Results from numerous animal studies and studies of typically developing humans suggest that these two neurotransmitters may be involved in ADHD, and that it is the cortical–striatal–pallidal system that may mediate ADHD symptoms (Papa, Berger, Sagvolden, Sergeant & Sadile, 1998); increased DA transporter density in the brain may be one cellular mechanism in the disorder (Roessner et al., 2011), as was indicated in the earlier neuroimaging studies using altropane to evaluate transporter density in adults with ADHD. These and other findings led Sagvolden and colleagues (2005) to propose a dynamic neurodevelopmental theory of ADHD (combined and hyperactive types) based on altered DA function that can arise from hypofunctioning in one of three DA branches identified in the brain. Low functioning in a mesolimbic pathway in the brain produces an altered sensitivity to reinforcement and deficient extinction of previously reinforced behavior that could give rise to the delay aversion, hyperactivity, impulsiveness, and poor sustained attention. Low functioning in the mesocortical DA pathway could also give rise to deficient attention toward a target, as well as poor planning and executive functioning. Finally, low functioning in the nigrostriatal DA pathway results in impaired modulation of motor behavior and deficient learning and memory, thereby giving rise to the motor delay, clumsiness, and poor motor inhibition seen in ADHD. Predispositions to low functioning in these DA pathways are hypothesized to interact with each other and with surrounding environmental factors to amplify or alter these initial predispositions. The theory provides a more comprehensive explanation of symptoms and deficits associated with ADHD (see Chapters 2 and 3), while presenting some testable hypotheses concerning which of these should be associated with hypofunctioning in particular pathways. As noted earlier, Makris and colleagues (2009) and others have proposed a similar set of pathways as being involved in ADHD.

PREGNANCY AND BIRTH COMPLICATIONS

As noted in the earlier discussion about genetic contributions to ADHD, genetic factors clearly play a large role in the structural and functional maldevelopment of the brain in ADHD. But a significant minority of cases, perhaps 35%, may develop from adverse environmental factors affecting brain development, resulting in acquired cases of ADHD (Nigg, 2006). One such avenue for environmental adversity to have such an impact is during early fetal brain formation during pregnancy. For more than 50 years, researchers interested in ADHD have examined the extent to which various pregnancy, birth complications, and maternal characteristics during pregnancy may be associated with or cause the disorder. A few early studies did not find a greater incidence of pregnancy or birth complications in children with ADHD compared to typically developing children (Barkley et al., 1990), but others have (e.g., Sprich-Buckminster et al., 1993). For instance, Claycomb, Ryan, Miller, and Schnakenberg-Ott (2004) found that the mother's age at delivery (younger), educational level (lower), time between onset of labor and birth (longer), and presence of delivery complications accounted for 42 percent of the variance in ADHD. The study, however, did not control for maternal ADHD symptoms, which may have resulted in the younger age at delivery and lower educational level of the mothers, given the risk that ADHD poses for earlier risky sexual behavior and limited education (see Chapters 11 and 12). These latter maternal characteristics may simply be markers for maternal ADHD and so explain their being associated with child ADHD.

Some early studies indicate a slightly higher prevalence of unusually short or long labor, fetal distress, low forceps delivery, and toxemia or eclampsia (Hartsough & Lambert, 1985; Minde, Webb, & Sykes, 1968). In keeping with these early findings, a recent very large population-based study found that *in utero* ischemic–hypoxic events, especially birth asphyxia, respiratory distress, and preeclampsia, were independently linked to risk for ADHD (Getahun et al., 2012). But another recent large-scale study of twins did not find pregnancy and delivery factors to be specifically linked to ADHD, with the exception of low birthweight (LBW; Wagner, Schmidt, Lemery-Chalfant, Leavitt, & Goldsmith,

2009). So the evidence for perinatal adversities other than LBW is rather mixed. In fact, in a recent, large study of children with ADHD, Owens and Hinshaw (2013) found that perinatal complications were related to the development of comorbid depression even after they controlled for maternal ADHD, depression, and other factors.

But the evidence for LBW specifically seems quite convincing as a risk factor for ADHD. Early on, Nichols and Chen (1981) found that LBW was associated with an increased risk of hyperactivity, inattention, disruptive behavior, and poor school adjustment. These results for LBW have subsequently been replicated in other studies reviewed over the next 15 years (Breslau et al., 1996; Schothorst & van Engeland, 1996; Sykes et al., 1997; Szatmari, Saigal, Rosenbaum, & Campbell, 1993). And more recently, after controlling for other factors that may be associated with LBW and ADHD (maternal smoking, alcohol use, ADHD, social class, etc.), Mick, Biederman, Faraone, Sayer, and Kleinman (2002) found that LBW was three times more common in children with ADHD than in control children, perhaps accounting for nearly 14% of all ADHD cases. Moreover, twin studies indicate that LBW has a causal relationship with attention problems (Groen-Blokhuis, Middeldorp, van Beijsterveldt, & Boomsma, 2011), and that this relationship to ADHD (and other psychiatric disorders) persists into young adulthood in LBW children (Elgen, Holsten, & Odberg, 2013). It is not merely LBW that seems to pose the risk for symptoms of ADHD or the disorder itself, among other psychiatric disorders, but the extent of white-matter abnormalities due to birth injuries, such as parenchymal lesions, intracerebral bleeding, and/or ventricular enlargement (Whittaker et al., 1997). Although LBW (< 2,500 grams) is a specific risk factor for inattention–hyperactivity and certain learning and motor problems (but not other behavioral or emotional problems) at age 6 (Willcutt, 2012), LBW is itself multiply determined by factors such as maternal health and nutrition, maternal smoking, maternal weight, low socioeconomic status (SES), stress, and other factors, making identification of specific biological mechanisms difficult (Nigg, 2006).

Another pregnancy factor that may be linked to ADHD risk is increased placental size, which may signal the occurrence of disturbances in the maternal environment during pregnancy (Khalife et al., 2013). The placenta may respond to such adversities in the maternal environment with structural and functional changes that can affect the fetus via altered nutrient and hormone supply. Prospective data from this large population-based study in Finland indicated a significant relationship between increased placental size and risk for ADHD, antisocial behavior, and psychopathology more generally, but this risk was limited to boys but not girls.

Among the strongest pregnancy factors associated with risk for ADHD are more chronic influences such as neurotoxins. Among these, the greatest evidence exists for the role of maternal tobacco smoking and, to a lesser extent, alcohol consumption (see Langley, Rice, van den Bree, & Thapar, 2005, for a meta-analysis), both of which can independently increase risk for ADHD about 2.5 times. These are further discussed next in "Environmental Toxins." One study suggests that maternal iodine deficiency may also contribute to risk for ADHD (Vermiglio et al., 2004). Also, other chronic factors, such as maternal toxemia (and also maternal smoking; Fielding, 1985), eclampsia, and genitourinary infections (Mann & McDermott, 2011) have been implicated rather than acute factors, such as traumatic or brief events, such as consuming a single alcoholic beverage or smoking a single cigarette. Another potentially chronic pregnancy factor related to attention and emotional regulation problems may be maternal obesity at the time of conception (Rodriguez, 2010) that may affect prenatal brain development via energy support and disturbed maternal metabolic functioning.

In one very unusual study, Sharp and colleagues (2003) studied possible pregnancy and environmental contributions to ADHD by identifying MZ twins in which only one twin was affected by ADHD. Given the striking genetic contribution to ADHD and the very high concordance rate for it in MZ twin pairs, such a study might find it difficult to find twin pairs in which only one twin was affected. This is precisely the case, in that out of 297 pairs of MZ twins initially screened for the study, just 10 pairs were eventually found in which the twins were discordant for the disorder. Consistent with the authors' hypothesis that the affected twin would be more likely to have birth complications (a nongenetic explanation for the twins' discordance on ADHD), the study found that the affected twin was smaller at birth and more likely to have experienced a breech delivery.

Several studies suggest that mothers of children with ADHD conceive these children at an age younger than that of mothers of control children, and that such pregnancies may have a greater risk of adversity (Claycomb et al., 2004; Denson, Nanson, & McWatters, 1975;

Hartsough & Lambert, 1985; Minde et al., 1968). Because pregnancy complications are more likely to occur in young mothers, mothers of children with ADHD may have a higher risk for complications that may act neurologically to predispose their children toward ADHD. However, the complications that have been noted to date are rather mild and are hardly compelling evidence of pre- or perinatal brain damage as a cause of ADHD. Furthermore, large-scale epidemiological studies have generally not found a strong association between pre- or perinatal adversity and symptoms of ADHD once other factors are taken into account, such as maternal smoking and alcohol use (see later), as well as socioeconomic disadvantage, all of which may predispose children to perinatal adversity and hyperactivity (Goodman & Stevenson, 1989; Nichols & Chen, 1981; Werner et al., 1968).

A few researchers have also examined stress during pregnancy, and their results have been inconclusive. They suggest a modest contribution of stress and anxiety to ADHD symptoms in the offspring of these mothers, but this finding is hardly definitive given the many methodological problems evident to date (for a review, see Linnet et al., 2003). For instance, Van den Bergh and Marcoen (2004) evaluated mothers and their firstborn children, and found that maternal state anxiety during pregnancy explained 22% of the variance in symptoms of ADHD in the offspring, with maternal anxiety during weeks 12–22 being specifically implicated. More recently, Clavarino and colleagues (2010) found that persistent anxiety antenatally in mothers was significantly related to attention problems at ages 5 and 14 years in the follow-up of children born to these mothers. And persistent severe psychosocial stress in mothers has been linked to risk for ADHD independently of other factors that may be related to such distress, such as higher levels of maternal smoking (Motlagh et al., 2011). Such anxiety or stress during pregnancy may result in some programming effect on the fetal brain, perhaps via increased secretion of stress-related hormones into the maternal bloodstream, with concomitant increased exposure for the fetus. Nevertheless, children in most of these studies did not have clinically diagnosed ADHD, and no attempt was made to control for maternal ADHD and its genetic contribution to the level of child ADHD. Anxiety and greater stress is related to ADHD in adults (Chapter 13); thus, it is not far-fetched to think that anxiety in the mothers may have been a proxy for maternal ADHD. Indeed, one recent large-scale study indicated that the relationship of maternal anxiety and depression to offspring ADHD was a genetic one rather than a direct effect causing child ADHD (Van Batenburg-Eddes et al., 2013). Nor was evidence of actual neural programming evaluated in these earlier studies. Therefore, the results remain merely correlational, suggesting some association of maternal anxiety and stress to child ADHD but not clarifying the direction of effect or whether the presence of a third variable, most likely genetic transmission of ADHD risk from the anxious or depressed parent to the child, explains (confounds) these results.

Mick, Biederman, and Faraone (1996) found that the season of a child's birth was significantly associated with risk for ADHD, at least among subgroups that also had learning disability or did not have any psychiatric comorbidity. Birth in September was overrepresented in this subgroup of children with ADHD. The authors conjectured that the season of birth may serve as a proxy for the timing of seasonally mediated viral infections to which these mothers and their fetuses may have been exposed, and that this may account for approximately 10% of cases of ADHD.

ENVIRONMENTAL TOXINS

As the twin and quantitative genetic studies suggest, the environment may play some small role in individual differences in symptoms of ADHD, but these environmental adversities usually involve biological events, not just family/parenting influences or those influences within the social realm. As noted previously, variance in the expression of ADHD that may be a result of environmental sources means all nongenetic sources more generally. These include pre-, peri-, and postnatal complications and malnutrition, diseases, trauma, and other neurologically compromising events that may occur during the development of the nervous system before and after birth. Among these various biologically compromising events, several toxins have been repeatedly linked to risks for inattention and hyperactive behavior.

One such event is exposure postnatally to environmental toxins, and specifically lead. For more than 40 years, *elevated body lead* burden has been shown to have a small but consistent and statistically significant relationship to ADHD symptoms (Nigg et al., 2008; Nigg, Nikolas, Knottnerus, Cavanagh, & Friderici, 2010; Roa et al., 1994). However, even at relatively high levels of lead, less than 38% of children were rated as being hy-

peractive on a teacher rating scale (Needleman et al., 1979), implying that most lead-poisoned children do not develop symptoms of ADHD. And most children with ADHD likewise do not have significantly elevated lead burdens, although one study did indicate that their lead levels may be higher than that in control subjects (Gittelman & Eskinazi, 1983). Researchers who have controlled for the presence of potentially confounding factors in this relationship (as well as type of assay method to detect lead; e.g., hair vs. blood or dentition), as well as a recent meta-analysis (Goodlad, Marcus, & Fulton, 2013), found the association between body lead burden and symptoms of ADHD to be small but still significant (.10–.19) with the more factors controlled, the more likely the relationship falls below .10 This finding suggests that 4% (at best) of the variance in the expression of ADHD symptoms in children with elevated lead is explained by their lead levels. Moreover, one serious methodological issue plagues even the better-conducted studies in this area: None of the studies assessed for the presence of ADHD in the parents and controlled its contribution to the relationship. Given the high heritability of ADHD, this factor alone could attenuate the already small correlation between lead and symptoms of ADHD by as much one-third to one-half its present levels. Interestingly, in a recent large-scale study in Korea, Byun and colleagues (2013) suggested that excess mobile phone use in children with excess body lead burden is linked to severity of ADHD symptoms. Yet the study acknowledges that reverse causality may be at work here, in which children with ADHD are more likely both to experience higher body lead burdens and to use mobile phones more than children without ADHD.

As noted earlier, two other types of prenatal environmental toxins found to have some relationship to inattention and hyperactivity are *prenatal exposure to alcohol and tobacco smoke* (Mick et al., 2002; Milberger, Biederman, Faraone, Chen, & Jones, 1996; Nichols & Chen, 1981; Streissguth, Bookstein, Sampson, & Barr, 1995). The relationship between maternal smoking during pregnancy and ADHD remains significant even after researchers control for symptoms of ADHD in the parent (Mick et al., 2002; Milberger et al., 1996) and shows the strongest association with risk for ADHD. Indeed, in a comprehensive review of the literature on maternal smoking and ADHD, Thakur and colleagues (2012) concluded that such cases represent a more severe form of the disorder than cases of ADHD in which maternal smoking was not implicated. There is some evidence as well that passive secondhand smoke exposure after birth may contribute to disruptive behavior disorders generally (Gatzke-Kopp & Beauchaine, 2007) and risk of having ADHD specifically (Max, Sung, & Shi, 2013). But it may be that the effect of maternal smoking during pregnancy on risk for ADHD is an indirect one, contributing to fetal risk for LBW that is then the more direct contributor to risk for ADHD (Kline, Stein, & Susser, 1989; Thapar et al., 2009). Or it is possible that a G × E interaction is operative here, in which children having risk genes for ADHD are more susceptible during fetal development to the adverse effects of prenatal smoking exposure (Neuman et al., 2007).

Maternal alcohol consumption, at least at moderate levels, may make some contribution to risk for ADHD. The evidence here is less conclusive than that for a relationship between maternal smoking and ADHD (see Linnet et al., 2003, for a review). The relationship of maternal alcohol consumption to ADHD may be due to its link to maternal smoking (Rodriguez et al., 2009): Women who smoke more tend to consume more alcohol during their pregnancies. Even so, other researchers suggest that alcohol consumption may still make a contribution to ADHD risk even if they control for other factors (O'Malley & Nanson, 2002). And recent neuroimaging researchers have suggested that fetal exposure to smoking (Ekblad et al., 2010; de Zeeuw, Zwart, Schrama, van Engeland, & Durston, 2012) and alcohol is associated with reduced brain volume in children with ADHD, especially in the cerebellum, even relative to children with ADHD who have not been exposed (de Zeeuw et al., 2012).

There has been far less research on prenatal cocaine exposure and risk for ADHD than on alcohol or tobacco smoking exposure. It has been suggested that such cocaine use by pregnant women may result in maternal hypertension, decreased uterine blood flow, fetal vasoconstriction and hypoxemia, and nutritional deficiency, among other effects. But some evidence does suggest a dose–response relationship between such maternal cocaine use and risk for a diagnosis of ADHD (Morrow et al., 2009).

Boucher and colleagues (2012) recently observed that placental cord levels of mercury at the time of birth are linked to an elevated level of ADHD symptoms at school age. This suggests yet another possible prenatal environmental toxin that may be implicated in the disorder, although replication of these findings is certainly in order.

Prospective population studies implicate household and outdoor pesticide exposures during critical periods in pregnancy as predictive of ADHD (Goldman et al., 1997; Sagiv et al., 2010; see Nigg, 2006, for a review). In a recent review of the literature, Polanska, Jurewicz, and Hanke (2013) likewise suggested a potential adverse effect of pesticide exposure to risk for ADHD. And a cross-sectional study of a large population sample revealed that children with elevated pesticide metabolite concentrations in urine were nearly twice as likely to have ADHD as were children without such elevated concentrations (Bouchard, Bellinger, Wright, & Weisskopf, 2010). But more research is needed to determine if this is merely a correlate of other causal processes or it is itself a cause of ADHD via neurotoxicity. A recent review of the literature on other such environmental toxins found the greatest evidence for maternal smoking, as discussed earlier. It found far less and inconsistent evidence for chemicals such as phthalates (often found in plastics), bisphenol-A (used in plastics and resins), polycyclic aromatic hydrocarbons (an organic pollutant related to fossil fuels and other carbon-based fuels), and polyfluoroalkyl (used in numerous consumer products, packaging, labeling, coatings, paper, and even personal care products) (Polanska et al., 2013). There is some initial, albeit preliminary, evidence that excess exposure to manganese found in soy-based infant formula may be neurotoxic at high levels and linked to ADHD symptom risk (see review by Crinella, 2012), but far more evidence is required to confirm and understand the nature of this potential relationship.

A crucial challenge in such research is to determine whether such correlates, even though they emerge in prospective population-based studies, are causal. Although G × E interactions, as well as gene–environment correlation can mask environmental effects, they can also mask genetic effects. Teratogens and toxins could be proxies for genetic risk because of gene–environment correlation. This cautionary remark applies to the previously discussed evidence for maternal smoking during pregnancy, secondhand smoke after birth, and even paternal smoking, in which such factors may be proxies for elevated ADHD in the parents that conveys a genetic ADHD risk to offspring (Langley, Heron, Smith, & Thapar, 2012). Moreover, some researchers suggest that such early environmental insults (e.g., pregnancy complications) and toxins may not operate directly on brain maldevelopment but may produce their effects via epigenetic mechanisms that become dysregulated, resulting in altered and abnormal genetic expression (Mill & Petronis, 2008).

Elevated levels of phenylalanine in mothers with PKU (phenylketonuria) have been associated with higher levels of hyperactive–impulsive symptoms in their offspring, whereas when children experience PKU it is more likely to be associated with symptoms of inattention (Antshel & Waisbren, 2003). This study implies that phenylalanine may contribute to some degrees to ADHD in some children, and that the timing of exposure to high levels of phenylalanine affects the two symptom dimensions of ADHD differently.

Other dietary factors that to a small extent may contribute to variation in ADHD traits are discussed in Chapter 25 on dietary treatments.

STREPTOCOCCAL INFECTION

Some earlier researchers suggested that obsessive–compulsive disorder (OCD) and Tourette syndrome may be a consequence of prior exposure to streptococcal infection (Kiessling, Marcotte, & Culpepper, 1993; Singer et al., 1998). In some individuals, such infections may result in autoimmune system antibodies that cross-react with and compromise neural proteins, particularly in the basal ganglia of the brain. Peterson and colleagues (2000) examined 105 individuals with OCD, chronic tic disorder, or ADHD and 37 controls without any disorder. Levels of antistreptococcal antibody titers in blood were measured, as was the integrity of the basal ganglia using MRI. Results indicated that ADHD is significantly related to such antibodies, even after researchers controlled for the effects of OCD and tic disorders, and these antibodies are related to basal ganglia volume. Additional evidence of the possible role of strep infection in ADHD came from the later study in which children with tic disorder, Tourette syndrome, or OCD were more likely to have had a strep infection than control cases, and that these children were also more likely to have ADHD (Leslie et al., 2008). Maddalena and colleagues (in press) found that children with ADHD alone (and no comorbidity) manifested higher antibasal ganglia antibodies and serum antistreptoylsin titers, both of which are indicative of strep infection-induced damage to the basal ganglia, than did control children. These studies suggest that some cases of ADHD may arise from or be exacerbated by streptococcal infection, perhaps via the damaging effects this may have on basal ganglia.

TRAUMATIC BRAIN INJURIES

For many years, dating back to the classic case of Phineas Gage (Harlow, 1848), research on the frontal lobes has indicated that traumatic injuries to the brain and specifically to this region are likely to result in symptoms resembling ADHD, among other disorders. Research in the past decade has shown that children who survive traumatic brain injuries (TBIs) sufficiently to warrant treatment at hospital trauma centers are likely to develop significant attention problems and clinically diagnosed ADHD as a consequence of their TBI. Yeates and colleagues (2005) compared children with severe TBI to those with moderate TBI and a control group with orthopedic injuries on ratings of inattention and neuropsychological tests of attention and EF. They found that the severe TBI group had worse inattention than the moderate TBI group at 4-year follow-up. By that follow-up, 46% of the severe TBI group had significant attention problems compared to 26% of the children with orthopedic injuries. More attention problems were associated with greater EF deficits on testing. Max and colleagues (2005a) found that 16% of children with TBI who had not previously had a diagnosis of ADHD developed ADHD within 6 months of their TBI. Importantly, the development of ADHD was associated significantly with evidence of injury to the orbitofrontal gyrus (Max et al., 2005a). Further follow-up of these children indicated that 15% had developed ADHD between 6 and 12 months of injury, and 21% had developed it in their second year after injury, suggesting a rising risk for ADHD over the 2 years after TBI (Max et al., 2005b). This study reported that secondary ADHD was associated with postmorbid personality changes and new-onset disruptive behavior disorders. In contrast to children developing ADHD within 6 months of TBI, development of ADHD later was predicted by children's lower preinjury adaptive functioning and higher levels of preinjury psychosocial adversity, not by injury location in the brain. In a larger subsequent study, Levin and colleagues (2007) compared samples of children who had preinjury ADHD and those who did not, all of whom had been treated for acute TBI. Among those with no preinjury ADHD, 14.5% had developed ADHD within 6 months and 18.3% by 24 months after TBI. Of the children with preinjury ADHD, 96% had the diagnosis at 6-month follow-up, and 85% at 12-month follow-up. TBI exacerbated the symptoms of ADHD in those who had the disorder preinjury and resulted in a more variable course of ADHD symptoms after injury in those with no history of ADHD before their TBI. Low SES prior to injury was the only predictor of risk for ADHD from TBI at follow-up in the group without preinjury ADHD. Treatment with stimulant medication prior to TBI in children with preinjury ADHD was associated with less exacerbation of their symptoms following TBI. Children who develop secondary ADHD from TBI may have a different profile of inhibitory problems than do children with primary ADHD (not secondary to TBI; Sinopoli, Schachar, & Dennis, 2012). Eme (2012) reviewed this literature, comprising seven separate studies, and concluded that the rate of ADHD secondary to TBI is at least 30% (ranging from 19 to 48%) and that rates may be even higher in those suffering severe TBI because many of these TBI cases were collapsed together regardless of severity. Indeed, ADHD, ODD, and organic personality disorder may be the most common psychiatric diagnoses given to children following TBI. Eme concluded that many more children having TBI are likely to experience emotional dysregulation than is recognized in these rates of formal DSM diagnoses of ADHD that do not incorporate symptoms of emotion regulation problems as part of their criteria (see Chapter 3). All this makes clear that ADHD can be caused by TBI at any stage of child development (and likely across adulthood).

PSYCHOSOCIAL FACTORS

Even the first medical references to an ADHD-like condition in the literature proposed that poor child-rearing and poor teaching, among other social factors, might contribute to ADHD (Crichton, 1798 [also see Palmer & Finger, 2001]; Weikard, 1775 [also see Barkley & Peters, 2012]; see Chapter 1). A few environmental theories of ADHD that were proposed nearly 30 years ago (Block, 1977; Willis & Lovaas, 1977) have neither shown any consistency with the subsequent scientific literature nor received much direct research attention. Willis and Lovaas (1977) claimed that hyperactive behavior is the result of poor stimulus control as a result of weak maternal commands, and that this poor regulation of behavior arises from poor parental management of the children. But if this were the case, there would be a substantial contribution to ADHD from shared or rearing environments in the numerous twin studies conducted to date (discussed earlier), and the exact opposite has been the result. As noted earlier in

"Twin Studies," there is no significant contribution of the rearing or common environment to the behaviors that comprise ADHD.

Others have also conjectured that ADHD results from difficulties in the parents' overstimulating approach to caring for and managing the child, as well as parental psychological problems (Carlson, Jacobvitz, & Sroufe, 1995; Jacobvitz & Sroufe, 1987; Silverman & Ragusa, 1992). But these theories have not clearly articulated just how deficits in behavioral inhibition and other cognitive deficits commonly associated with clinically diagnosed ADHD (Chapters 2, 4, and 10) could arise from such social factors. Moreover, many of these researchers claiming to have evidence that parental characteristics potentially cause ADHD did not use clinical diagnostic criteria to identify their children as having ADHD; instead, they relied merely on elevated parental ratings of hyperactivity or laboratory demonstrations of distractibility to classify the children as ADHD (Carlson et al., 1995; Silverman & Ragusa, 1992). Nor have these theories received much support in the available literature on clinically diagnosed children with ADHD (Danforth, Barkley, & Stokes, 1991; Johnston & Mash, 2001; see Chapter 7). Again, in view of the previously discussed twin studies that show no significant contributions of the common or shared environment to the expression of symptoms of ADHD, theories based entirely on explanations of shared social experiences to explain the origins of ADHD are difficult to take seriously, especially when they do not explain the precise social mechanism by which this effect is supposed to occur. Nor do they involve genetically informed study designs that could easily tease out genetic effects from shared environmental effects. When that is done, the shared environment contributes no significant variance to symptoms of the disorder (see the earlier section on genetics).

Despite the large role heredity seems to play in ADHD symptoms, they may be associated with or even shaped by unique environmental influences, psychosocial adversities, and nonshared social learning. The actual severity of the externalizing symptoms generally, the continuity of those symptoms over development, the types of secondary symptoms, and the outcome of the disorder are related in varying degrees to environmental factors such as psychosocial adversities (parental mental illness, substance abuse, and criminality; family violence, psychical abuse, sexual abuse, and neglect; divorce, and lower SES, among others) (Biederman et al., 1995, 1996; Green et al., 2010; Lingineni et al., 2012; Milberger, Biederman, Faraone, Guite, & Tsuang, 1997; van den Oord & Rowe, 1997; Weiss & Hechtman, 1993). Yet even here care must be taken in interpreting these correlational findings because such adversities are not specific to any single disorder; they are associated with a general risk for psychopathology or disruptive behavior disorders, not ADHD specifically; and they cluster together and are subject to recall bias (Green et al., 2010). Moreover, the direction of causation here is not usually specifiable from the findings (i.e., correlation is not evidence of causation). And some evidence suggests that such childhood adversities are more related to the onset of mood and anxiety disorders, as well as substance use disorders, than to disruptive behavior disorders such as ADHD, yet even here the amount of variance explained is modest (McLaughlin et al., 2010). These studies are also not evidence of a purely social-environmental contribution of childhood adversities to ADHD because many measures of family function and adversity are genetically influenced, which is to say that they also have a strong heritable contribution, largely owing to the presence of similar symptoms and disorders in the parents and the children who share the genes for these disorders and not just their social environments (Pike & Plomin, 1996; Plomin, 1995). Thus, there is a genetic contribution to the family environment, and that genetic contribution may account for the largest degree of risk for ADHD specifically and psychopathology more generally in the children, a fact that often is overlooked in studies of family and social factors involved in ADHD.

Moreover, concerning the role of parenting as a cause in ADHD, as noted in Chapter 7 (see also Danforth et al., 1991), several investigators attempted to evaluate the direction of effects within parent–child interactions. They did so by investigating the effects of stimulant medication and placebo on these mother–child interactions. The studies consistently found that the medications resulted in significant improvements in child hyperactivity and compliance. There was a corresponding reduction in mothers' use of commands, direction, and negative behavior when the children were on medication, indicating that much of the negative behavior of the mothers appeared to be in response to the difficult behavior of these children.

Taken together, these findings suggest that the overly critical, commanding, and negative behavior of mothers of hyperactive children is most likely a reaction to the difficult, disruptive, and noncompliant behavior of these children rather than the cause of it.

And such disrupted parenting is not only likely to be a reaction to the child's behavioral control problems, but it may also arise from the parents' own ADHD and the parents' higher likelihood of experiencing other psychological disorders, such as depression, anxiety, antisocial disorders, and substance dependence/abuse. This is not to say that the manner in which parents attempt to manage their children's ADHD behavior cannot exacerbate it or maintain higher levels of conflict between mother and child over time. Studies have shown that the continuation of hyperactive behavior over development, and especially the maintenance of oppositional behavior in these children, is related in part to parents' use of commands and criticism, and an overcontrolling and intrusive style of management. But all this tells us is that comorbid ODD, when seen in ADHD may, in part, be a function of parental management practices, which is quite consistent with theories of ODD (Barkley, 2013). Yet this does not mean that the child's ADHD is a result of those practices. Indeed, recent twin studies suggest that the high association of ADHD with ODD/CD is likely the result of a shared genetic liability for these two disorders, with ODD/CD also being influenced by additional genetic factors (Nadder et al., 2002). Theories of the causation of ADHD can no longer be based solely or even primarily on social factors, such as parental characteristics, caregiving abilities, child management, or other family environmental factors.

There is no question that parenting is related to risk for ODD and CD (see Barkley, 2013, for a review). And because those disorders are often comorbid with ADHD, researchers may carelessly attribute family, parenting, or social correlates of ADHD as causes of ADHD itself. But in fact, these psychosocial adversities are related to and likely cause the comorbidity of these other disruptive, externalizing disorders that often coexist with ADHD. Researchers who do not take such relationships into account risk misattributing psychosocial risk factors, such as parenting, as correlates or causes of ADHD when they are either the result of ADHD in the child, shared genetic risk with parental mental disorder, or contributors to comorbid disruptive disorders instead.

Block (1977) proposed that an increase in "cultural tempo" in Western civilization may account for the prevalence of hyperactivity in these countries. Precisely what is meant by "cultural tempo" is not operationally defined, nor is evidence presented to suggest that underdeveloped or Eastern cultures have less hyperactivity than do more developed cultures. This theory and its modification by Ross and Ross (1982) remain speculative to this day and seem almost to be scientifically untestable. Moreover, such theories, once again, conflict with a wealth of information on genetics and heritability of this behavior pattern and disorder, and the nonsignificant role of the common environment (of which this tempo would be considered a part) argues against these theories as explanations for the occurrence of most ADHD in children.

One psychosocial factor that periodically receives attention in the popular media as a cause of ADHD is the degree of children's exposure to television or other televised media (video games). Various commentators imply that ADHD, or at least its attention symptoms, could arise from watching too much television in early childhood. And they admonish parents about this detrimental effect and warn them to reduce TV viewing so as to reduce the risk of their child having ADHD. The occasional research study appears to support these critics, but a closer look often indicates that the article overstates the results or, more likely, confuses a correlation with a cause: Children with ADHD watch more TV; therefore, TV causes ADHD

For instance, Christakis, Zimmerman, DiGiuseppe, and McCarty (2004) examined the relationship between hours of television viewed at ages 1 and 3 years, and attention problems at age 7 years, as measured by five items from the Hyperactivity subscale of the Behavior Problems Index. They defined children as having an attention problem if they were 1.2 standard deviations above the mean on this set of five items—a very generous definition of attention problems. Ten percent of their sample was so classified at age 7 years. After statistically controlling for a number of other variables, the authors found that number of hours of television exposure at ages 1 and 3 years was slightly yet significantly associated with being classified as having attention problems at age 7 years. The hypothesis was that early TV viewing shortens children's attention spans because of the unrealistic pace with which TV events unfold relative to real life. The exact mechanism for this causal influence is suggested to be exposure to TV during critical periods of synaptic development in brain neurons. Measures of synaptic development were not taken in the study. While the authors claimed that their findings supported their hypothesis, they did note that their study design permitted no causal inferences from these associations. They then quickly forgot this limitation by stating that they have now added inatten-

tion to the list of detrimental effects of excessive television viewing (such as violent behavior and obesity). They even recommended implementing preventive strategies based on this causal conclusion even going so far as to say that reducing TV exposure might reduce the later risk of developing ADHD.

This is not the only study to find such an association (Landhuis, Poulton, Welch, & Hancox, 2007; Mehmet-Radji, 2004; Miller et al., 2007; Nathanson, Alade, Sharp, Rasmussen, & Christy, in press; Swing, Gentile, Anderson, & Walsh, 2010). But when affirmative results are found, they are small (< 5% of variance explained) even if significant (usually resulting from the use of large sample sizes), and may be found just on teacher-rated inattention, not parent-rated inattention (Miller et al., 2007). And as Miller and colleagues noted, they cannot determine the causal direction from their findings.

Several problems are remarkable about the Christakis and colleagues (2004) study (and others). If, as the authors rightly noted, this study can say absolutely nothing about early TV exposure *causing* attention problems in children, much less ADHD, then why go on to make such sweeping conclusions based on so weak a correlation? One could just as easily say that attention problems lead children to watch more TV. Critically missing in these affirmative studies is the very real possibility that genetics may actually mediate this relationship. Nowhere do these various studies and their authors even acknowledge that genetic effects may mediate these relationships of inattention to TV viewing. Attention problems such as found in ADHD have a strikingly high genetic influence (average heritability of 71–73% across studies and higher in studies using DSM symptom lists; discussed earlier). This means that much of the variation in attention problems in children is the result of genetic effects. Even more important, twin studies have found no compelling evidence that the shared or rearing environment makes any contribution to these symptoms (discussed earlier). TV viewing within families is often a shared event among children in the family, not a unique event that is specific to just one of them.

This is not just conjecture. In another study of this issue, Reitveld, Hudziak, Bartels, van Beijsterveldt, & Boomsma, 2004) assessed children's attention problems at age 3, then later at 7—the same time frame as in the Christakis and colleagues (2004) study. (Reitveld et al. also assessed them again at ages 10 and 12 years of age.). The beauty of their study is that it was a longitudinal examination of 11,938 twins, so it tells us a great deal about genetic and environmental factors that explain the variation in attention problems. Reitveld and colleagues (2004) found that average heritability across ages for attention problems ranged from 70 to 74%, as expected from numerous other twin studies. All residual variation in this trait was due entirely to unique environmental effects (events not shared among twins or siblings). *None was accounted for by shared events* (!). The authors concluded as well that the stability of attention problems in these twins was also accounted for by genetic factors. This suggests that the children with attention problems at age 7 were highly likely to have already had attention problems at age 3 (and probably age 1), and that the presence of those problems at both ages and their persistence over development are largely explained by genetic factors, along with a more modest contribution of unique events that befall these children. They are not due to any shared event such as TV viewing within the family.

Furthermore, children and adults with ADHD are known to be more likely to watch TV and to watch more TV (Acevedo-Polakovich, Lorch, & Milich, 2007; Barkley, Murphy, & Fischer, 2008; Lingineni et al., 2012) and report enjoying it more than do children without ADHD (Acevedo-Polakovich et al., 2007). This makes it just as likely that the opposite causal direction is operative here: Children with more attention problems prefer and watch more TV than do less inattentive children or those without ADHD and the more severe their inattention the more likely they are to do so over time. Inattentive children also likely have more inattentive parents who may permit their children more time viewing TV than would more attentive parents.

Does content of the programs matter or is it merely quantity of exposure that is so harmful? Interestingly, Christakis and colleagues (2004) say nothing about this issue, yet they confide that educational programs might well have had a *beneficial* effect and moderated their results, thereby making those results a conservative estimate of TV's potential harm to children's attention spans. This is having your cake and eating it too: TV is bad for your children's attention, they want to say, but they are quick to dismiss educational TV from this indictment. In a later study, Zimmerman and Christakis (2007) examined TV content and found that time watching educational TV was not related to attention problems later in childhood, but that watching entertainment programs before age 3 was so related. Interest-

ingly, TV viewing at age 4 or 5 was not related to later attention problems. Likewise, later research indicated that viewing child-directed TV programs from ages 1–4 years was not linked to problems with attention or EF, but watching adult-directed content was so related.

However, efforts to replicate these findings failed to find the reported relationship of early TV exposure and later attention problems. Some of these studies used the same database as Christakis and colleagues (2004), whereas others used even larger and more representative samples, and more appropriate statistical analyses (e.g., Ferguson, 2011; Mistry, Minkowitz, Strobino, & Borzekowski, 2007; Stevens, Barnard-Brak, & To, 2009; Stevens & Muslow, 2006). Others who reviewed this literature have reached the same conclusions as I have here about the lack of convincing evidence on the causal role of televised media exposure and ADHD (e.g., Banerjee, Middleton, & Faraone, 2007). Some suggest a more complicated relationship and indicate that the influence here could be bidirectional, at least for playing video games, which young children who are more inattentive and impulsive play more, and playing games feeds back to exacerbate inattentive and impulsive behavior (Gentile, Swing, Lim, & Khoo, 2012). This suggests that the affirmative studies provide examples of how investigator bias toward correlational findings, inappropriate methods and statistics, a media propensity for sensational findings, and especially a lack of genetically informed methodology can all lead to inappropriate conclusions about the causes of ADHD and to feeding the public an exceptionally mistaken impression—that TV causes ADHD. Of course, the trade media failed to report on these failures to replicate the initial findings. It is little wonder that the vast majority of reports in the media on scientific discoveries are never subsequently replicated given this bias to report mainly on sensational and unexpected findings, without regard to their methodological shortcomings (Gutting, 2013).

SUMMARY

It should be evident from the research reviewed here that neurological and genetic factors make a substantial contribution to symptoms of ADHD and the occurrence of the disorder. A variety of genetic and neurological etiologies (e.g., pregnancy and birth complications, acquired brain damage, toxins, infections, and genetic effects) can give rise to the disorder, likely through some disturbance in a final common pathway in the nervous system. That final common pathway appears to date to be the integrity of the prefrontal cortical–striatal–cerebellar network. It now appears that hereditary factors play the largest role in the occurrence of ADHD symptoms in children. Yet the condition can also be caused or exacerbated by pregnancy complications, exposure to toxins, or neurological disease. Social factors alone are not supported as causal of this disorder, but such factors may possibly interact with genetic risks for the disorder and may contribute to the forms of comorbid disorders associated with ADHD. Cases of ADHD can also arise without a genetic predisposition to the disorder provided the child is exposed to significant disruption or neurological injury to this final common neurological pathway. But this would seem to account for only a small minority of children with ADHD. In general, then, research conducted since the previous edition of this volume was published has further strengthened the evidence for genetic and developmental neurological factors, along with biohazardous events during brain development, as likely causing this disorder, while greatly reducing the support for the role of purely social factors in causing ADHD.

KEY CLINICAL POINTS

- ✓ There is no current, credible scientific theory of ADHD that can account for its existence by purely social means.
- ✓ The totality of evidence indicates that genetic factors related to brain development and functioning, as well as nongenetic neurological factors, play a substantial and majority role in the origins and expression of this disorder.
- ✓ Family studies show a markedly elevated risk of ADHD among the biological relatives of children with ADHD (10–35%), rising to as much as 55% risk to at least one parent in families with two affected children. Parental ADHD coveys a risk of up to 57% to offspring. Adoption studies indicate no increased risk of ADHD among adoptive parents of adopted children with ADHD, further supporting a genetic contribution to ADHD.
- ✓ Numerous studies of large samples of twins in many countries find a genetic contribution accounting for 50–95% of the variation in the traits comprising ADHD

averaging 70–80% or higher. No significant contribution of shared or common environmental factors (rearing environment) has been evident, while nonshared or unique environmental factors make a small but significant contribution to variation in these traits. The strong genetic contribution to ADHD is now a "fact in the bag," and the consistent absence of a rearing environmental contribution rules out within-family factors as contributing to the expression of the disorder but suggests some role for unique events in the lives of children (pregnancy complications, biohazards, developmental risks, and possibly unique social effects).

- ✓ Molecular genetic studies indicate that multiple gene sites are likely to contribute to ADHD risk, with up to 26 candidate genes implicated across studies and possibly as many as 40+ sites in the genome being possible gene polymorphisms contributing to the disorder. Genomewide scans have yet to find evidence for specific genes, largely owing to small sample sizes available at this time that preclude adequate power to detect genes having small effects on the traits of the disorder. Larger samples are now being accumulated that permit more powerful tests for risk genes to ADHD. Meanwhile, some promise is evident in identifying suites of genes that contribute to neurotransmitter pathways. Other studies suggest that some gene polymorphisms, as well as accumulated rare CNVs, may contribute to risk for the disorder.
- ✓ Neuropsychological research finds substantial evidence of deficits in behavioral inhibition, sustained attention (task persistence), resistance to distraction, and EF (the internalization of speech and verbal working memory, temporal-sequential working memory, motor coordination, and the timing of fine-motor movements, emotional and motivational self-regulation, verbal fluency, and planning; see Chapter 3). The EFs are mediated by the prefrontal cortex and its networks with the basal ganglia, anterior cingulate cortex, and cerebellum, among other structures, suggesting that these regions may play a prime role in underlying ADHD.
- ✓ Psychophysiological research demonstrates reduced arousal in response to stimulation (particularly on averaged evoked responses), diminished sensitivity to reinforcement, and increased slow-wave (associate with drowsiness and poor focus of attention) or theta activity, and often decreased beta or fast-wave activity (associated with decreased concentration and persistence) on EEG.
- ✓ Studies of cerebral blood flood indicate reduced flow to the frontal lobes, striatum, and cerebellum, consistent with underactivity in these regions.
- ✓ PET scan studies are inconsistent but suggest some reduced activation in the insular and hippocampal regions and greater activation in the right anterior cingulate during decision-making tasks.
- ✓ MRI studies indicate smaller total brain size, with greatest reductions in brain volumes of the anterior frontal lobes (mainly on the right), the basal ganglia, anterior cingulate cortex, cerebellar vermis (mainly on the right), and corpus callosum (mostly the splenium or frontmost section).
- ✓ fMRI indicates differences from normal brain activity in the frontal region, basal ganglia, anterior cingulate cortex, and cerebellum, among other regions.
- ✓ Deficits in specific neurotransmitters have not been definitively established, but a clear role for DA and NE is suggested by the positive response of those with ADHD to stimulants (DA reuptake inhibitors and agonists) and atomoxetine (noradrenergic reuptake inhibitors), by the distribution of these two transmitter networks in the brain regions implicated in ADHD, and by some peripheral metabolite indices of these neurotransmitters.
- ✓ Pregnancy complications are associated with risk for ADHD, especially maternal smoking, maternal alcohol consumption, LBW and associated minor brain hemorrhaging, possibly maternal phenylalanine levels, and an arguable role for stress/anxiety during pregnancy.
- ✓ Several prenatal toxins have been associated with risk for ADHD, two of which are maternal smoking and alcohol consumption, as noted earlier. Another environmental toxin is postnatal elevated body lead burden during the first 2–3 years of child development.
- ✓ One study suggests a potential contribution of streptococcal infection to some cases of ADHD, wherein the infection triggers an immune response of antibodies that destroy cells of the basal ganglia.
- ✓ Evidence for a contribution of psychosocial factors to ADHD is weak. The recent suggestion from several studies of a role for television viewing during early childhood contributing to ADHD seems to have been overstated, may be more a correlate of attention problems than a cause, did not employ genetically informed designs, and has not been replicated in some studies.

CHAPTER 15

Theories of ADHD

Erik G. Willcutt

The next chapter clearly describes a strong theoretical model of executive functioning (EF) and self-regulation as forming a phenotype that extends outward into the physical and social ecology to produce adaptive effects at a considerable distance over space and time from the individual. It then extrapolates that theory to understanding attention-deficit/hyperactivity disorder (ADHD) and its management (Chapter 16; Barkley, 2012). My overarching objective in this chapter is to describe and evaluate several other theoretical models of ADHD that have been proposed in the literature. The most prominent competing theories hypothesize that ADHD may arise from more general weakness in EFs—specifically, inhibition and working memory (e.g., Pennington & Ozonoff, 1996), pronounced aversion to the experience of delay (e.g., Sonuga-Barke, Taylor, Sembi, & Smith, 1992), dysfunctional responses to reward and/or punishment contingencies (e.g., Luman, Oosterlaan, & Sergeant, 2005), increased intraindividual variability in response time due to attentional fluctuations (e.g., Sergeant, Geurts, Huijbregts, Scheres, & Oosterlaan, 2003; Sonuga-Barke & Castellanos, 2007), or overall slow cognitive processing speed (e.g., McGrath et al., 2011; Shanahan et al., 2006).

META-ANALYSES OF NEUROPSYCHOLOGICAL STUDIES OF ADHD

The neuropsychological literature on ADHD is immense. As of December 2013, over 500 studies had examined some aspect of the neuropsychological correlates of ADHD, and many of these studies were published after the previous edition of this book was completed (Barkley, 2006). This rapid accumulation of new knowledge has not only provided a key resource to facilitate continued refinement of theoretical models of the pathophysiology of ADHD, but it has also underscored the complexity of the neuropsychological dysfunction that is associated with ADHD.

"Meta-analysis" is a statistical procedure that is used to combine effect sizes from multiple studies to compute a single pooled estimate of the overall effect size in the population. Over the past 10 years our group and several others have completed a series of metaanalyses of different aspects of the neuropsychology of ADHD (e.g., Frazier, Demaree, & Youngstrom, 2004; Hervey, Epstein, & Curry, 2004; Huang-Pollock, Karalunas, Tam, & Moore, 2012; Lansbergen, Kenemans, & Van, 2007; Lijffijt, Kenemans, Verbaten, & van Engeland,

2005; Martinussen, Hayden, Hogg-Johnson, & Tannock, 2005; Pauli-Pott & Becker, 2011; Schoechlin & Engel, 2005; Sonuga-Barke, Sergeant, Nigg, & Willcutt, 2008; van Mourik, Oosterlaan, & Sergeant, 2005; Willcutt & Bidwell, 2011; Willcutt, Brodsky, et al., 2005; Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005; Willcutt, Sonuga-Barke, Nigg, & Sergeant, 2008; Woods, Lovejoy, & Ball, 2002), culminating in our recent meta-analysis of all available neuropsychological studies of DSMIV ADHD symptom dimensions and subtypes (Willcutt et al., 2012). For the purposes of this chapter, all effect sizes have been converted to Cohen's *d*, a widely used measure that reflects the mean difference between groups with and without ADHD, divided by the pooled standard deviation (Cohen, 1988). Therefore, an effect size of 0.5 would indicate that the ADHD and control group differ by half of a standard deviation.

In the subsequent section, I first describe each competing theoretical model and provide a streamlined summary of the neural circuits that are implicated by the theory (because the inhibition–EF extended phenotype model proposed by Barkley is described in detail in Chapter 16, it is described only briefly here). I then summarize results from the latest meta-analyses to evaluate of the validity of each competing model as a theoretical explanation of ADHD. In the penultimate section of the chapter, I discuss the important constraints that are provided by these results for current and future theoretical models of ADHD, then examine the strengths and weaknesses of a recent shift toward theoretical models that explicitly hypothesize that ADHD arises from weaknesses in two or more domains. Finally, I conclude the chapter by describing several key directions for future research that are needed to facilitate the continued development and refinement of a comprehensive theoretical model of ADHD.

COMPETING THEORETICAL MODELS OF ADHD

EFs and Behavioral Inhibition

In addition to Barkley's extended phenotype theory of EF and its application to ADHD (Chapter 16), several other theoretical models have proposed that symptoms of ADHD arise from a more general weakness in the EFs, cognitive processes that facilitate the maintenance of an optimal problem-solving set to attain a future goal (e.g., Barkley, 1997; Pennington & Ozonoff, 1996). In a simplified model of cognitive control and decision-making processes, EFs represent "top-down" cognitive inputs that facilitate decision making. They do so by maintaining information about possible choices in working memory, suppressing irrelevant information, and inhibiting responses that are maladaptive or simply off-task. This knowledge is then integrated with information about reinforcement probabilities to select the optimal action for the situation. Although executive control processes involve several distributed brain networks, studies of primates and neuropsychological, neuroimaging, and lesion studies of humans suggest that the primary neural circuit(s) include the thalamus, basal ganglia, and dorsolateral and ventrolateral regions of the prefrontal cortex (Chapter 14; also see Pennington, 2002).

Although initial studies often described EF as a single unitary construct, subsequent exploratory and confirmatory factor analyses and more recent functional neuroimaging studies suggest that EFs are more accurately characterized as a collection of at least six related but separable processes. These include response inhibition, verbal and spatial working memory, set shifting, planning, and interference control (e.g., Collette et al., 2005; Friedman et al., 2008; Miyake et al., 2000; Willcutt, Pennington, Olson, Chhabildas, & Hulslander, 2005).

Meta-analyses of studies of both children and adults indicate that ADHD is associated with significant weaknesses on measures of most EF domains (Figure 15.1). Results of individual studies indicate that these group differences remain significant when any group differences in intelligence, reading ability, and symptoms of other disorders are controlled (e.g., Barkley, Murphy, & Bush, 2001; Nigg, Hinshaw, Carte, & Treuting, 1998; Willcutt, Betjemann, et al., 2010; Willcutt, Pennington, et al., 2005). Pooled effect sizes were largest for measures of response inhibition ($d = 0.73$; Figure 15.1). This effect size falls in the range that Cohen (1988) classified as a medium to large effect, and suggests that poor inhibitory control accounts for approximately 10% of the variance in ADHD symptoms in the population. Effect sizes were similar but slightly lower on measures of working memory and planning, whereas substantially smaller effects were reported for measures of other EF constructs such as set shifting and interference control on the Stroop task (labeled "Other EF" in Figure 15.1; for meta-analytic reviews of these constructs, see van Mourik et al., 2005; Willcutt, Doyle, et al., 2005).

These phenotypic results are also consistent with results from twin studies, which suggest that the mod-

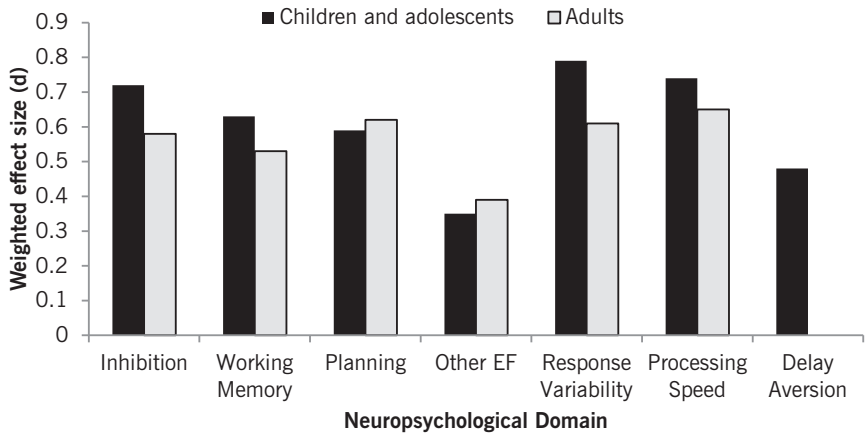

FIGURE 15.1. Weighted mean effect sizes of the difference between groups with and without ADHD on measures of competing theoretical models of ADHD. Effect sizes are based on studies included in previous meta-analyses of neuropsychological studies of children and adults with ADHD, updated to include papers published after the latest meta-analysis (e.g., Frazier et al., 2004; Hervey et al., 2004; Huang-Pollock et al., 2012; Lansbergen et al., 2007; Lijffijt et al., 2005; Martinussen et al., 2005; Pauli-Pott & Becker, 2011; Schoechlin & Engel, 2005; Sonuga-Barke et al., 2008; van Mourik et al., 2005; Willcutt & Bidwell, 2011; Willcutt, Brodsky, et al., 2005; Willcutt, Doyle, et al., 2005; Willcutt et al., 2008, 2012; Woods et al., 2002).

erate covariance among response inhibition, working memory, and ADHD symptoms is primarily explained by common genetic influences (e.g., Willcutt, Betjemann, et al., 2010). However, in addition to the subset of etiological influences that are shared, twin analyses indicate that the majority of the genetic and environmental influences on ADHD symptoms are independent of the influences that lead to weaknesses in inhibition and other aspects of executive control.

In summary, meta-analyses of over 250 studies provide strong support for the theory that ADHD is due at least in part to weaknesses in inhibitory control and other aspects of EF. However, the overall effect sizes from meta-analyses of studies of children and adults indicate that each specific EF weakness accounts for no more than 10% of the variance in ADHD symptoms, suggesting that none of these weaknesses is necessary or sufficient to cause ADHD in isolation.

Motivational Dysfunction

Motivational explanations of ADHD have several variants, but all of these theories suggest that ADHD is attributable to a dysfunctional response to reward and/or punishment contingencies (see Luman et al., 2005, for a comprehensive review). Damage to a neural circuit that includes ventromedial prefrontal cortex, the amygdala, and other limbic structures often leads to difficulty in learning from mistakes and monitoring subtle shifts in reward and punishment probabilities to maximize the short- and long-term benefits of a choice (Bechara, Damasio, & Damasio, 2000; Rolls, 2004). Although only a handful of neuroimaging studies have examined this network in individuals with ADHD, two studies did find a significant correlation between reduced ventromedial prefrontal cortex volume and ADHD symptomatology (Carmona et al., 2009; Hesslinger et al., 2002).

Studies of ADHD that manipulated reward and punishment contingencies have reported mixed results. Because the wide range of tasks and study designs precluded a meta-analysis of these results, I provide a qualitative summary of these results rather than a meta-analysis. One subset of studies found that response contingencies improved and even normalized task performance in individuals with ADHD (e.g., Carlson & Tamm, 2000; Slusarek, Velling, Bunk, & Eggers, 2001). In contrast, several others found a main effect of reinforce-

ment or response cost on the task performance of all children, but no differential effect on individuals with ADHD (e.g., Scheres, Oosterlaan, & Sergeant, 2001; Shanahan, Pennington, & Willcutt, 2008). Finally, a set of studies found that when both reward and punishment were possible outcomes depending on an individual's behavior, individuals with elevations of ADHD symptoms exhibited higher rates of impulsive behavior than they did in a condition with response cost alone (Farmer & Rucklidge, 2006; Hartung, Milich, Lynam, & Martin, 2002).

Taken together, these results suggest that additional research is warranted to clarify the inconsistent results of studies of the impact of motivational contingencies on children with ADHD. However, with the possible exception of the delay aversion model described in the subsequent section, existing data provide minimal support for theoretical models that suggest ADHD is due primarily to a motivational dysfunction.

Delay Aversion

The delay aversion theory suggests that individuals with ADHD find the experience of delay extremely aversive and frustrating, which then leads to choices that minimize delay even when an alternative option would result in a larger reward after a longer delay (e.g., Bitsakou, Psychogiou, Thompson, & Sonuga-Barke, 2009; Sonuga-Barke, 2002; Sonuga-Barke et al., 1992). Individual differences in the capacity to tolerate delay are hypothesized to reflect activity in a neural circuit that includes feedback loops between ventromedial prefrontal cortex, limbic structures, and other areas of the prefrontal cortex (e.g., Sonuga-Barke, Dalen, & Remington, 2003; Sonuga-Barke & Sergeant, 2005). Dopamine, a key neuromodulator for this circuit, is implicated in signaling of rewards, coding incentive value, and coordinating interactions between motivation and cognition during decision-making processes (e.g., Rolls, 2004; Schultz, Tremblay, & Hollerman, 2000).

A number of studies have tested the delay aversion theory by assessing how often individuals with and without ADHD select a small immediate reward rather than a larger delayed reward during a laboratory task. The weighted mean effect size for delay aversion is significant and medium in magnitude, although slightly smaller than the effect sizes for response inhibition and working memory (Figure 15.1). Interestingly, a meta-analysis of studies of preschool children suggested that effect sizes for delay aversion are medium to large in early childhood, then tend to decline over time (Pauli-Pott & Becker, 2011). In contrast, a recent functional neuroimaging study found that experience of a delay was associated with increased right amygdala activity in adults with ADHD but not in adults without ADHD (Wilbertz et al., 2013). This result provides important evidence that adults with ADHD continue to experience negative arousal when exposed to delay, suggesting that additional research is needed to clarify the relation between delay aversion and ADHD across development.

Despite some inconsistent results across studies, the overall literature suggests that delay aversion is one component of a comprehensive neuropsychological model of ADHD. Delay aversion appears to be distinct from general cognitive ability and inhibitory control (e.g., (Karalunas & Huang-Pollock, 2011; Solanto et al., 2001; Sonuga-Barke et al., 2003), but additional studies are needed to test the relations between delay aversion and other cognitive processes such as working memory (Karalunas & Huang-Pollock, 2011) and response variability (e.g., Sonuga-Barke, Wiersema, van der Meere, & Roeyers, 2010).

Response Variability

One of the most consistent results in cognitive studies of ADHD is the finding that the responses of individuals with ADHD are slower and more variable than those of individuals without ADHD (e.g., Alderson, Rapport, & Kofler, 2007; Sergeant et al., 2003; Willcutt et al., 2008, 2012). Meta-analyses of studies that compared groups of children and adults with and without ADHD yielded medium to large effect sizes that are similar in magnitude to the effects that have been reported for response inhibition (Figure 15.1).

Although theoretical models of response variability were initially slow to develop, several theories have recently been proposed. One key theoretical issue concerns whether increased response variability is a unique weakness that is separable from the other cognitive weaknesses associated with ADHD, or whether response variability occurs as a secondary consequence of dysfunction in another cognitive process. For example, an initial parsimonious explanation suggested that increased response variability might be a simple consequence of slow overall reaction time (RT), but most subsequent studies have found that the association between ADHD and reaction time variability remains significant when simple reaction time is controlled (but see Karalunas, Huang-Pollock, & Nigg, 2012).

Studies that used sophisticated statistical models of RT distributions suggest that increased response variability is attributable to a relatively small number of trials with extremely long RTs rather than systematically slower and more variable responses across all trials (Hervey et al., 2006). These sporadic slow responses may potentially reflect attentional lapses due to weak executive control, inconsistent regulation of arousal during lengthy tasks, or dysfunction in short-duration timing mechanisms that are mediated by cerebellar circuits (e.g., Castellanos & Tannock, 2002; Johnson et al., 2007; Sergeant et al., 2003; Toplak & Tannock, 2005).

In summary, while additional research is needed to test competing theoretical models of response variability, the available literature clearly indicates that increased response variability is a robust correlate of ADHD. Of particular importance in the future are studies that administer measures of response variability along with measures of key constructs from other theoretical models of ADHD. By including measures of EF, motivational processing, delay aversion, and processing speed in the same battery as measures of response variability, future studies will be able to test directly whether response variability is independent from these other processes, interacts with weaknesses in one or more of these domains, or is best understood as a secondary consequence of another dysfunctional process.

Processing Speed

Finally, recent evidence from our laboratory and others indicates that groups with ADHD exhibit large and consistent deficits on measures of naming speed and general processing speed (e.g., McGrath et al., 2011; Rucklidge & Tannock, 2002; Shanahan et al., 2006). Effect sizes are medium to large in studies of both children and adults with ADHD (Figure 15.1), and remain significant when group differences in intelligence, reading achievement, and symptoms of other disorders are controlled (e.g., Willcutt, Pennington, et al., 2005).

To my knowledge, no theoretical models have proposed that slow processing speed is a primary weakness that is necessary and sufficient to cause ADHD. However, theoretical models of processing speed have received less attention than the models of the other processes discussed in this chapter. Nonetheless, the robust and consistent effect sizes reported for a range of measures of processing speed indicate that a comprehensive theoretical model of ADHD must account for this specific weakness and clarify its relation with measures of executive control, aversion to delay, and response variability.

DIAGNOSTIC ACCURACY OF MEASURES OF COMPETING THEORETICAL MODELS

The results summarized earlier clearly confirm that groups with ADHD differ from groups without ADHD on measures of multiple neuropsychological processes. To assess the clinical relevance of these group differences it is also important to examine the ability of each measure to predict categorical ADHD diagnostic status. To address this question for this chapter, I completed a series of analyses to calculate the proportion of individuals with ADHD who exhibited significant impairment on measures of each of the competing theoretical models of ADHD.

Analyses were completed in three independent samples in our laboratory. As part of their participation in the Colorado Learning Disabilities Research Center (CLDRC), a sample of 505 participants with ADHD between 8 and 15 years old completed an extensive test battery that includes multiple measures of response inhibition, working memory, response variability, delay aversion, and processing speed (e.g., Willcutt, Betjemann, et al., 2010; Willcutt, Pennington, et al., 2005). A similar battery was administered to a separate population-based sample of 350 children with ADHD who were between 7 and 13 years of age at the time of the assessment (e.g., Willcutt, 2012; Willcutt et al., 2011), and a sample of 190 young adults with ADHD completed all of these measures with the exception of delay aversion (e.g., Willcutt & Bidwell, 2011). In each sample, the 10th percentile of the control group was used as a cutoff score to define significant neuropsychological impairment on each measure, a procedure that is consistent with the approach used in previous analyses by our group (e.g., Nigg, Willcutt, Doyle, & Sonuga-Barke, 2005; Willcutt, 2009) and others (e.g., Sjowall, Roth, Lindqvist, & Thorell, 2013; Wahlstedt, Thorell, & Bohlin, 2009).

Diagnostic Sensitivity

With the exception of a marginally significant finding for delay aversion in the CLDRC sample, participants with ADHD were significantly more likely than individuals without ADHD to exhibit deficits in all five do-

mains (Figure 15.2), indicating that each neuropsychological weakness had significant sensitivity. However, fewer than half of the individuals who met full diagnostic criteria for ADHD exhibited a significant deficit on any specific measure, a pattern that is consistent with earlier results from our studies and other samples of children and adolescents (e.g., Nigg et al., 2005; Sjowall et al., 2013; Wahlstedt et al., 2009; Willcutt, 2009; Willcutt, Brodsky, et al., 2005).

Consistent with the significant group deficits across a wide range of measures in the meta-analyses, these analyses suggest that no single weakness provides a necessary or sufficient explanation of all cases of ADHD. These results also illustrate why neuropsychological measures have limited clinical utility despite the large and consistent effect sizes observed in comparisons of groups with and without ADHD (as discussed in Chapters 4, 10, and 18). Although a higher proportion of individuals with ADHD have each weakness than would be expected by chance, analyses of each measure indicated that over half of the individuals who met full criteria for ADHD did not exhibit significant impairment on that measure.

Diagnostic Specificity

Another important complicating factor for theoretical models of ADHD is the high rate of comorbid disorders in individuals with ADHD. Over 80% of children, adolescents, and adults with ADHD also meet criteria for another disorder, and many meet criteria for multiple additional diagnoses (Chapters 5 and 13; also Faraone, Biederman, Weber, & Russell, 1998; Willcutt, Pennington, Chhabildas, Friedman, & Alexander, 1999). In a comprehensive meta-analysis of studies of DSM-IV ADHD, Willcutt and colleagues (2012) found that children and adults with ADHD combined type were 10 to 15 times more likely than individuals without ADHD to meet criteria for oppositional defiant disorder (pooled estimate from the meta-analysis = 52%) and nearly 20 times more likely to meet criteria for conduct disorder (pooled estimate = 22%; e.g., Hinshaw, 2002; Volk, Neuman, & Todd, 2005). Rates of comorbidity were significant but lower between ADHD and anxiety disorders (12–20%), depression (10–15%), and bipolar disorder (7–12%). Adults with ADHD were three times more likely than adults without ADHD to meet criteria for a substance use disorder (pooled estimate = 41%; e.g., Murphy, Barkley, & Bush, 2002; Sobanski et al., 2008). Finally, children with ADHD were three to four times more likely than children without ADHD to meet criteria for a speech–language disorder (15%) or learning disorder (24%; e.g., Hinshaw, 2002; Willcutt, Betjemann, et al., 2010).

The nearly ubiquitous comorbidity exhibited by individuals with ADHD initially called into question whether the significant neurocognitive weaknesses observed in groups with ADHD might be associated

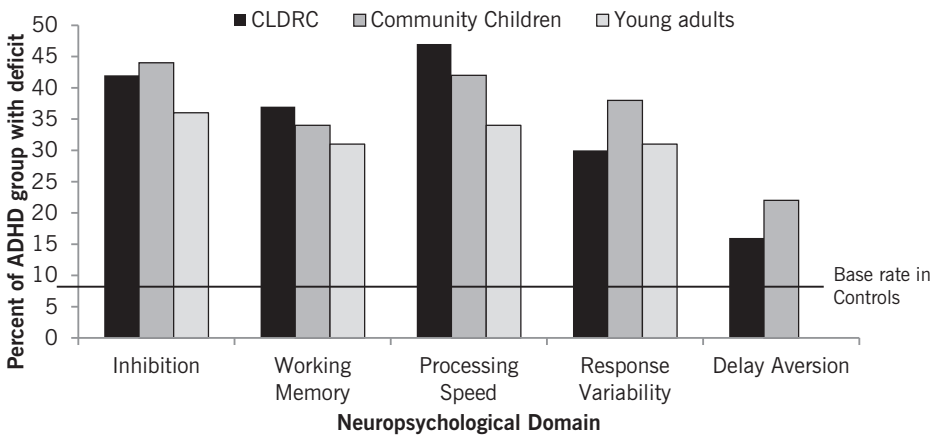

FIGURE 15.2. Percentage of children and adults with ADHD who scored below the 10th percentile of the comparison sample on each neuropsychological composite measure.

with one of the comorbid disorders rather than ADHD per se. However, subsequent studies showed that differences between ADHD and control groups on measures of response inhibition, working memory, delay aversion, response variability, and processing speed all remained significant when symptoms of most comorbid disorders were controlled (e.g., Rucklidge & Tannock, 2002; Solanto et al., 2007; Willcutt, Betjemann, et al., 2010). These results provide important evidence that each of these neuropsychological weaknesses is independently associated with ADHD, and is not simply a consequence of a comorbid disorder.

On the other hand, a meta-analysis of neuropsychological studies of nine childhood disorders indicated that none of these neuropsychological weaknesses are specific to ADHD (Willcutt et al., 2008). Weaknesses in response inhibition, working memory, processing speed, and response variability have been reported consistently in studies of children with pervasive developmental disorders (autistic spectrum disorders; e.g., Geurts, Verte, Oosterlaan, Roeyers, & Sergeant, 2004; Ozonoff & Jensen, 1999; Verte et al., 2005), childhood-onset psychosis (e.g., Karatekin, Bingham, & White, 2009), learning disabilities (e.g., Purvis & Tannock, 2000; Willcutt, Betjemann, et al., 2010; Willcutt et al., 2001), and mood disorders (Bearden et al., 2007; Rucklidge, 2006), suggesting that dysfunction in each of these processes may be a shared risk factor for ADHD and other disorders.

SUMMARY OF FINDINGS ON COMPETING THEORETICAL MODELS

The results summarized in this chapter clearly indicate that ADHD is associated with weak inhibitory control, providing strong support for one the key predictions of the theoretical model proposed by Barkley (1997) over 15 years ago and updated in Chapter 16. In addition to this specific weakness in response inhibition, ADHD is also associated with significant weaknesses on measures of working memory, delay aversion, response variability, and processing speed.

Meta-analyses of studies of both children and adults reported medium to large (d = 0.50–0.70) effect sizes for each of these measures when groups with and without ADHD were compared. However, all of these effects are far smaller than the effect size of the difference between groups on measures of ADHD symptoms (d = 3.0–4.0), and each weakness accounts for a maximum of 10% of the variance in ADHD symptoms. Similarly, whereas individuals with ADHD are three to four times more likely than individuals without ADHD to exhibit a clinically significant weakness on measures of each of these constructs, fewer than half of all individuals with ADHD exhibit a significant deficit in any specific domain. Taken together, these results suggest that no neuropsychological weakness is necessary or sufficient to cause all cases of ADHD, and they underscore the neuropsychological heterogeneity of ADHD.

A SHIFT TOWARD MULTIPLE-DEFICIT MODELS

The converging results summarized in this chapter have precipitated a significant reconceptualization of theoretical models of ADHD (Pennington, 2006; Willcutt et al., 2008). Rather than attempting to identify a single neuropsychological weakness that is necessary and sufficient to cause ADHD, recent theoretical models explicitly hypothesize that ADHD is a complex and heterogeneous disorder that is associated with weaknessess in multiple domains (Nigg, 2006; Sonuga-Barke, 2005; Sonuga-Barke et al., 2003; Willcutt et al., 2008). To illustrate some of the different approaches that may be used to conceptualize these more complex models, I describe in the remainder of this chapter two broad types of theoretical models that incorporate multiple neurocognitive deficits.

Multiple-Pathway Models

Independent pathway models suggest that dysfunction in any of two or more pathophysiological substrates may independently lead to the same final behavioral manifestation of a disorder. In other words, these models propose that there are distinct *neuropsychological subtypes* of ADHD (e.g., Nigg et al., 2005). For example, Sonuga-Barke (2002, 2003) and his colleagues have proposed a dual-pathway model in which some individuals exhibit ADHD symptoms due to significant aversion to delay, whereas others have ADHD due to weak inhibitory control. This model received some support from studies in which delay aversion and response inhibition predicted ADHD symptoms independently (e.g., Solanto et al., 2001; Sonuga-Barke et al., 2003). However, other studies found that a significant subset of individuals with ADHD exhibit weaknesses in both domains, suggesting that these pathways may not be entirely independent (Sonuga-Barke et al., 2008).

Multiple-Deficit Models

In contrast to the distinct neuropsychological subtypes proposed by independent pathway models, multiple-deficit models suggest that ADHD symptoms arise from the additive and interactive combination of multiple neuropsychological weaknesses, none of which is necessary or sufficient to cause the disorder when it occurs in isolation (e.g., Pennington, 2006; Willcutt, Betjemann, et al., 2010). The specific cluster of weaknesses may then differ across individuals, providing a potential explanation for clinical heterogeneity. For example, individuals with weaknesses in executive control and processing speed may be most likely to exhibit significant inattention and comorbid learning difficulties, whereas EF weaknesses coupled with aversion to delay or disruption in other motivational processes might lead to impulsive behaviors and comorbidity with other disruptive disorders, such as conduct disorder.

To illustrate further these two competing models, I conducted a final set of analyses for this chapter using the three samples that were described previously (to simplify the presentation of the results, the two samples of children were combined for this analysis). Figure 15.3 summarizes the total number of neuropsychological deficits exhibited by individuals in the ADHD and comparison groups. Nearly 30% of the individuals who met full DSM-IV diagnostic criteria for ADHD did not exhibit a significant weakness on any of the measures in our test battery, a pattern that is highly consistent with the results reported by others who have completed similar analyses (e.g., Karalunas & Huang-Pollock, 2011; Sjowall et al., 2013; Sonuga-Barke et al., 2008). This subgroup may potentially have subclinical weaknesses on one or more of the dimensions assessed in this study, or a weakness in a process that we simply did not measure despite the extensive neuropsychological batteries that were administered in each study.

Slightly more than 70% of the individuals with ADHD exhibited at least one neuropsychological weakness, and 25–30% exhibited significant impairment in a single domain (Figure 15.3). The cases with a single deficit included subsets of individuals who were only impaired on measures of delay aversion, response variability, or response inhibition. These results are consistent with the predictions of the independent pathway model, which hypothesized that the overarching diagnosis of ADHD would include multiple subgroups with separate neurocognitive weaknesses.

Finally, approximately 40% of the individuals with ADHD exhibited significant impairment in at least two domains, and over 20% exhibited three or more weaknesses. These results are consistent with a recent study in which 27% of participants with ADHD had weaknesses in two or more neurocognitive domains, with 22% exhibiting weaknesses in EF and response variability (Sjowall et al., 2013). The pattern of results in both of these samples is consistent with the expectations of the multiple-deficit model.

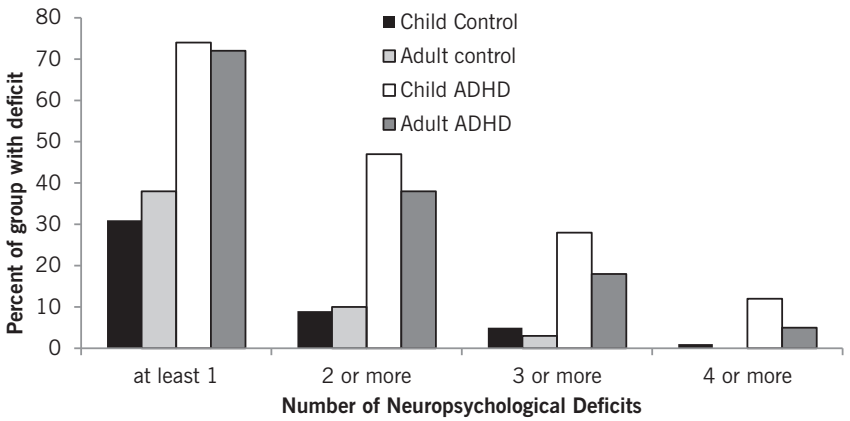

FIGURE 15.3. Percentage of children and adults with and without ADHD who exhibited significant weaknesses in at least one, two, three, or four or more neuropsychological domains.

Summary

A growing literature suggests that a comprehensive neurocognitive model of ADHD is likely to involve dysfunction in multiple cognitive processes that are mediated by neural networks distributed across many locations in the brain. Further research is needed to test whether dysfunction in these different networks leads to distinct neuropsychological subtypes within the overall population of individuals with ADHD, or whether multiple dysfunctional processes act in combination to increase susceptibility to ADHD in an individual. Perhaps the most likely scenario is a hybrid of these two models, in which some cases of ADHD are attributable to a primary deficit in a relatively specific neurocognitive process, whereas others may be caused by the combined effects of dysfunction in multiple substrates.

KEY ISSUES AND FUTURE DIRECTIONS

The transition from theories positing a single primary deficit to multiple-deficit models represents an important shift in the conceptualization of theoretical models of ADHD (Pennington, 2006). In this final section, I summarize several key remaining issues for the field and highlight important future directions for studies that test theoretical models of ADHD within a multiple-deficit framework.

Diagnostic Heterogeneity

Although this book focuses on the DSM diagnosis of ADHD and neuropsychological hetereogeneity within this group, ADHD is also clearly heterogeneous at the level of behavioral symptoms. The importance of this behavioral heterogeneity is underscored by the results of our comprehensive meta-analysis of the DSM-IV symptom dimensions and diagnostic subtypes (Willcutt et al., 2012). As expected, pooled results across studies indicated that zero-order correlations were significant between both inattention and hyperactivity–impulsivity symptoms and a wide range of neurocognitive measures. However, nearly all of these measures were more highly correlated with inattention than hyperactivity–impulsivity, and none were more highly correlated with hyperactivity–impulsivity.

Analyses of the DSM-IV subtypes indicated that the combined and inattentive types performed significantly worse than comparison groups without ADHD on measures of response inhibition, planning, vigilance, processing and naming speed, and some aspects of motor functioning. In contrast, there were few differences between the combined and inattentive types on these measures. The absence of any prominent differences between the combined and inattentive subtypes was unexpected based on initial hypotheses proposed by our group and others (e.g., Chhabildas, Pennington, & Willcutt, 2001; McBurnett, Pfiffner, & Frick, 2001; Milich, Balentine, & Lynam, 2001), but it is consistent with the dimensional results that suggested that most neuropsychological weaknesses are primarily driven by symptoms of inattention.

In contrast to the consistent neuropsychological weaknesses associated with the inattentive and combined types, effect sizes were much smaller and often not significant when the hyperactive–impulsive type was compared to a group without ADHD. Furthermore, the hyperactive–impulsive type performed significantly better than the inattentive and combined types on most neuropsychological measures. Taken together, these results suggest that the inattentive and combined types (now presentations in DSM-5; American Psychiatric Association, 2013) may share a common neuropsychological etiology, whereas the minimal evidence of neuropsychological dysfunction underscores ongoing questions regarding the diagnostic validity of the hyperactive–impulsive type.

Direct Tests of Competing Theoretical Models

Most previous studies have examined the neuropsychological correlates of ADHD with a limited test battery that is designed to assess constructs derived from a single theoretical perspective. While the primary effect sizes from studies of different theories can be compared to provide a preliminary appraisal of the relative merits of different theoretical models, interpretation of these comparisons is often compromised by important differences in study design or sampling procedures. To continue to move the field forward, future studies should be explicitly designed to facilitate direct comparisons of alternative theoretical models in the same sample. As summarized earlier in this chapter, studies that have adopted this approach have already had an important impact on our understanding of competing theoretical models of ADHD (e.g., Karalunas & Huang-Pollock, 2011; Solanto et al., 2001; Sonuga-Barke et al., 2003; Willcutt, Pennington, et al., 2010).

Clinical Utility

I realize that the debate about major and minor details of competing theoretical models may seem esoteric and far removed from any concrete clinical application. But the overarching long-term objective of each of these theoretical models and all neuropsychological research is to improve clinical diagnostic procedures and subsequent interventions for children, adolescents, and adults with ADHD. Because only a minority of individuals with ADHD exhibits a significant weakness on any of the measures of competing theoretical models that have been proposed to date, no measures that are currently available have sufficient sensitivity or specificity to be useful for clinical diagnosis. Furthermore, the clear evidence of pervasive neuropsychological and behavioral heterogeneity in individuals with ADHD suggests that it is likely to remain difficult or impossible to develop a single diagnostic test with positive and negative predictive power that is adequate for diagnostic purposes.

Even if it is not possible to use measures based on the competing theoretical models for diagnostic purposes, results of neuropsychological studies are still likely to have several important clinical implications and utility (Willcutt & Bidwell, 2011). For example, although it appears unlikely that a single neuropsychological measure will have sufficient diagnostic utility in isolation, it may eventually be possible to combine neuropsychological data with information about an individual's genetic background, family history, environmental circumstances, and other etiological factors to create a probabilistic measure of overall risk for ADHD. This profile could then be used to supplement parent and teacher ratings to identify individuals who are at high risk for ADHD, facilitating primary prevention or early intervention.

Neuropsychological measures may also facilitate the identification and implementation of interventions that target the specific areas of weakness that are most impairing for a particular individual. This might involve pharmacological interventions that target dysfunction in a specific neural substrate or environmental interventions designed to remediate or accommodate the specific pattern of weaknesses exhibited by an individual. For example, an individual with significant EF difficulties might benefit from a structured behavioral and organizational system that provides consistent reminders about appointments and tasks that must be completed, whereas an individual with a pronounced elevation of response variability might require frequent breaks to maintain an optimal response set when completing lengthy assignments. Similarly, an individual with severe processing speed difficulties might benefit from increased time to complete tests and assignments, so that slow processing speed does not compromise his or her ability to demonstrate mastery of the material.

CONCLUSIONS

The neuropsychology of ADHD is complex and multifactorial, with no single deficit that is necessary or sufficient to explain all cases of ADHD. A comprehensive theoretical model of ADHD must account for weaknesses in response inhibition and other aspects of executive control, increased aversion to delay, and slower and more variable response speed. Additional research is needed to clarify the relations among these complex cognitive processes and to determine the best approach to describe the behavioral and neuropsychological heterogeneity that characterizes ADHD.

KEY CLINICAL POINTS

- ✓ Several theoretical models of ADHD exist in the literature: the extended phenotype model of executive functioning and behavioral inhibition (see Chapter 16); the concept of ADHD as a motivational dysfunction; the theory of ADHD as comprising delay aversion (Sonuga-Barke et al., 2008); and conceptualizations focusing on excessive response variability (Kinsbourne, De Quiros, & Rufo, 2001), deficient arousal regulation (Sergeant, 2005; Van der Meere & Stemerdink, 1999), and impaired processing speed, among others.
- ✓ Each is briefly reviewed along with the evidence that exists to support it.
- ✓ It seems clear that no single theory or concept can account for all of the findings in the neuropsychological literature on ADHD, in that some subsets of ADHD have deficits in one or more of these concepts, while others do not or have them in different domains.
- ✓ Neuropsychological tests that are purported to assess these various concepts are not sufficiently accurate for use in diagnosis. Deficits on these tests also are often shared with other psychiatric disorders.
- ✓ The findings to date support the need for a multiple-

pathways or multiple-deficits model of ADHD, in which its symptoms and neuropsychological deficits can arise from a variety of cognitive origins that would more easily explain the heterogeneity of findings across cases and studies. Results of research to date appear to be more supportive of a multiple-deficits model of ADHD than of subtypes of ADHD that arise via different pathways.

- ✓ Future research should focus on direct tests of the various competing models of ADHD and identifying tests that may have greater diagnostic accuracy for the disorder than do existing ones.

ACKNOWLEDGMENTS

During the preparation of this chapter, my colleagues and I were supported in part by National Institutes of Health Grant Nos. R01 HD 47264 (Principal Investigator: E. Willcutt), R01 HD 68728 (Principal Investigator: E. Willcutt), R01 DA 24002 (T. Ito); by National Institute of Child Health and Human Development (NICHD LDR Research Hub No. R24 HD 75460 (Hub Principal Investigator: S. Petrill); and NICHD Center Grant No. P50 HD 27802 (Center Director: R. Olson). My thanks to Bruce F. Pennington, John C. DeFries, and Richard K. Olson for sharing a portion of the data presented in this chapter.
